14-Gastroenterology	831
15-General Internal Medicine	905
16-Psychiatry	973

Welcome to the 19th Edition of MedStudy's *Internal Medicine Core*!

This 19th edition represents the knowledge, expertise, and labor of love of superb physician educators from Internal Medicine residencies and teaching hospitals across the U.S. This edition has been extensively rewritten to ensure that the information is tightly focused on what you need to know, reflects the current standards of care, and references the most recent practice guidelines.

Think of your *Internal Medicine Core* as a series of well-crafted lectures given by the best teachers you've ever had—those teachers who had a knack for connecting with you and for clearly explaining obtuse concepts. These lectures are casual, yet concise, and focused on the medical knowledge needed for a strong Internal Medicine practice and to easily pass the boards. This Core is foundational and is used as the source for all of MedStudy's Q&As, Flashcards, Audio Pearls, Live Courses, and Video Board Review.

But casual, concise, and focused content is not enough—there's still a lot of material! How can you determine what, out of all this content, is the most important to know; what you're most likely to be tested on? And how in the world do you get it into your long-term memory?

First: How do you identify what's most important?

Our writers and editors know what you need to know, they teach it every day. They've identified the must-know, most-asked information from each main topic and highlighted it in yellow. The Preview | Review questions at the beginning of each main topic are based on the most board-relevant info from this highlighted material.

Second: How do you get this must-know information into your long-term memory?

We'll show you! We call it the MedStudy Method. You can read about this method in the *StudyWise* guide that came with your Core. Hint: The Preview | Review questions are key! Be sure to read this carefully and thoroughly before you jump into the Core. This may be the most important little book you can read at this moment. It will unsettle you by de-bunking 6 learning myths that may be holding you back—and will reveal the 2 secrets to long-term learning.

When I started MedStudy in 1990, I set out to cut through the clutter and make learning the essentials of medicine as easy as possible. This is still my focus and that of every one of MedStudy's 50+ employees and 200+ physician contributors. We are truly honored to be a part of your medical education, and we hope our efforts will allow you to have a more balanced life, more confidence in your practice, and a lot more fun. Welcome to the community of over 100,000 MedStudy physicians who strive for excellence in patient care.

Study Strong,

Robert A. "Tony" Hannaman, MD
MedStudy's Founder and Editor in Chief

Core Features Bring the Reading to Life

While you're reading these pages, it's meant to feel like you're sitting in a live lecture from your favorite professor.

Preview | Review Questions

Preview, study, and review the highest-yield material. See highlighted text for the answers

PREVIEW | REVIEW

- What are the urine serum Na⁺, and serum with SIADH?

Highlighted text

Must-know content—including answers to Preview | Review questions—is highlighted in yellow

primary thyroid abnormalities of thyroidism. If the TSH hypothyroidism. If the for hyperthyroidism is 1

Bold text

Low	Normal	Print
High	High	Sub

Tables & charts

Synthesize the most relevant and related information

Medical images & figures

Visualize concepts with medical images—including diagnostic scans and x-rays, photos, ECGs, and exquisitely drawn figures

The Truth About Learning Medicine

For 30 years, we've been creating innovative study materials that make learning medicine easier. A few years ago, MedStudy's Founder and Editor-in-Chief, Robert A. "Tony" Hannaman, MD started a quest to determine the best way to transfer all this required medical knowledge into long-term memory so it would be durable and easily accessible. He dove into the latest brain science on how memories are made and the best evidence-based learning techniques. He discovered that many of our assumptions and much of what we're taught about learning is simply wrong!

After much study, consultation with experts, pondering, writing, and rewriting, he sculpted what he'd learned into a new study method that we call the MedStudy Method. This is a prescription for the most effective way to truly *learn* medicine. The accompanying *StudyWise* guide is a fun, must-read presentation of the MedStudy Method and the science behind it.

Every MedStudy product—from this Core, to our Q&A bank, to the Flashcards, to the Video Board Review—has been hand-crafted to match best practices from the MedStudy Method. And the result is something unprecedented and powerful. By following the Method, you'll learn, retain, and easily recall all the medical information you need, whether you're seeing patients or taking boards.

The MedStudy Method helps you get off that proverbial hamster wheel of cramming, testing, forgetting... repeat.

We included *StudyWise* with your Core—it's a quick read, but it's a game-changer. The following is a sneak peek into the 3-phased approach to studying.

PREVIEW

The day before you dig into the study material, recall everything you can about it using the Preview | Review questions as prompts.

STUDY

Read through your material carefully, seeking understanding. Don't memorize!

RETRIEVE

Again, using the Preview | Review questions as prompts, practice recall of the same study material over progressively longer intervals. This moves your study material into easily accessible long-term memory!

REFRESH

Go back through the study material only as needed to refresh your understanding.

19th Edition *Internal Medicine Core*

CME START DATE:
December 1, 2020

CME EXPIRATION DATE:
December 1, 2023

Eligible for a maximum 150 CME Credits and 150 ABIM MOC Credits

CME ACCREDITATION

MedStudy is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians.

MedStudy designates this enduring material for a maximum of 150 AMA PRA Category 1 Credits™. Physicians should claim only the credit commensurate with the extent of their participation in the activity.

This credit may be submitted to the American Osteopathic Association (AOA) for Category 2 Credit. All other health care professionals completing this continuing education activity will be issued a certificate of participation.

AMERICAN BOARD OF INTERNAL MEDICINE (ABIM) MOC POINTS

Successful completion of this CME activity, which includes participation in the evaluation component, enables the participant to earn 150 Medical Knowledge MOC points in the American Board of Internal Medicine's (ABIM) Maintenance of Certification (MOC) program. Participants will earn MOC points equivalent to the amount of CME credits claimed for the activity. It is the CME activity provider's responsibility to submit participant completion information to ACCME for the purpose of granting ABIM MOC credit.

HOW TO APPLY FOR CME CREDIT AND ABIM MOC POINTS

Please note: CME credit is available only to the original purchaser of this product (directly from MedStudy), and issuance of CME credit is subject to verification of product ownership. CME and MOC credits for MedStudy 19th Edition Internal Medicine Core are available until CME Expiration Date. CME and MOC credits will be available only after passing the required online posttests with a score of at least 70%.

To claim your CME credits and/or MOC points:

1. Log into your myMedStudy account with your email address and password.
2. Follow the instructions for completing the CME credit application and posttest.
3. Return to your Eligible Credits page to claim the ABIM MOC points (optional).
4. MedStudy will report claimed MOC points directly to the ABIM within 1–2 business days.

Note: For any questions, please email us at cme@medstudy.com or call 1-800-841-0547.

LEARNING OBJECTIVES

As a result of participation in this activity, learners will be able to:

- integrate and demonstrate increased overall knowledge of internal medicine,
- identify and remedy areas of weakness (gaps) in knowledge and clinical competencies,
- describe the clinical manifestations and treatments of diseases encountered in internal medicine and effectively narrow the differential diagnosis list by utilizing the most appropriate medical studies, and
- apply the competence and confidence gained through participation in this activity to both a successful board exam-taking experience and daily practice.

TARGET AUDIENCE

Participants in this MedStudy educational activity are those physicians seeking to assess, expand, and reinforce their knowledge and clinical competencies in internal medicine, focusing their learning on subjects that are directly relevant to clinical scenarios that will be encountered on the ABIM Certification board exam or the Maintenance of Certification (MOC) board exam and the American Osteopathic Board of Internal Medicine (AOBIM) board exams, as well as in the contemporary clinical setting. The content of this activity is intended to help learners assess their own key knowledge and clinical competencies with evidence-based standards of care, as reflected on the board exams, and remedy any potential competency gaps that may exist.

METHOD OF PARTICIPATION

The content of this CME activity is intended to help learners assess their key knowledge and clinical competencies with evidence-based standards of care, which are reflected on the board exams and in day-to-day practice. Internists or other physicians preparing for the ABIM certification or MOC exam—or who simply want to update their knowledge of internal medicine—should:

- Preview the section material the day before a study session by reading the Preview | Review questions and recalling whatever knowledge they might already have.
- Read the Core, paying special attention to yellow-highlighted text, which is the must-know material for the ABIM certification and MOC exams, based on ABIM content outlines. Review tables and figures to reinforce study and to see concise summaries of interrelated facts and clinical examples in key topic areas. Self-test again later by answering Preview | Review questions.
- One to two days after reading the Core, go back to the Preview | Review questions again, and try to recall as much as possible. Repeat this again in 7–10 days, 1–2 months, and 4–6 months to improve knowledge and proficiency and, ultimately, to ensure mastery of the material.
- The learner will be required to complete a posttest as part of the requirements for receiving CME or MOC credit for this product.

Without these people,
the 19th Edition *Internal Medicine Core* wouldn't exist.
Thank You.

MEDSTUDY DISCLOSURE POLICY

It is the policy of MedStudy to ensure balance, independence, objectivity, and scientific rigor in all its educational activities. In keeping with all policies of MedStudy and the ACCME, any contributor to a MedStudy CME activity is required to disclose all relevant relationships with any entity producing, marketing, reselling, or distributing health care goods or services consumed by, or used on, patients. Failure to do so precludes acceptance by MedStudy of any material by that individual. All contributors are also required to submit a signed Good Practices Agreement, affirming that their contribution is based upon currently available, scientifically rigorous data that is free from commercial bias and that any clinical practice and patient care recommendations offered are based on the best available evidence for these specialties and subspecialties. All content is carefully reviewed by MedStudy's in-house physician editors, as well as on-staff copyeditors, and any perceived issues or conflicts are resolved prior to publication of an enduring product or the start of a live activity.

MEDSTUDY DISCLOSURE STATEMENT

As the provider of this continuing medical education activity, MedStudy Corporation, including all its employees, has no financial interest, arrangement, or affiliation with any commercial entity producing, marketing, reselling, or distributing health care goods or services consumed by, or used on, patients. Furthermore, MedStudy complies with the AMA Council on Ethical and Judicial Affairs (CEJA) opinions that address the ethical obligations that underpin physician participation in CME: 8.061, "Gifts to physicians from industry," and 9.011, "Ethical issues in CME," and 9.0115, "Financial Relationships with Industry in CME."

FOR FURTHER STUDY

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub:

medstudy.com/hub

The Hub contains an online consolidated list of all current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source.

BECOME OUR NEXT STAR CONTRIBUTOR

Are you a great writer? Want to teach? Looking for an opportunity for a side hustle? We're looking for contributors who are able to translate their rich experience as physicians and teachers into writing or presenting concise, engaging, and clearly explained concepts. DISCLAIMERS

NOTICE: Medicine and accepted standards of care are constantly changing. We at MedStudy do our best to review and include in this publication accurate discussions of the standards of care and methods of diagnosis. However, the authors, reviewers, section editors, medical editors, editor in chief, publisher, and all other parties involved with the preparation and publication of this work do not guarantee that the information contained herein is in every respect accurate or complete. We recommend that you confirm the material with current sources of medical knowledge whenever considering presentations or treating patients.

ABIM and AOBIM: For over 30 years, MedStudy has excelled in determining and teaching what a clinically competent internist should know. The American Board of Internal Medicine (ABIM) and the American Osteopathic Board of Internal Medicine (AOBIM) test this same pool of knowledge. MedStudy's expertise, demonstrated by the superb pass rate of those who use MedStudy products, is in the teaching of this knowledge in a clear, learner-friendly manner that results in a stronger knowledge base, improved clinical skills, and better board exam results. Although what we teach is in sync with what the boards test, MedStudy has no affiliation with the ABIM or AOBIM, and our authors, reviewers, and editors have no access to ABIM or AOBIM exam content. Our material is developed as original work by MedStudy physician authors, with additional input from expert contributors, based on their extensive backgrounds in professional medical education. This content is designed to include subject matter typically tested in certification and recertification exams as outlined in the ABIM and AOBIM publicly available exam blueprints but makes no use of, and divulges no details of, the ABIM or AOBIM proprietary exam content.

GENERAL PRINCIPLES

PREVIEW | REVIEW

- What is meant by positive and negative feedback regulation in endocrine diseases? Which is most common: positive or negative feedback?

If you want to test for **hypo**secretion of a hormone, try to **stimulate it**. Example: In adrenal insufficiency, adrenocorticotropic hormone (ACTH) fails to stimulate cortisol production (the ACTH stimulation test).

If you want to test for **hyper**secretion of a hormone, try to **suppress it**. Example: In Cushing syndrome, dexamethasone fails to suppress production of cortisol (the dexamethasone suppression test).

Laboratory findings must always be interpreted within a clinical context. Example: In primary hyperparathyroidism, parathyroid hormone (PTH) is expected to be high but may be **inappropriately normal** for the lab range; this **inappropriately normal** PTH level is consistent with PTH hypersecretion because the proper PTH response to hypercalcemia is suppression to a very low level.

Biochemical confirmation of hormonal disease (with labs and dynamic testing) **always** precedes imaging because benign, nonfunctional masses are common in all endocrine glands (incidentalomas). Know what you are looking for before you image!

Important characteristics to know about a hormone:

- What is its function?
- Where is it produced and secreted?
- What stimulates and inhibits its release?
- Where are these controls?
- How is it secreted? Is it diurnal, pulsatile, or under tonic inhibition?

Note: Many endocrine glands respond to feedback mechanisms that regulate hormone secretion by negative and/or positive feedback. Positive feedback stimulates hormone release, whereas negative feedback inhibits or suppresses hormone release. Feedback is important in maintaining homeostasis. Most endocrine glands are under negative feedback control. Example: Excess cortisol inhibits both corticotropin-releasing hormone (CRH) and ACTH production.

Note on plasma vs. serum: **Plasma** is the liquid component of blood that has no cells. **Serum** is plasma with the clotting factors removed. In the body, the liquid component of the blood is plasma. Serum is the liquid in a red-top tube after clotting occurs. You will see these terms used interchangeably, and it is okay because it usually doesn't matter. For example, you are actually measuring plasma osmolality by doing a serum osmolality test. In this section, we generally stick with the term **plasma** when talking about the body and **serum** for lab tests.

PRIMARY, SECONDARY, AND TERTIARY GLANDULAR DISEASES

PREVIEW | REVIEW

- What are the definitions of primary, secondary, and tertiary hormone diseases?

With regard to glandular abnormalities:

Primary glandular disease refers to disease of the gland that secretes the hormone.

Secondary glandular disease refers to disease of the gland that controls the primary gland.

Tertiary glandular disease refers to disease of the gland that controls the secondary gland that controls the primary gland.

Let's look at some examples:

Primary hypothyroidism results from a diseased thyroid gland underproducing thyroid hormone.

Secondary hypothyroidism is caused by a diseased pituitary gland underproducing thyroid-stimulating hormone (TSH). Consequently, the thyroid underproduces thyroid hormone.

Tertiary hypothyroidism begins with a diseased hypothalamus underproducing thyroid-releasing hormone (TRH). Because of this, the pituitary underproduces TSH. As a result, the thyroid underproduces thyroid hormone.

Here are 2 more examples:

Primary hyperaldosteronism results from a diseased adrenal gland overproducing aldosterone. This condition is caused by an aldosterone-secreting tumor or adrenal hyperplasia.

Secondary hyperaldosteronism originates with a diseased kidney overproducing renin. As a consequence, adrenal glands overproduce aldosterone. So, disease is at the level of the kidney: renovascular disease or a renin-secreting tumor.

HYPOTHALAMUS

The hypothalamus sits in the forebrain just below the thalamus and above the pituitary gland. It controls the endocrine function in the body by assessing many bodily and external environmental signals and then using hormones and nerves to output new control signals to the pituitary gland.

Input to the hypothalamus is from the cortex, autonomic nervous system, peripheral endocrine system, and external environment (e.g., temperature and light).

The hypothalamus controls output of the **anterior** pituitary by means of **releasing hormones**, such as CRH and TRH, and inhibiting hormones, such as dopamine. It controls the output of the **posterior** pituitary (i.e., neurohypophysis) by direct **nerve** stimulation.

POSTERIOR PITUITARY GLAND

The pituitary gland is considered the master gland. Functionally, it is composed of the anterior pituitary and the posterior pituitary, which participate in different hormonal axes. Each axis has different positive and negative feedback controls.

It helps to think of the posterior pituitary as an extension of the hypothalamus. The antidiuretic hormone (ADH; a.k.a. vasopressin) and oxytocin synthesized in the hypothalamus are transported and stored in the posterior pituitary. (All other pituitary hormones are made in and secreted by the anterior pituitary gland). The posterior pituitary secretes these hormones in response to nerve stimuli from the hypothalamus.

ADH regulates plasma osmolality. Normal plasma osmolality is 285–295 mOsm/kg (285–295 mmol/kg), and it can be either measured directly or estimated. Be familiar with the formula:

$$\text{Osmolality} = (2 \times [\text{Na}^+]) + (\text{glucose}/18) + (\text{BUN}/2.8)$$

Plasma osmolality is the most important determinant of ADH secretion, and the main effect of ADH is decreasing renal free water excretion in the late distal tubule and cortical collecting duct. Osmoreceptors of the hypothalamus are exquisitely sensitive to small changes in plasma osmolality; small increases in the plasma osmolality sensed in the hypothalamus lead to large increases in ADH secretion, increased renal water retention, and a concentrated urine.

ADH secretion causes the kidneys to conserve water and concentrate the urine (antidiuresis), which prevents hyperosmolarity from getting worse. However, free-water intake is needed to correct hyperosmolarity, even when the urine is maximally concentrated. Hence, high plasma osmolality also stimulates thirst. Thirst produces the needed increase in free-water intake.

The osmotic threshold (i.e., set point) for ADH release is decreased (ADH is released at a lower osmolality) in pregnancy, leading to mild physiologic hyponatremia.

ADH also is released in response to nonosmotic factors; the most potent of these is nausea, which increases ADH levels to several hundred times normal. Other factors that stimulate ADH include pain, medications, lung disorders (including lung cancer), and central nervous system disorders. In these states, ADH impairs free-water excretion, causing hyponatremia—this is termed the syndrome of inappropriate antidiuretic hormone (SIADH). ADH release is also triggered by severely decreased effective arterial blood volume (i.e., true hypovolemia, heart failure, liver cirrhosis).

More on SIADH is in the [Nephrology](#) section.

ANTERIOR PITUITARY GLAND

PREVIEW | REVIEW

- What are the hormones of the anterior pituitary?
- What are the signs and symptoms of a pituitary tumor?
- What is the workup for a pituitary tumor?
- Aside from a prolactinoma, what are the other causes of hyperprolactinemia?
- What is the best initial medical therapy for hyperprolactinemia?
- How do you test for acromegaly?
- Which cancers most commonly metastasize to the pituitary?
- What is the clinical presentation of pituitary apoplexy? What is the treatment?

OVERVIEW

The anterior pituitary produces 6 hormones (and without them, you feel like a **FLAT PiG**):

- 1) Follicle-stimulating hormone (FSH)
- 2) Luteinizing hormone (LH)
- 3) Adrenocorticotropic hormone (ACTH)
- 4) Thyroid-stimulating hormone (TSH)
- 5) Prolactin (PRL)
- 6) Growth hormone (GH)

It secretes these hormones in response to releasing and inhibiting hormones that are made in the hypothalamus and released into the hypophyseal portal system (a specialized portal system that connects the hypothalamus with the anterior pituitary).

The anterior pituitary hormones are controlled by both positive and negative feedback. High plasma hormone levels inhibit hormone production, and low plasma hormone levels stimulate hormone production. This feedback system is termed the hypothalamus-pituitary-target gland axis.

With positive feedback, low hormone levels cause the hypothalamus to produce releasing hormones (e.g., TRH, corticotropin-releasing hormone [CRH]) that induce pituitary hormone secretion (e.g., TSH, ACTH), which, in turn, stimulates target gland hormone production (e.g., thyroxine, cortisol).

With negative feedback, higher-than-normal levels of the target gland hormones (e.g., thyroxine, cortisol) inhibit hormone production in both the pituitary and the hypothalamus. The exception to the rule is prolactin, which is continuously inhibited by dopamine from the hypothalamus. When there is a decrease in dopamine, prolactin increases.

ACTH has a **diurnal variation** with a peak at 6 a.m. and a nadir at midnight. ACTH stimulates the adrenal gland to produce corticosteroids and adrenal androgens, and it has a regulatory effect on production of mineralocorticoids. ACTH increases in response to CRH from the hypothalamus and to physical or psychological stresses, and ACTH is suppressed in response to high cortisol levels.

GH is secreted in a **pulsatile fashion** and is regulated by 2 hypothalamic hormones: growth hormone-releasing hormone (GHRH) and somatostatin (a.k.a. growth hormone-inhibiting hormone). GHRH causes release of GH from the pituitary, and somatostatin tonically inhibits release of GH from the pituitary. Note: **Somatostatin** can also **inhibit** the release of TSH from the pituitary, as well as regulate other neuroendocrine cell activity. Because the release of GH is pulsatile, a random GH level is not useful. As a screen for GH excess or deficiency, measure the more stable GH product, insulinlike growth factor 1 (IGF-1).

LH and FSH regulate sex hormone production. LH and FSH production is regulated by **pulsatile secretion** of gonadotropin-releasing hormone (GnRH) from the hypothalamus. **Inhibin**, produced in the ovary and testis, inhibits **only FSH** secretion.

PRL is different from the other hormones because it is under **tonic inhibition** by hypothalamic dopamine sent down the pituitary stalk. This is an important concept because stalk compression is a cause of **hyperprolactinemia**.

TSH secretion is stimulated by hypothalamic TRH and inhibited by thyroid hormone and **somatostatin**. When thyroid hormone levels are high (i.e., primary hyperthyroidism), TSH levels will be low.

PITUITARY TUMORS

Pituitary tumors can present with symptoms of hormonal hypersecretion, hypopituitarism, and vision loss. They can also be detected as an incidental finding (after imaging of the brain for unrelated symptomatic complaints, such as headache). These are sometimes called incidentalomas. Pituitary tumors are due to the abnormal proliferation of cells of the anterior pituitary.

The **1st step in evaluating** a pituitary tumor is to determine if it is **functional** (secreting hormones). The **2nd step** is to determine if it is causing a **mass effect** leading to anterior pituitary hormone hyposecretion or to vision loss. The size of the tumor determines the evaluation process. A pituitary adenoma > 1.0 cm (macroadenoma) is evaluated for hormonal **hypersecretion**, **hyposecretion**, and vision loss, and those < 1.0 cm (microadenoma) are evaluated only for **hypersecretion** as they are generally not large enough to cause hormone **hyposecretion** or vision loss.

Clinical presentation depends on the type of adenoma:

- **Lactotrophs (prolactinomas):** hyperprolactinemia, resulting in amenorrhea and galactorrhea in women, hypogonadism in men, and infertility in both; the most common **functioning** adenoma

- **Gonadotrophs:** most are clinically silent until they become macroadenomas and cause mass effect and/or pituitary hypofunction; the most common **non-functioning** adenoma
- **Thyrotrophs (TSHoma):** hypersecretion of TSH, resulting in hyperthyroidism; least common adenoma (Labs show a normal/high TSH and high free T₄ [FT₄].)
- **Somatotrophs:** hypersecretion of GH, resulting in acromegaly (best screen = IGF-1)
- **Corticotrophs:** hypersecretion of ACTH, resulting in Cushing disease
- **Mixed cell type:** most often combines somatotrophs + lactotrophs, called **somatomammotrophs**, with cosecretion of both GH and prolactin

Remember: Mixed cell type tumors exist; therefore, it is important to always check a prolactin level in somatotroph tumors and IGF-1 in lactotroph tumors because prolactin- and GH-producing cells are from a common cell line.

Typical mass effect symptoms include headaches, diplopia, or visual field defects (e.g., bitemporal hemianopsia). Less commonly, adenomas can extend and cause CSF rhinorrhea.

Acute hemorrhage into an adenoma causes **apoplexy**, manifesting as acute severe headache, nausea, vomiting, vision impairment and loss, and altered mental status. This is an **endocrine emergency** and requires immediate **corticosteroids** and a neurosurgical consult. Although all types of pituitary hormonal deficiencies can occur, only the sudden loss of ACTH production is life threatening; it stops cortisol production and precipitates an adrenal crisis, which can rapidly progress to shock.

Suspect a pituitary adenoma when a patient presents with multiple hormone abnormalities or a mixture of symptoms, such as low libido, weight loss, anorexia, weakness, and (in women) amenorrhea.

When interpreting FSH and LH levels, always consider whether the levels are appropriate for the reproductive stage of the female (pre- vs. postmenopausal). For example, if a postmenopausal female patient has low or inappropriately normal FSH and LH levels, there is a gonadotropin deficiency. (Remember: Postmenopausal women should have an elevated FSH level, so a normal level is **inappropriately normal**).

Diagnosis: MRI is the imaging of choice for the tumor. When a patient presents with an incidental pituitary tumor, the size of the tumor determines biochemical evaluation.

If < 1 cm, check the following for **hypersecretion**:

- Prolactin level
- IGF-1 to screen for GH excess
- TSH and FT₄ (TSH helps in evaluation if FT₄ is high.)
- Screen for cortisol excess with:
 - 24-hour urine free cortisol,
 - low-dose (1 mg) overnight dexamethasone suppression test, **or**
 - midnight salivary cortisol.
- LH, FSH, and α subunit tests are generally not done.

If > 1 cm, do formal **visual field** testing and check for both **hypersecretion** (with these same tests) and **hyposecretion**. To work up for hyposecretion, do the following:

- ACTH stimulation test (screening for cortisol deficiency)
- LH and FSH in postmenopausal women (both are normally high) and testosterone in men to screen for hypogonadism
- IGF-1 to screen for GH deficiency
- TSH and FT_4 (TSH helps in evaluation if FT_4 is low.)
- In premenopausal women, ask about changes in menses. A regular menstrual cycle off OCPs excludes gonadotrophin deficiency.

If the hormone labs are normal, the tumor is nonfunctional and is likely a gonadotroph tumor that is inefficient in making the active hormone β subunit.

Remember: Gonadotropins (LH and FSH), TSH, and human chorionic gonadotrophin (hCG) have an α and a β subunit. The β makes it unique, whereas α subunits are just inactive glycoprotein. Finding high levels of α subunits supports a diagnosis of **gonadotroph or nonfunctional tumor**.

If the tumor is nonfunctional, it does not impinge on the optic nerve or chiasm, and there is no hypersecretion of hormones, then the tumor can be reimaged in about 6 months if it's a macroadenoma or in 1 year if it's a microadenoma. If there is no change in size, then repeat yearly for macroadenomas, and for microadenomas repeat every 1-2 years for the following 3 years.

Indications for surgical removal of a pituitary tumor include:

- visual field or other ophthalmologic defects,
- a lesion in or abutting the optic chiasm or compressing the optic nerve,
- apoplexy, or
- hypersecretion of ACTH, GH, or TSH.

Prolactinomas have their own criteria for surgical removal, which we will cover in **Hyperprolactinemia and Prolactinomas**.

On MRI, other sellar masses can be seen, including craniopharyngiomas, which often present as calcified cystic suprasellar lesions. They are considered benign, but they can cause symptoms secondary to mass effect and impingement on the optic nerve.

Radiologists may occasionally report an "empty sella," which is a description of an imaging finding and not a diagnosis, because the majority of people have normal hormonal function. In empty sella, the pituitary has been displaced and squished by CSF but still **functions normally**; it has been described in **multiparous women**. No treatment is needed for empty sella syndrome if there are no associated hormone deficiencies.

Hyperprolactinemia and Prolactinomas

A serum PRL concentration that is repeatedly elevated (> 20 ng/mL) is termed hyperprolactinemia. This is the most frequent functional abnormality of the pituitary gland.

When hyperprolactinemia is not caused by a prolactinoma, prolactin levels are generally < 200 ng/mL.

Nonprolactinoma causes of hyperprolactinemia:

- Drugs that are dopamine antagonists; i.e., certain antipsychotics (e.g., phenothiazines, haloperidol, risperidone), metoclopramide, and verapamil
- Diseases of the hypothalamus and/or pituitary stalk that interfere with production or transport of dopamine, thus removing the negative inhibition on prolactin production (e.g., sarcoidosis, stalk compression, and trauma). Stalk compression is when a pituitary tumor pushes on the stalk and interferes with transport of dopamine.
- Pregnancy or estrogen use. Pregnancy is the most common cause of physiologic hyperprolactinemia.
- Nipple stimulation (e.g., due to lactation)
- Orgasm: Recommend patients abstain from sexual intercourse for 24 hours prior to test.
- Chest wall injuries, including skin lesions (e.g., piercing, herpes zoster)
- Hypothyroidism (Always check a TSH.)
- Chronic kidney disease

Prolactinoma is the most common functional pituitary tumor. Prolactinomas are usually < 1 cm (**microadenomas**), but they can also be **macroadenomas** causing visual field defects. PRL levels generally correlate with tumor size (> 100 ng/mL for macroadenomas). **Elevated PRL** level inhibits the release of GnRH, **decreasing LH** and **FSH**. Therefore, hyperprolactinemia of any cause results in hypogonadism and erectile dysfunction in men and amenorrhea and galactorrhea in women.

If you see a macroadenoma with only mild hyperprolactinemia (prolactin < 100 ng/mL), then it is not a prolactinoma—the prolactin elevation is likely due to pituitary stalk compression. In this case, dopamine delivery to the lactotrophs is impaired, removing the tonic inhibition of prolactin production.

Note: Watch for the following pitfall in the lab! A markedly elevated prolactin can be masked (falsely low) due to a lab artifact called the "hook effect." If the tumor is ≥ 1 cm and the PRL level is < 100 ng/mL, check a diluted prolactin test before diagnosing stalk effect.

Due to amenorrhea, prolactinomas are diagnosed earlier in women than in men. Decreased libido is the earliest symptom of a prolactinoma in males but is often ignored, so men tend to present later and with larger masses and visual field defects. Galactorrhea occurs in most women with prolactinomas but rarely in men. **Longstanding hypogonadism** is associated with decreased skeletal bone mineralization in both men and women.

Management options for prolactinomas include medical treatment, surgical resection, and observation. Indications for medical or surgical treatment include:

- Tumor size > 1 cm
- Hypogonadal symptoms (e.g., amenorrhea, infertility, erectile dysfunction)
- Galactorrhea affecting the patient's quality of life
- Women with impaired fertility

Always check TSH and pregnancy test (in women) before deciding to treat.

Microadenomas usually do not grow to > 1 cm, so observation alone can be an appropriate option for certain groups: postmenopausal women, premenopausal women who do not desire fertility and do not have or are not troubled by galactorrhea, and men who are not interested in fertility. Conservative management should include estrogen replacement in premenopausal women (oral contraceptive pills [OCs]), testosterone replacement in men, and observation in postmenopausal women. Follow with serial MRIs and prolactin levels to assess any change in size. Stable prolactin levels predict a stable tumor size.

Prolactinomas are extremely sensitive and responsive to medical treatment. For most patients, treatment with dopamine agonists is the best initial option. Dopamine agonists decrease both the PRL level and tumor size. Cabergoline is 1st line because of its efficacy and safety profile. Cabergoline can cause increased cardiac valvulopathy when administered at a very high dosage, as in the treatment of Parkinson's. Cabergoline is contraindicated in patients with known lung, heart valve, and retroperitoneal fibrotic disease. Bromocriptine is the 2nd line agent; it causes more nausea and orthostatic hypotension than cabergoline.

Transsphenoidal surgery is only used when the patient cannot tolerate drug therapy, or when it is ineffective. Postoperatively, an elevated PRL level is indicative of persistent or recurrent disease, particularly in the case of macroadenomas. Radiation is usually reserved for post-surgical cases to eradicate any remaining tumor.

When a woman on drug therapy for a prolactinoma becomes pregnant, stop the medication and monitor clinically for symptoms, physical exam, and visual field testing. Do not check prolactin levels; they are expected to increase with pregnancy. About 1/3 of macroadenomas enlarge during pregnancy; however, a normal pituitary also enlarges during pregnancy. MRI is only recommended if there is clinical evidence of growth, such as new headaches or visual field changes. If the tumor enlarges enough to cause symptoms, cabergoline or bromocriptine can be restarted. If vision is threatened, surgery is a therapeutic option. Both bromocriptine and cabergoline appear to be safe in early pregnancy, but data on fetal effects with long-term exposure are limited.

Acromegaly

Growth hormone (GH) is required for normal growth. GH production is suppressed by hyperglycemia and somatostatin and is stimulated by hypoglycemia.

When excess GH presents in childhood before growth plates are closed, it is termed gigantism. When it occurs in adulthood, it is termed acromegaly because the growth plates are closed; there is not excessive linear growth, but there is acral growth (i.e., hands, feet).

> 99% of acromegaly cases are due to a benign, well-defined adenoma, which is recognized on CT or MRI. Affected patients typically become symptomatic in their late 30s to mid 40s. Signs and symptoms of acromegaly include:

- Enlarging hands and feet
- Coarsening of the facial features
- Deepening of the voice
- Carpal tunnel syndrome, often bilateral
- Acanthosis nigricans
- Skin tags
- Pronounced jaw growth (which leads to multiple dental problems)
- Excessive sweating, body odor

Acromegaly has an insidious onset associated with an increased mortality when untreated. The most important long-term problem associated with acromegaly is cardiovascular disease. Patients have increased risk of:

- Ischemic heart disease
- Cardiomyopathy
- Diastolic dysfunction
- Hypertension
- Left ventricular hypertrophy
- Stroke

Acromegaly is also associated with obstructive sleep apnea, insulin resistance/diabetes mellitus, colon polyps, and colorectal cancer.

Screen for acromegaly by checking an IGF-1 level. Do not order a random GH level because a single value of GH is not useful in diagnosing acromegaly; its secretion is pulsatile, and levels in the blood can vary greatly in a healthy individual. IGF-1 is produced by the liver and mediates the growth-promoting effect of GH. Unlike GH, IGF-1 levels are stable throughout the day. A normal age-adjusted IGF-1 level almost always excludes the diagnosis of acromegaly. If the IGF-1 level is elevated, confirm the diagnosis by demonstrating a failure of GH to suppress after a 75-g oral glucose load (via an oral glucose tolerance test [OGTT]). A post-OGTT GH level > 1 ng/mL (1 µg/L) is diagnostic of acromegaly. Also check prolactin levels (elevated due to cosecretion in 25% of GH tumors). If the tumor is > 1 cm, check for visual field deficits and for other hormonal deficiencies.

Order a screening colonoscopy and echocardiogram on all patients diagnosed with acromegaly, regardless of age.

Treat all patients with transsphenoidal surgery, even if they are asymptomatic. Some experts recommend medical therapy with somatostatin analogs as initial therapy prior to surgery for a better chance for a cure and possibly safer intubation.

Radiation is used as initial therapy only in poor surgical candidates.

Medical treatment may be used as adjuvant therapy in patients with residual tumor after surgical resection and in poor surgical candidates. Options include somatostatin analogs (e.g., octreotide) +/- dopamine agonists (e.g., cabergoline or bromocriptine), and GH receptor antagonists (i.e., pegvisomant).

Other Pituitary Tumors

We mentioned **gonadotroph adenomas** under **Pituitary Tumors** on page 1-3. Recall that they are the most common type of nonfunctioning adenomas, usually macroadenomas. Gonadotroph tumors can present variably:

- Incidentally on imaging and hormonally silent
- Mass effect and hormonally silent
- Mass effect with symptoms of hypogonadism/partial panhypopituitarism
- Mass effect with symptoms of gonadotropin excess (very, very rare)

A diagnosis of gonadotroph adenoma is usually supported by finding an increase in free α subunits (inactive) or rarely, high levels of FSH and/or LH.

Transsphenoidal surgery is indicated for **symptomatic** nonfunctioning or functional gonadotroph adenomas.

For asymptomatic patients with preserved endocrine function and a normal visual field assessment, observation with serial imaging studies is appropriate.

Radiation is an option for certain types of tumors but primarily is used postsurgically to contain residual tumor mass. Patients who have had pituitary radiation need life-long monitoring of anterior pituitary function for adrenal insufficiency and secondary hypothyroidism.

Pituitary hyperplasia is expected in **pregnancy** and can mimic a pituitary tumor if imaging is done (for more on pituitary adenoma during pregnancy, see the **Women's and Men's Health** section). **Severe primary hypothyroidism** (disease of the thyroid gland) can also cause pituitary hyperplasia as the pituitary thyrotrophs become hyperplastic from the over demand for TSH; imaging shows a pituitary mass. Clinically, the patient is hypothyroid; biochemically, the FT_4 is low and the TRH and the TSH are high. The elevated TRH suppresses dopamine, causing an increase in PRL; thus, the patient can be mistakenly diagnosed with a prolactinoma. Treatment with thyroxine replacement causes the thyrotrophs to shrink and PRL levels to normalize.

Metastatic cancer can be seen in the pituitary; the posterior part of the gland is most often involved. These metastases can present as isolated central **diabetes insipidus** (DI; absent or deficient ADH production). Breast and lung cancer metastases are most common. Infiltrative diseases, such as sarcoidosis, can also cause isolated DI. Lymphoma and leukemia can present as primary cancer of the pituitary.

Acquired Hypopituitarism

Pituitary apoplexy is a **neurosurgical emergency** caused by hemorrhage into a pituitary mass, usually an adenoma. Suspect apoplexy in the patient who presents with severe headache, N/V, diplopia, +/- altered mental status. Symptoms can begin suddenly ("mule kick in the head" or "the worst headache of my life") or can develop over 1-2 days. Diabetes with microvasculature changes, radiation therapy, and current warfarin use are risk factors. The patient's history may include indications or a diagnosis of an adenoma causing hormone excess or deficiency.

Pituitary hormones are abnormal in apoplexy. Apoplexy causes hypopituitarism, which can cause a decrease in all the pituitary hormones, the most life-threatening of which is ACTH. No ACTH means no cortisol (i.e., secondary adrenal insufficiency), shock, and death. Apoplexy can be difficult to distinguish from subarachnoid hemorrhage (SAH) occurring in the same area; however, in SAH, pituitary hormones are normal.

Suspect pituitary apoplexy when the patient has the acute symptoms mentioned above; the diagnosis is confirmed by finding a dense pituitary mass on CT or MRI. Test pituitary hormones (remember: the most critical one is ACTH), along with a cortisol level. Again, urgent recognition and treatment of secondary adrenal insufficiency is necessary to prevent life-threatening hypotension.

Treatment: If the symptoms are mild, only corticosteroids are necessary. Edema can cause a mass effect and require emergent decompression. Consult a neurosurgeon to make the call on whether to use corticosteroids alone or take the patient to surgery.

Sheehan syndrome (1/10,000 deliveries) is **postpartum** hypopituitarism. It always involves the anterior pituitary and sometimes also affects the posterior pituitary, but it rarely causes central diabetes insipidus (i.e., low ADH from posterior pituitary).

Severe cases can manifest with symptoms of adrenal insufficiency and/or hypothyroidism (e.g., weakness, lethargy, anorexia, hypotension).

Sheehan syndrome results from hypovolemic shock following severe obstetrical bleeding that causes necrosis of the enlarged anterior pituitary of pregnancy. This classic form of Sheehan syndrome nowadays occurs rarely in medical resource-rich countries. Instead, patients may present with failure to lactate, postpartum amenorrhea, or **chronic** hypopituitarism.

Acute postpartum hypopituitarism may indicate underlying unsuspected pituitary disease, e.g., autoimmune hypophysitis with resulting cortisol deficiency, growth hormone deficiency, and hypoglycemia (especially seen with growth hormone deficiency). Confirm cortisol deficiency by measuring the serum cortisol level. Hypoglycemia can also be due to the sudden increase in insulin sensitivity that occurs immediately postpartum.

Treat all causes of acute hypopituitarism emergently with high doses of hydrocortisone as well as IV glucose as needed to correct any hypoglycemia. If the patient is hypothyroid, delay thyroid therapy until the patient has been stabilized with hydrocortisone. Treating with thyroid hormone first can precipitate an adrenal crisis.

Other causes of hypopituitarism include pituitary and parasellar tumors, radiation, infections, inflammation, and infiltrative processes, such as sarcoidosis, hemochromatosis, and histiocytosis X.

Remember: If one anterior pituitary hormonal deficiency is found (independent of the etiology), all other anterior pituitary hormones should be assessed for concomitant deficiencies.

DIABETES INSIPIDUS (DI)

PREVIEW | REVIEW

- What happens to the urine osmolality and serum Na^+ during water deprivation in a patient with diabetes insipidus?

DI occurs when the kidneys are unable to retain **free water**, causing a dilute urine despite progressively increasing plasma osmolality. It is characterized by thirst (with polydipsia) and the production of large volumes of dilute urine (usually $> 3 \text{ L/day}$). Serum Na^+ is normal if the patient has access to water, but hypernatremia occurs if access to water is limited. Nocturia typically is the 1st symptom of DI. Volume depletion rarely occurs, as long as there is an intact thirst mechanism and patients have access to water. Infants, nursing home patients, and those who are unconscious are vulnerable to these complications.

DI can be **central** (decreased ADH **production**) or **nephrogenic** (renal **resistance** to the effect of ADH).

Neurogenic DI (a.k.a. central DI) is either acquired or congenital. Acquired central DI occurs when there is disease or damage to the posterior pituitary. It can be caused by brain cancer or metastases, trauma, neurosurgery, or systemic infiltrative diseases (e.g., eosinophilic granuloma, sarcoidosis, granulomatosis with polyangiitis).

Figure 1-1 shows what's going on with ADH and plasma osmolality in central DI. Normally, as plasma osmolality increases (e.g., when there is lack of access to water),

plasma ADH increases. In central DI, plasma ADH does not increase with rising plasma osmolality. The kidneys do not get the signal (ADH) to conserve water, urine osmolality stays low, and, unless the patient drinks, hypernatremia will get worse.

Figure 1-1: Central DI

Nephrogenic DI (a.k.a. ADH-resistant DI) can be acquired or due to gene mutations in the ADH receptor or in an aquaporin. (Aquaporins are transmembrane proteins that increase water permeability of the renal collecting tubule in response to ADH.) **Important causes of acquired nephrogenic DI:**

- Drugs (especially **lithium**)
- Hypercalcemia (serum $\text{Ca}^{2+} > 11 \text{ mg/dL}$ [2.75 mmol/L])
- Chronic hypokalemia (serum $\text{K}^+ < 3 \text{ mEq/L}$ [3 mmol/L])
- Intrinsic renal disease (especially **Sjögren syndrome**)

Figure 1-2 illustrates the pathogenesis of nephrogenic DI. Normally, as plasma ADH rises in response to rising plasma osmolality, ADH acts on the kidneys to increase urine osmolality. High urine osmolality means high renal water reabsorption, which helps correct the hypernatremia. With **nephrogenic DI**, ADH increases appropriately; however, the kidney does not respond, and the urine osmolality remains low.

Figure 1-2: Nephrogenic DI

Both central and nephrogenic DI can be complete or partial. In partial central DI, the ADH release in response to hyperosmolality is present but inadequate. In partial nephrogenic DI, there is a blunted renal response to the effects of ADH. In both cases, disease is milder than in the complete forms.

Diagnose central vs. nephrogenic DI with the **water restriction test**. This test ideally should be done in the hospital; it can be done in the office only when there is access to phlebotomy and quick turnaround on lab results.

Note: Do **not** restrict water if the serum Na^+ is already high ($> 145 \text{ mEq/L}$ [145 mmol/L])! These patients have already self-restricted; measure plasma and urine osmolality and skip to desmopressin administration.

If serum Na^+ is **not** already high, the first step is to restrict water/fluid intake. Then measure the urine osmolality, plasma osmolality, and serum Na^+ every 2 hours. If the urine osmolality rises to $> 600 \text{ mOsm/L}$ (600 mmol/kg), you are done: the patient does not have DI, so there is no need to give desmopressin. If the urine osmolality remains $< 600 \text{ mOsm/L}$, wait until the serum Na^+ rises to $144\text{--}145 \text{ mEq/L}$, then give desmopressin (i.e., synthetic ADH). Assess the renal response to desmopressin by measuring the urine osmolality every 30 minutes for 2 hours.

When interpreting the results of the water restriction test, refer to [Figure 1-1 on page 1-7](#) and [Figure 1-2 on page 1-7](#).

In central DI, ADH does not increase in response to a rising plasma osmolality, so the urine osmolality remains low (i.e., the urine remains dilute). However, the kidneys respond normally to exogenous desmopressin with an increase in urine osmolality. Therefore, diagnose central DI when the urine does not concentrate with water deprivation but **does** concentrate after desmopressin administration.

In nephrogenic DI, exogenous desmopressin has no (or little) effect. So, diagnose nephrogenic DI if the urine does **not** concentrate with water restriction or desmopressin administration.

Primary polydipsia (a.k.a. psychogenic polydipsia) mimics DI; consider it in patients with polydipsia and polyuria +/- psychiatric illness. The water restriction test quickly differentiates psychogenic polydipsia from DI because patients with psychogenic polydipsia concentrate the urine normally with water restriction. Also, psychogenic polydipsia patients will never have hypernatremia; in fact, they are at risk for hyponatremia due to excessive water ingestion.

Treat **central** DI with either subcutaneous or intranasal **desmopressin**, a synthetic vasopressin analog. Desmopressin effectively reduces polyuria and

nocturia. Because the kidneys immediately respond to ADH, giving desmopressin results in a quick increase of the urine concentration and reduction in urine output. The intranasal preparation is more potent than the oral; injectable is the most potent. Be careful to titrate the dose properly and counsel the patient to drink only when thirsty because hyponatremia can easily occur (i.e., drug-induced SIADH). **Mild** cases of partial central DI can occasionally be managed with an oral drug that stimulates ADH (e.g., chlorpromazine, carbamazepine) or with thiazides and salt restriction, but desmopressin acetate (DDAVP) is preferred.

In **nephrogenic** DI, the urine is persistently dilute, even when ADH is high. Giving desmopressin does not increase the concentration of the urine. Treat nephrogenic DI with a low-solute diet first, then add thiazide diuretics or amiloride if needed. NSAIDs are used to treat rare hereditary forms.

Note: In central DI, if the thirst center and ADH osmoreceptors are damaged, which can occur with a hypothalamic lesion (e.g., craniopharyngioma), the patient can have recurrent hypernatremic dehydration without thirst (adipsic hypernatremia). These patients are often very difficult to treat.

Remember: **DI** typically presents as polyuria/polydipsia, with or without **hypernatremia**, with normal volume status. SIADH usually presents as **hyponatremia**, also with normal volume status.

SIADH

PREVIEW | REVIEW

- What are the urine osmolality, urine Na^+ , serum Na^+ , and serum osmolality in a patient with syndrome of inappropriate secretion of antidiuretic hormone?

The syndrome of inappropriate secretion of antidiuretic hormone (**SIADH**) is sometimes idiopathic but may be caused by CNS trauma or infection, pulmonary disease, drugs, and ectopic hormone production, especially with **small cell lung cancer**.

These patients have hyponatremia with normal volume status. High ADH causes renal free-water reabsorption, which lowers **serum** osmolality. Urine osmolality is inappropriately high, and urine Na^+ concentration is also **high**. Remember to always rule out hypothyroidism and adrenal insufficiency, because these can present similarly to SIADH.

Treat SIADH with fluid restriction.

See the [Nephrology](#) section for further discussion of SIADH.

THYROID GLAND

- Thyroid lymphoma is associated with which autoimmune disease?

NORMAL PHYSIOLOGY

TRH is made and secreted by the **hypothalamus**, which stimulates the **anterior pituitary** to make and secrete TSH, which in turn stimulates formation and secretion of thyroid hormone by the **thyroid gland**. The majority of the thyroid hormone produced is thyroxine (T_4), but it does make a small amount of triiodothyronine (T_3). T_3 is considered the more active hormone, and the majority is produced locally by deiodination of T_4 in the peripheral tissues. T_4 binds very tightly to TBG (thyroxine-binding globulin) and weakly to albumin. T_3 also binds to these proteins but not as strongly. Only a very small fraction of the total T_4 and total T_3 is unbound and, therefore, free and active (i.e., FT_4 , FT_3). The FT_4 free component (in addition to the TSH) is generally the fraction that you want to measure when testing for thyroid disorders.

The activity of the thyroid gland is regulated by a negative feedback process in which the serum levels of T_4 and T_3 stimulate or inhibit TRH production by the hypothalamus (Figure 1-3).

Figure 1-3: HTH-pituitary-thyroid axis

THYROID FUNCTION TESTS

Thyroid **function** tests (TFTs) include TSH, FT_4 , and sometimes FT_3 . The FT_4 assay has replaced the T_3 resin uptake test.

When screening for primary thyroid disease, start with a **TSH** to detect abnormalities of thyroid function—both **hyper-** and **hypothyroidism**. If the TSH is high, then order a FT_4 to assess for hypothyroidism. If the TSH is low, then order a FT_4 to assess for hyperthyroidism (Table 1-1 on page 1-10). Remember that 80% of the thyroid hormone production by the thyroid is T_4 whereas the majority of T_3 is production is by extrathyroidal deiodination of T_4 peripherally. Note: If the patient is being treated with a thyroid axis altering drug (thioamides or thyroid hormone), the pituitary hormone (TSH) may have some delay in returning to physiological levels compared to the thyroid hormones (T_3 and T_4).

During the 1st trimester of pregnancy, you can expect a physiological TSH drop due to elevation in hCG (remember, they both have a common α subunit so HCG can stimulate the receptor). Do **not** confuse this with hyperthyroidism! As a rule of thumb, the lower limit of normal TSH in pregnancy is $0.1 \times$ the trimester of pregnancy (1st trimester is 0.1 mU/L; 2nd trimester is 0.2; 3rd trimester is 0.3).

Table 1-1: Overview of Thyroid Function Tests		
TSH	FT ₄	Diagnosis
High	Low	Primary hypothyroidism
	Normal	Subclinical hypothyroidism
	High	Pituitary (secondary; TSH-induced) hyperthyroidism Thyroid hormone resistance syndromes
Low	High	Primary hyperthyroidism Subacute or silent thyroiditis
	Normal	Subclinical hyperthyroidism Euthyroid sick syndrome
	Low	Pituitary (secondary) hypothyroidism Severe euthyroid sick syndrome

OTHER THYROID TESTS

Uptake and Scan

If primary hyperthyroidism is diagnosed (with a low TSH and high FT₄), the next step is to determine its cause. Two tests, the radioactive iodine uptake (RAIU) and **thyroid scan** (also called “scintigraphy”), help to establish a diagnosis by measuring the degree and pattern of iodine uptake by the thyroid. In clinical practice, these tests are often referred to as “the thyroid uptake and scan,” but recognize these are 2 different tests (the uptake; the scan). The RAIU measures the degree of iodine uptake (given as a percent uptake) by the thyroid. The scintigraphy scan assesses the pattern of iodine uptake (takes a “picture”), showing a diffuse, focal, or multifocal distribution.

RAIU: The patient is given a small dose of radioactive iodine; and then later, a radiation detector over the thyroid determines the percentage of the dose that was taken up by the gland. Know the uptake results (**high**, **low**, or **normal**) for various causes of thyroid disease.

RAIU is **increased** in:

- Graves disease
- TSH-secreting pituitary tumor
- Hot nodules (solitary or toxic multinodular goiter [MNG]), if hot enough
- High hCG states, such as an hCG-secreting tumor and gestational thyrotoxicosis (due to the hCG activating the TSH receptor)
- Iodine deficiency

RAIU is **decreased** in:

- Thyroiditis (“dumping” of thyroid hormone)
- Excess exogenous T₄ or T₃
- Iodine excess (e.g., contrast dye, diet, amiodarone)
- Factitious hyperthyroidism

Thyroid scan (scintigraphy): The patient is given a dose of technetium-99m or radioactive iodine and a scintillation scanner produces a rough **picture** indicating how these isotopes localize in the thyroid (**Figure 1-4**). The scan gives information on the size, shape, and overall activity of the gland and shows **hot** (hyperfunctioning) and **cold** (underfunctioning) spots. In Graves’, the scan shows diffuse increased uptake, in a hot nodule it’s local.

The thyroid RAIU and scintigraphy scan are essential in determining the cause of **hyperthyroidism** and are **never** used in the workup of a **hypothyroid** or **euthyroid** patient. Thyroid scintigraphy can be used in the evaluation of thyroid nodules, but only if the TSH is low (If the TSH is normal, then ultrasound is the best way to determine if a thyroid nodule biopsy is needed.) Hyperfunctioning (hot) nodules are rarely malignant and do not require biopsy.

Figure 1-4: Thyroid scintigraphy (i.e., thyroid scan). (A) Normal thyroid: normal diffuse uptake. (B) Graves disease: diffusely increased uptake. (C) Painless thyroiditis: very low uptake. (D) Hot (autonomous) nodule: discrete area of increased uptake, sometimes with suppression of the surrounding gland. (E) Cold (nonfunctioning) nodule: area of reduced or absent uptake. (F) Toxic multinodular goiter: several areas of increased uptake.

Ultrasound

Thyroid ultrasound (U/S) is used to:

- Determine the size and **number** of nodules.
- Determine whether a nodule is **cystic or solid**.
- Stratify a nodule's malignancy **risk** by U/S characteristics (low, medium, or high).
- Localize a nodule for fine needle aspiration.
- Follow up a nodule's size over time.
- Follow up in a patient after thyroid cancer resection.

When a patient presents with a **palpable nodule** and is **hyperthyroid**, an RAIU and scintigraphy should always precede a thyroid U/S. If the palpable nodule is "hot" (functional), then no biopsy is needed; consider radioactive iodine (^{131}I) therapy. When a patient presents with a **palpable nodule** and is **hypothyroid** or **euthyroid**, the next step in the workup is to go directly to U/S to see if the nodule meets criteria for a biopsy. This is discussed further under **Nodule Workup on page 1-17**.

Biopsy

Fine needle aspiration (FNA) is a biopsy method used to evaluate a thyroid nodule (also discussed under **Nodule Workup on page 1-17**) and results dictate the next step.

HYPOTHYROIDISM

Findings

Symptoms of hypothyroidism are nonspecific but include:

- Cold intolerance
- Weight gain
- Fatigue
- Menstrual irregularities; infertility
- Mental slowness and concentration issues
- Depressed mood
- Constipation
- Puffiness in the face
- Extremity swelling
- Hoarseness
- Coarse hair/alopecia
- Brittle nails
- Dry skin
- Decreased tolerance to exercise
- Carpal tunnel syndrome

Signs on physical exam include:

- Goiter
- Cool/pale skin
- Coarse hair
- Periorbital and nonpitting edema
- Tongue enlargement (severe cases)
- Bradycardia
- Delayed reflexes

In addition to a high TSH and a low FT_4 , abnormal labs/studies include:

- Hyponatremia (euvolemic)
- Macrocytic anemia
- Hyperlipidemia (increased total cholesterol and LDL)
- Pericardial effusion on echocardiograms (rare)
- Increased prolactin level

Hypothyroidism is a cause of hyperprolactinemia, amenorrhea and galactorrhea. If a woman has an elevated prolactin and amenorrhea, check thyroid function after confirming that she is not pregnant. If symptoms are due to hypothyroidism, the elevated prolactin, amenorrhea, and galactorrhea resolves with thyroxine treatment.

Diagnosis of Hypothyroidism

The best screening test for hypothyroidism is the TSH, which is elevated. Add an FT_4 if secondary (pituitary) or tertiary (hypothalamic) hypothyroidism is suspected:

- High TSH and low FT_4 = primary hypothyroidism.
- High TSH and normal FT_4 = "subclinical" hypothyroidism.
- Low or inappropriately normal TSH and low FT_4 = secondary (problem with pituitary) or tertiary (problem with hypothalamus) hypothyroidism or euthyroid sick syndrome.

Our understanding of **subclinical hypothyroidism** is still evolving. We know TSH normally drifts up with age. Patients with TSH 5-10 mU/L (mildly elevated) develop overt hypothyroidism at a rate of about 4% per year, which is low, so not everybody needs to be treated. A family history of autoimmune thyroid disease and positive anti-thyroid peroxidase (**anti-TPO**) antibodies are risk factors for subclinical disease.

Low or inappropriately normal TSH with a low normal FT_4 is secondary or tertiary hypothyroidism except in hospitalized, sick patients who may have euthyroid sick syndrome. (See **Euthyroid Sick Syndrome on page 1-16**.) Less than 1% of those with hypothyroidism have central hypothyroidism (i.e., secondary or tertiary). Secondary hypothyroidism is due to TSH deficiency and tertiary hypothyroidism is due to TRH deficiency. Suspect **secondary/tertiary disease** when you see a deficiency of **multiple** hormones (e.g., adrenal insufficiency and hypothyroidism occurring in the same patient) or in patients with a history of pituitary mass, pituitary surgery, or traumatic brain injury. (Isolated hypothyroidism due to pituitary or hypothalamic dysfunction is very rare and is usually genetic in nature.)

Secondary and tertiary hypothyroid diseases are differentiated by **imaging** the sella. **Routine TRH** stimulation test is **not** done because management is the same: Replace thyroid hormone to achieve a normal FT_4 level (not a TSH level).

Treatment of Hypothyroidism

Treatment for hypothyroidism is **levothyroxine** (T_4) alone. Adding T_3 might help with some neuropsychological symptoms, but multiple randomized trials have shown **no** benefit of combined T_3/T_4 beyond that achieved with T_4 monotherapy. In addition, T_3 therapy is harder to regulate due to its short half-life and may cause hyperthyroid effects, such as atrial fibrillation and bone loss. T_3 is not recommended in the treatment of hypothyroidism.

T_4 has a long half-life and takes weeks to equilibrate. In most cases, you can start patients on 50–100 mcg/day or 1.6 mcg/kg/day while fasting (an hour before breakfast). For patients with the potential for **coronary artery disease**, especially the **elderly**, start low (50 mcg/day) and slowly titrate up. Adjust the dose of levothyroxine every 6 weeks in increments of 12.5–25 mcg.

For primary hypothyroidism, the main treatment target is the TSH: Keep the level within the lower half of the normal reference range for your laboratory. Allow enough time for the blood level to come to a steady state, so do not check the TSH again until a full 6–8 weeks after a dose adjustment. Do not overtreat because you risk inciting complications of **hyperthyroidism**, such as **atrial fibrillation** and **osteoporosis**.

Know that a TSH elevation $> 10 \mu\text{U/mL}$ (10 mU/L) in a patient prescribed $> 200 \text{ mcg/day}$ of T_4 is most commonly due to **nonadherence**.

Watch out for food, drinks, and drugs that interfere with absorption of thyroxine (e.g., iron/calcium/aluminum supplements and bile acid sequestrants), raise TBG levels (estrogens), or increase the metabolism of T_4 . These, in addition to malabsorption (think celiac), cause persistently elevated TSH despite therapeutic dosages of T_4 .

If a patient is hypothyroid and needs emergent surgery for another reason, do it! Otherwise, try to restore euthyroidism before surgery.

Always treat pregnant hypothyroid patients and follow their TSH levels every 4 weeks during pregnancy because their requirements increase (the dose needs to be adjusted upwards $\geq 50\%$ over the prepregnancy dose). The goal in pregnancy is to keep TSH in the lower half of the trimester-specific reference range (approximately $< 2.5 \mu\text{U/mL}$ [2.5 mU/L]). Failure to treat maternal hypothyroidism during pregnancy can adversely affect the baby. For more on hypothyroidism during pregnancy, see the **Women's and Men's Health** section.

Treating **subclinical** hypothyroidism is controversial. In clinical practice, the decision to treat is individualized. American Association of Clinical Endocrinologists/American Thyroid Association guidelines (2012) generally recommend treatment for patients with a TSH $> 10 \mu\text{U/mL}$ (10 mU/L) and **no** treatment for patients with TSH $< 10 \mu\text{U/mL}$. When to start thyroid hormone for a TSH $< 10 \mu\text{U/mL}$: in pregnancy, in those attempting pregnancy, in the presence of a large goiter, and, most controversially, when symptoms suggest hypothyroidism + anti-TPO antibodies.

Myxedema Coma

Myxedema coma is 1 of 2 **thyroid emergencies** (the other being thyroid storm). Mortality is 30–40% and is higher in the elderly and in those with heart disease. It is a **clinical** and not a biochemical diagnosis, so the diagnosis depends on recognition of the classic signs and symptoms—**not** on the absolute value of T_4 or elevation of TSH.

Any cause of hypothyroidism can lead to myxedema coma. Undiagnosed, longstanding hypothyroidism can progress to myxedema coma. In patients with known but inadequately treated hypothyroidism, myxedema coma can be precipitated by infection, exacerbation of heart disease, opiates, or cold temperature.

Patients usually present with a history of progressive hypothyroid symptoms. Decreased mentation, bradycardia, and hypothermia (even body temperatures down to 74°F [23.3°C]!) are classic findings. Other signs indicate a **generalized slowing of systemic processes**: hypoventilation, hypoglycemia, and hypotension.

For the patient who presents to the emergency department obtunded with multisystem failure, quiz relatives for possible antecedent signs and symptoms of thyroid dysfunction.

Other symptoms depend on why the patient has thyroid disease:

- If the disease is primary, there may be no other symptoms, but be aware that rarely, primary autoimmune processes can affect both the thyroid and the adrenal, called **Schmidt syndrome**.
- If the disease is secondary, the patient may have symptoms of other hormone deficiencies; **adrenal insufficiency** is **especially important**.
- Patients may have a pericardial effusion.
- Up to 25% of patients have seizures.

Other lab abnormalities include hyponatremia, hypoglycemia, anemia, and hyperlipidemia.

Diagnose myxedema coma by history and physical examination in combination with hypothyroidism on labs. If the patient is stable, assess for adrenal insufficiency with an ACTH stimulation test prior to treating with thyroid hormone. (See **Steroid Synthesis on page 1-20**.) If the patient is unstable, just empirically treat with **glucocorticoids** without doing the ACTH stimulation test.

Give **empiric stress-dose glucocorticoids** until adrenal insufficiency is excluded by ACTH stimulation testing. Note: This should **always** be done prior to giving thyroid hormones because giving thyroid hormones first can precipitate adrenal crisis.

Treat myxedema coma with thyroid hormone. Optimal treatment is controversial; options include:

- T_3 (advantages: rapid onset and decreased conversion of T_4 to T_3 during acute illness), **or**
- intravenous T_4 (due to reduced absorption with oral), **or**

- **combined T₃ and T₄** (preferred by most experts) using a loading dose and a smaller daily dose thereafter.

Give empiric broad-spectrum antibiotics until infection is excluded. Pay particular attention to gradually warming the body temperature, maintaining adequate blood pressure with IVF and/or vasopressors, and normalizing the serum Na⁺.

Know that the mortality of myxedema coma is directly related to the degree of hypothermia and that **passive rewarming** (i.e., with blankets) is one of the most important elements of supportive care. Active rewarming can worsen hypotension (due to vasodilation) and should be avoided.

HYPERTHYROIDISM

Etiology

The **most common** cause of hyperthyroidism is autoimmune **Graves disease** (see **Graves Disease**). Most other causes occur in the context of **nodular disease** or **thyroiditis** and are discussed under **Thyroid Nodules and Cancer** on page 1-17 and **Thyroiditis** on page 1-15, respectively. Causes of hyperthyroidism:

- Toxic multinodular goiter (MNG)
- Toxic adenomas
- Thyrotoxicosis due to autoimmune thyroiditis (hashitoxicosis)
- Factitious thyrotoxicosis (exogenous thyroid hormone ingestion)
 - Thyroglobulin is a protein made by thyroid cells. Thyroglobulin levels are used mainly for thyroid cancer surveillance but can also be used when factitious thyrotoxicosis is suspected. Thyroglobulin is elevated in all endogenous hyperthyroidism etiologies (including thyroiditis) and low in factitious thyrotoxicosis.
- Iodine-induced hyperthyroidism (e.g., amiodarone, contrast)
- Subacute (i.e., painful) thyroiditis
- Postpartum thyroiditis
- TSH-producing adenoma (rare)

A good history and a thyroid scan and uptake will often get you the right diagnosis.

Findings

Symptoms of hyperthyroidism, regardless of cause, include:

- Anxiety and restlessness
- Irritability
- Insomnia
- Impaired concentration (even confusion or psychosis)
- Weight loss
- Diarrhea/hyperdefecation (increased frequency of stools with normal consistency)

- Heat intolerance
- Alopecia
- Onycholysis
- Dyspnea
- In women: menstrual irregularities (oligomenorrhea or amenorrhea, impaired fertility)
- In men: gynecomastia, decreased libido, infertility, and/or erectile dysfunction

Exam may reveal:

- Goiter
- Warm skin
- Exophthalmos (the “hyperthyroid stare”) in patients with Graves disease
- Lid lag
- Tremor
- Tachycardia
- Atrial fibrillation or ectopy in up to 20% of patients (more common in **elderly**)

Note: β -blockade (propranolol) is indicated in the setting of symptomatic hyperthyroidism, even prior to establishing the cause of hyperthyroidism, because β -blockade can control the symptoms of thyrotoxicosis (palpitations/anxiety) and decrease peripheral T₄ to T₃ conversion.

Abnormal general labs/studies (in addition to a low TSH and elevated FT₄):

- Low total cholesterol and LDL
- Normochromic, normocytic anemia
- Hypercalcemia with increased bone alkaline phosphatase
- Osteopenia/osteoporosis
- Dilated cardiomyopathy

Consider the diagnosis of hyperthyroidism in elderly patients with **new-onset atrial fibrillation** or depression without classic symptoms of hyperthyroidism—this is termed **apathetic hyperthyroidism**. Hyperthyroidism in the elderly can look like failure to thrive with apathy, anorexia, and weight loss. You may need to distinguish thyroid disease from polymyalgia rheumatica and clinical depression or adjustment disorder.

Graves Disease

Graves disease is the most common cause of thyrotoxicosis. It is caused by thyroid-stimulating immunoglobulins, IgG antibodies that bind to and stimulate the TSH receptors in the thyroid gland.

Physical findings **specific** for Graves disease (in addition to those listed in **Findings**; also see **Figure 1-5 on page 1-14**):

- A diffuse, soft, symmetric goiter (See **Nontoxic Goiter on page 1-19**.)
- Presence of bruit on thyroid auscultation
- Ophthalmopathy: proptosis and periorbital edema with impaired extraocular movements $\rightarrow$ diplopia, corneal ulcerations, visual impairment. Know that the risk of Graves ophthalmopathy (GO) is **increased** in

both **active and passive smokers** and **after radioactive iodine (RAI) therapy**. Smoking is also associated with progression of GO **after** RAI therapy and adversely affects the course of GO **during** treatment with steroids and orbital radiotherapy. Know that 90% of patients with Graves' have ocular involvement on MRI or CT. Clinically apparent GO requires formal eye testing and imaging to determine the degree of eye inflammation. If a patient with mild-to-moderate GO decides on RAI treatment, pretreatment with steroids is warranted in order to prevent the progressions of GO. RAI is **contra-indicated** in patients with **severe** eye inflammation.

- Dermopathy: Pretibial myxedema is a thickening and redness of the dermis due to a **lymphocytic** infiltrate that gives it a *peau d'orange* appearance (looks different from the myxedema seen in hypothyroid patients).

Figure 1-5: Graves disease: proptosis and lid retraction

Diagnosis

To diagnose Graves', use a good clinical exam (GO +/- goiter with a bruit) + TFTs + thyroid uptake and scan. TSH is low (usually $< 0.01 \mu\text{U/mL}$ [0.01 mU/L]), FT_3 and FT_4 are elevated (rarely, only FT_3 is increased with normal or low FT_4), and the thyroid uptake and scan shows an enlarged gland with **diffusely increased uptake** (see Figure 1-4 on page 1-10). Other common lab abnormalities: elevated alkaline phosphatase, hypercalcemia, anemia, and thrombocytopenia. Autoantibodies are generally not measured unless the diagnosis is unclear or a thyroid uptake and scan cannot be done (e.g., pregnant, recent contrast), but TSI (thyroid-stimulating immunoglobulins, a.k.a. thyroid receptor antibodies) are specific for and positive in $> 90\%$ of cases of Graves disease.

Treatment

Treatment options for Graves disease are antithyroid drugs (i.e., methimazole [**MMI**] or propylthiouracil [**PTU**]), radioactive iodine, or surgery.

MMI is the preferred drug in **nonpregnant** patients because of a lower toxicity than PTU. PTU received an **FDA boxed warning** for increased risk of death due to acute liver failure or severe liver injury, so PTU is no longer the 1st line therapy in nonpregnant patients and children. Vasculitis and lupus-like side effects have also been reported. PTU is still the 1st line treatment for **thyroid storm and in the 1st trimester** of pregnancy.

The most serious side effects of PTU and MMI are hepatic toxicity and agranulocytosis, which are rare and unpredictable. LFTs and CBCs do **not** require monitoring. Check only if the patient becomes symptomatic (e.g., jaundice,

dark urine, prolonged fever/sore throat), and discontinue the drug at that time. Side effects almost always disappear when the drug is discontinued. Mild side effects include skin rash and polyarthritis.

β -blockers can be used independent of the etiology of the hyperthyroidism to help with adrenergic symptoms, including tremor, tachycardia, and anxiety, while waiting for PTU or MMI to take effect.

Remission in Graves' is seen in 30% of patients after 1-2 years on antithyroid medication; relapse is common. Relapse is much less likely if thyroid stimulating immunoglobulins disappear with treatment, but this happens in a small minority of cases—usually young, female patients with relatively small thyroid glands.

In the United States, most patients with Graves disease receive definitive treatment with thyroid ablation using ^{131}I . Pretreat virtually all patients with β -blockers, and many with MMI (or PTU), prior to radioactive iodine ablation. Remember to rule out pregnancy in female patients (as radioiodine is contraindicated in pregnancy), and counsel patients to avoid pregnancy for 6 months to 1 year after thyroid ablation. Most patients become hypothyroid in response to ^{131}I therapy; it can take several months for the TSH to normalize and then become elevated.

Surgery may be indicated in patients who are pregnant (2nd trimester is optimal; for more on hyperthyroidism during pregnancy, see the **Women's and Men's Health** section), in patients with an associated cold nodule and a concerning FNA, relapse after radiation, or severe allergic reactions to antithyroid drugs and in some young patients with a large goiter. **Complications** of surgery include loss of all parathyroids and damage to recurrent laryngeal nerves. Remember, all patients need lifelong thyroid hormone therapy after surgery.

Thyroid Storm

Thyroid storm is the 2nd thyroid emergency that carries a **high mortality rate** (the other is myxedema coma). Thyroid storm is often precipitated in patients with undiagnosed or inadequately treated hyperthyroidism. Precipitating events include surgery, infections, or an iodine load, such as amiodarone or contrast dye.

Symptoms of thyroid storm are similar to symptoms of hyperthyroidism, only more severe: tachycardia, heart failure, fever, psychosis, or delirium. Some patients have GI symptoms of nausea, vomiting, and diarrhea. As with myxedema coma, thyroid storm is a **clinical** rather than a biochemical diagnosis, so the diagnosis depends on recognition of the classic signs and symptoms, **not** on the severity of T_4 or TSH abnormalities. Suspect thyroid storm with clinical presentation of fever, tachycardia, and altered mental status in the context of overt hyperthyroidism. In virtually all cases, **TSH is very low** and **FT_4 is markedly increased**.

Thyroid storm is characterized by severe metabolic stress that the patient can no longer tolerate. This

severe stress results in a **relative adrenal insufficiency**, even though the adrenal glands may be functioning perfectly and secreting a large amount of cortisol. Patients in thyroid storm die from cardiovascular collapse. A very important aspect of treatment is **supraphysiologic doses** of **glucocorticoids**.

Treatment of thyroid storm includes the following:

- Glucocorticoids, as described above
- Interrupt the physiologic response to excess thyroid hormone: IV **propranolol** or esmolol
- Block **new** hormone synthesis: high-dose thioamide (PTU preferred)
- Block release of **preformed** hormone from the gland: stable iodide
- Block peripheral conversion of T_4 to T_3 : iodinated contrast agent, propranolol, and corticosteroids. PTU—but not MMI—also does this, although the clinical relevance of this is unknown.
- Give empiric broad-spectrum **antimicrobial** coverage until infection is excluded.
- Provide **supportive** care in the ICU with diligent attention to volume status, temperature, and heart rate.

THYROIDITIS

Thyroiditis (thyroid inflammation) can be the result of multiple disease processes, each causing a different type of inflammation in the thyroid gland. All causes of thyroiditis that completely resolve follow a typical pattern of changes in thyroid function: from hyperthyroidism (caused by inflammation-induced cell death) to euthyroidism (as the inflammation resolves) to hypothyroidism and then back to euthyroidism again at the end of the healing process (see Figure 1-6). Some types do not completely resolve and lead to persistent hypothyroidism (mainly Hashimoto's).

Figure 1-6: Normal course of a thyroiditis that completely resolves

Review of the labs during the phases of thyroiditis:

- 1) Hyperthyroidism: High FT_4 and FT_3 ; TSH is suppressed; high ESR; RAIU is low because low TSH is suppressing production. (High FT_4 and FT_3 are due to thyroid destruction.)
- 2) Euthyroid: all labs normal

- 3) Subclinical hypothyroidism: normal FT_4 , high TSH (typically 5–10 mU/L)
- 4) For those that go to overt hypothyroidism: low FT_4 , high TSH (typically > 10 mU/L)
- 5) Back to euthyroid state: all labs normal

The most inflammatory disease processes cause the most pain and tenderness and indicate a need for a quicker workup. So let's review thyroiditis from this standpoint—painful vs. painless.

Painful and Tender

Subacute thyroiditis (a.k.a. granulomatous or de Quervain thyroiditis) is a common problem in 30- to 50-year-olds and in females > males (~4:1) and is the most common cause of a painful and tender thyroid. Subacute thyroiditis is presumed to be caused by a **viral** infection. Pathology shows thyroid inflammation and granulomas; fibrosis can occur but eventually resolves with a return to normal histology. Patients complain of a **tender and painful anterior neck** with pain that can radiate to the ear; they also often have constitutional symptoms including fever, chills, sweats, and malaise. On occasion, constitutional symptoms dominate the presentation.

Subacute thyroiditis follows the typical pattern of changes in thyroid function: from hyperthyroidism to euthyroidism to subclinical hypothyroidism to either complete normalization with euthyroidism (~85%) or long-term overt hypothyroidism (~15%).

Subacute thyroiditis is typically (85%) **self-limited** and usually does not require treatment other than NSAIDs for the inflammatory symptoms. When NSAIDs are not sufficient, give **glucocorticoids** as an 8-week taper. Occasionally, a patient may need β -blockers for thyrotoxic symptoms or levothyroxine for overt hypothyroidism. Reevaluate periodically until the patient's thyroid function normalizes.

Infectious thyroiditis (a.k.a. suppurative thyroiditis) is a rare problem that is most commonly the result of a staph or strep infection, and much less commonly, fungal or other bacterial infections. It usually occurs in children and can have an acute or chronic presentation. With the acute presentation, patients typically have severe pain, fever, and unilateral swelling. Do an ultrasound and fine needle aspiration with a Gram stain and C+S. Treat with the appropriate antibiotic.

Radiation thyroiditis can develop shortly (7–10 days) after exposure to radiation, which may be in the form of radioactive iodine treatment, radiotherapy of head and neck cancer, or accidental exposure (e.g., nuclear accident). Note that radiation thyroiditis is **painful**, but it **resolves** without therapy.

Painless and Nontender

Hashimoto thyroiditis (a.k.a. chronic autoimmune thyroiditis) is the **most common thyroiditis** (4% of the population, women:men 8:1) and the most common

cause of hypothyroidism in the U.S. (Worldwide, iodine deficiency is the most common cause.) Both genetic and environmental factors are part of Hashimoto's; however, this is not well understood. Cases are clustered in families, and the thyroiditis is sometimes associated with other autoimmune diseases, such as Type 1 diabetes, primary adrenal insufficiency, pernicious anemia, and vitiligo.

Hashimoto thyroiditis is characterized by a painless, chronic, lymphocytic infiltration of the gland causing a **firm and often irregular goiter**, which sometimes is confused for multiple nodules (ultrasound helps distinguish).

Up to **95%** of patients with Hashimoto's have measurable **anti-TPO antibodies**. Immune-mediated thyroid cell apoptosis is the ultimate cause of hypothyroidism, but how these antibodies specifically cause cell death is unclear.

Virtually all patients become hypothyroid over time as the gland is gradually destroyed, but some present with thyrotoxicosis ("Hashitoxicosis"). Presenting symptoms, therefore, are variable and depend on what phase of the disease they have on presentation. Most patients present with persistent hypothyroidism and are treated with levothyroxine.

Painless thyroiditis (a.k.a. silent thyroiditis, subacute lymphocytic thyroiditis) can present as hyper- or hypothyroidism. The disease process generally starts with a hyperthyroid stage (2–4 weeks), which progresses to a hypothyroid stage (4–12 weeks). Most patients recover. The gland is nontender and may be enlarged. Thyroid scans done during the hyperthyroid phase show diffusely low uptake (**Figure 1-4 on page 1-10**). This is helpful in distinguishing painless thyroiditis from Graves disease, in which uptake is high. **50%** of these patients later develop chronic autoimmune hypothyroidism associated with anti-TPO antibodies.

Postpartum thyroiditis is fairly common, affecting up to **10–15%** of postpartum women within 1 year of delivery. Patients present with hyper- or hypothyroid symptoms and a painless goiter. ESR is normal, but many patients do have anti-TPO antibodies. RAIU is decreased. Treat

symptomatic hypothyroidism with low-dose levothyroxine, and treat symptomatic hyperthyroidism with β -blockers. Patients usually recover completely, although some stay hypothyroid. Those that recover need annual follow-up because of the risk of overt hypothyroidism later.

Because many of those with anti-TPO antibodies progress to overt hypothyroidism, painless thyroiditis and postpartum thyroiditis are considered variants of Hashimoto's.

See **Table 1-2** for a comparison.

Remember: RAIU helps distinguish Graves' from thyroiditis as a cause for hyperthyroidism. RAIU is **high** in Graves' and **low** in patients who are hyperthyroid due to thyroiditis, **iodine excess**, **exogenous T_4 or T_3 ingestion**, and **struma ovarii** (thyroid tissue in an ovarian teratoma).

EUTHYROID SICK SYNDROME

Euthyroid sick syndrome (a.k.a. nonthyroidal illness syndrome) is seen in seriously ill or starving patients and can be confused with secondary hypothyroidism. In states of significant illness, the body does not need much FT_3 (the active hormone). Instead, the body converts FT_4 to **reverse T_3 (rT_3)**, an inactive compound. The FT_3 is very low while both the FT_4 and TSH are low or low-normal. In addition to low T_4 and T_3 , thyroid-binding globulins are also decreased.

Clinically, you see a severely ill, hospitalized patient with a mildly decreased FT_4 and low-normal TSH.

Patients with euthyroid sick syndrome are **not** given thyroid supplementation. Do **not** check TFTs in sick patients unless their acute illness is possibly due to a thyroid emergency (i.e., thyroid storm or myxedema coma).

Generally, the diagnosis of euthyroid sick syndrome is presumptive because central hypothyroidism is a very rare entity. In the recovery phase, the TSH can be elevated, but a TSH level $> 20 \mu U/mL$ ($20 mU/L$) makes it very unlikely to be a finding in euthyroid sick recovery and more likely to indicate overt hypothyroidism.

Table 1-2: Types of Thyroiditis and Their Treatments

Symptoms	Type	Antibody	T_4 Levels	Treatment
Painful and tender	Subacute	–	Hyper to hypo to eu	Resolves without therapy; NSAIDs for pain
	Infectious	–	Variable	Resolves after infection treated; NSAIDs prn
	Radiation	$\pm$	Hyper to hypo to eu	Resolves without therapy; NSAIDs prn
Painless and nontender	Hashimoto's	Anti-TPO	Hypo!	Levothyroxine
	Painless	Anti-TPO, anti-Tg	Hyper to hypo to eu	Treat hyper with β -blockers; hypo with low-dose thyroxine.
	Postpartum	Anti-TPO	Hyper to hypo to eu	Treat hyper with β -blockers; hypo with low-dose thyroxine.

THYROID NODULES AND CANCER

Thyroid nodules are common, especially in females and in the elderly. Incidental thyroid nodules are seen in > 50% of patients who undergo ultrasound, CT, or MRI to evaluate anterior carotid disease! < 10% of these nodules are **malignant**; however, these incidentomas require the same evaluation as nodules that present clinically (see below). Incidental thyroid nodules can also be found on PET scan; up to 40% of nodules found on PET scan in patients with a normal TSH are malignant, and workup is indicated. (Note: Diffuse thyroid uptake on PET is more suggestive of Hashimoto's than malignancy.)

Nodules can be multiple or single, hot or cold. Most solitary nodules are cold, and most of those are benign. Virtually all **hot** or **purely cystic** nodules are **benign**.

A malignant nodule can be primary thyroid carcinoma or a metastasis. Neck radiation as a child (especially with > 100 rads) is a major risk factor for malignant nodules (mostly papillary carcinoma), as well as nonmalignant nodules (colloid adenomas).

So, the task for the internist is to determine which nodules are malignant and which ones aren't, keeping in mind that **most nodules are not malignant**.

Basic evaluation of thyroid nodules: First, check the TSH and ultrasound. If the TSH is low, do a thyroid scan (scintigraphy) to see if the nodule is hyperfunctioning (i.e., hot). If TSH is normal or high, possibly do a fine needle aspiration to rule out malignancy based on U/S results. More on this is found in [Nodule Workup](#).

Here are some helpful generalities:

- Autonomously functioning nodules (hot nodules) are **rarely** malignant, so a single hot nodule does not require a biopsy if U/S is low suspicion. Histology from a **hot** thyroid nodule can be **indistinguishable** from a **follicular** thyroid malignancy, which can lead to false-positive biopsies and unnecessary surgery or RAI. In general, **hot** nodules should not be biopsied!
- The majority of nodules are cold, and the majority of these are benign, but **thyroid malignancies** also present as **cold nodules**.
- Cold** nodules in a patient with **Graves'** are still evaluated with a biopsy because they can be malignant.
- Multinodular goiters** (MNGs) can have **both** hot and cold nodules. As with solitary nodules, do a thyroid scan only if the TSH is low. If the thyroid scan shows cold areas, use the thyroid U/S to determine if a biopsy is warranted. If the TSH is normal or high, a thyroid scan is not needed, and the U/S alone will dictate if an FNA is needed. See also [Multinodular Goiter – Nontoxic and Toxic on page 1-19](#).
- Purely cystic nodules may appear as cold nodules on a thyroid scan but do not need a biopsy because they have a low malignancy risk. Always confirm cold nodules with a thyroid ultrasound prior to biopsy.

- All nodules should have an U/S to evaluate for suspicious characteristics and help determine if FNA is needed.

Risk Factors for Thyroid Cancer

The following risk factors increase the likelihood that a nodule is malignant:

- Hx of head/neck irradiation
- Family Hx of thyroid cancer
- New nodules in those < 20 or > 70 years of age
- Male
- Growing nodule (If the rate of growth is rapid, you must rule out a thyroid lymphoma.)
- Firm or hard consistency
- Lymphadenopathy
- Fixed
- Symptoms of compression in a patient without comorbid goiter: dysphonia, dysphagia, and cough
- Suspicious U/S features (See [Nodule Workup](#).)
- Hypermetabolic nodule detected by PET scan (focal uptake; diffuse thyroid uptake is consistent with autoimmune thyroiditis)

Nodule Workup

Thyroid nodules can be discovered by the patient, by routine physical examination, or incidentally during imaging done for another indication (incidentoma). Nodules can be solitary, or with multinodular goiter. The 2015 American Thyroid Association (ATA) thyroid nodule guidelines determine the need for FNA based on risk factors, U/S features, and nodule size. General rule: If a thyroid nodule (single, multiple, or within an MNG) has any suspicious characteristics by U/S or there is clinical concern, refer for FNA.

Know the workup for thyroid nodules. Start with a good history and physical exam with focus on risk factors for malignancy, including prior neck radiation and a family history of thyroid cancer. Then, check the TSH and thyroid U/S:

- Normal or high TSH:** Check a thyroid **U/S** (even if the nodule was found on CT or MRI). If the nodule has suspicious ultrasound features (see below), perform an FNA. Patients with high TSH also require evaluation for hypothyroidism (see [Hypothyroidism on page 1-11](#)).
- Low TSH** indicates that the nodules may be hyperfunctioning. In addition to U/S, do a thyroid **scan** (scintigraphy; [Figure 1-4 on page 1-10](#)). Patients with low TSH should also be evaluated for hyperthyroidism (see [Hyperthyroidism on page 1-13](#)).
 - In the context of a low TSH, hot nodules with low suspicion U/S are rarely malignant and do not require FNA. Histologically, hot nodules can look very similar to cancer, and biopsies often lead to false-positive results.
 - If the nodule is cold and U/S criteria are met, proceed with FNA.

Ultrasound criteria for biopsy (FNA) are as follows:

- High-risk U/S findings (biopsy high-risk nodules if they are ≥ 1 cm in size):
 - Solid or hypoechoic
 - Irregular margins
 - Microcalcifications
 - Taller-than-wide shape
 - Rim calcifications
 - Extrathyroidal extension
- Low-risk U/S findings:
 - Partially cystic, hyperechoic, or isoechoic
 - None of the high-risk U/S features above

Biopsy low-risk nodules only if ≥ 1.5 – 2 cm in size.

Purely cystic nodules (i.e., with no solid component) are benign and generally not biopsied/drained unless there are compressive symptoms or for cosmetic reasons.

What you do after FNA of thyroid nodules depends on what the **pathology** shows. Malignant or suspicious pathology goes to surgery. Nondiagnostic and follicular lesion of undetermined significance (FLUS) pathology goes for repeat FNA. Follicular neoplasm generally gets a hemithyroidectomy or repeat FNA with molecular markers. Benign nodules are followed with repeat U/S.

Benign Nodular Disease

In euthyroid patients with nodules and/or an MNG established as benign on FNA, consider surgery only if compressive symptoms develop, such as difficulty breathing or swallowing. Consider repeat biopsy if there is significant growth or development of high-risk U/S features. Recurrence of a cystic nodule after several aspirations is considered to be an indication for surgical excision, as is persistent patient anxiety and concern about cosmetic appearance.

Toxic Adenoma

A toxic thyroid adenoma is a benign area of **autonomous** hyperfunctioning thyroid tissue. Most occur as a single hyperfunctioning nodule within normal tissue that grows slowly, eventually becoming large enough to suppress TSH production. The end result is an autonomous, hyperfunctioning nodule in the midst of “turned-off” thyroid tissue (i.e., a **hot nodule**). These are usually diagnosed by TFTs, which demonstrate overproduction of FT_3 and FT_4 with suppression of TSH, and are confirmed on thyroid scan (focal uptake in hot nodule; see [Figure 1-4 on page 1-10](#)).

Treatment of thyroid adenomas: If the patient is hyperthyroid, 1st line therapy is radioactive iodine for **ablative** treatment or surgical resection. If the thyroid adenoma is compressing underlying structures or is cosmetically problematic, surgery is the best treatment.

Antithyroid drugs work but are not curative, so they generally are not offered.

For the euthyroid patient with a thyroid adenoma, **do not** use suppressive therapy with thyroxine because the risks of overt hyperthyroidism outweigh the benefits of mild shrinkage.

Percutaneous ethanol injection of autonomous functioning thyroid nodules is an alternative to surgery and RAI (e.g., in patients who are not a candidate for either), with restoration of normal thyroid function in the majority of cases. This treatment is not routinely done in the U.S.

To review RAIU and scan findings in hyperthyroid disorders:

- Hyperthyroidism with high RAIU. Distinguish these three with a thyroid scan!
 - **Graves** disease
 - Toxic multinodular goiter
 - Toxic adenoma
- Hyperthyroidism with a decreased RAIU
 - **Thyroiditis**
 - Overmedication with thyroxine supplements
 - Medications containing iodine (e.g., amiodarone)

Thyroid Carcinoma

Thyroid cancer is the most common endocrine cancer and incidence rates are increasing. There are 4 histologic types of carcinoma:

- 1) **Papillary**: most common; well-differentiated; usually indolent; spreads via lymphatics to local lymph nodes, and later to bone/lungs
- 2) **Follicular**: less common; differentiated; spreads hematogenously to bone/lungs/CNS. Capsular and/or vascular invasion is crucial in differentiating a follicular carcinoma from a benign adenoma. This is why a hemithyroidectomy is necessary after a biopsy showing follicular neoplasm. If surgical pathology confirms carcinoma, then a completion thyroidectomy is performed.
- 3) **Anaplastic**: rare; highly undifferentiated and highly malignant; death within 6 months of diagnosis; no good treatment available
- 4) **Medullary**: associated with hyperplasia of parafollicular C cells and elevated serum calcitonin. It can be sporadic or inherited with ~ 15% occurring as a component of multiple endocrine neoplasia syndromes (i.e., MEN2A and MEN2B) and familial medullary thyroid cancer (FMTC) syndrome. MEN cases are associated with point mutations in the *RET* protooncogene. If *RET*+, always screen for pheochromocytoma; if confirmed, resect the pheo before resecting the medullary thyroid cancer.

Note: You do not need to know the specific staging systems of the various thyroid cancers.

Treatment of the thyroid cancer is usually a near-total thyroidectomy, which always leaves part of the posterior capsule around the recurrent laryngeal nerve intact. A thyroid **lobectomy** can be done as treatment for **papillary** cancer that is very small and limited to one lobe.

Frequently, a small amount of residual thyroid tissue also remains after near-total thyroidectomy. **Postoperative RAI therapy** can be given to higher-risk patients to destroy any remaining normal cells (remnant ablation) and any thyroid cancer cells.

There is higher risk of **recurrence** with:

- Incomplete tumor resection
- Extrathyroidal extension
- Distant metastases
- Poor tumor differentiation or advanced tumor grade
- Mediastinal or bilateral cervical lymph node metastases (if papillary cancer)
- Extensive capsular and vascular invasion (if follicular cancer)

The decision to treat with RAI, as well as the dose of ^{131}I used, is individualized, but patients with risk factors for recurrence definitely should receive postoperative RAI. Following surgery, thyroxine therapy is necessary but sometimes is not started immediately after thyroidectomy if RAI is going to be given. Instead, the TSH is allowed to rise over several weeks; once the TSH level is $> 25 \mu\text{U/mL}$ (25 mU/L), RAI is given. After RAI, thyroid hormone is started. If thyroid hormone withdrawal is not the best option (mostly for patients with comorbidities), then increase the TSH with recombinant human thyrotropin alfa (Thyrogen). If Thyrogen is used, then thyroid hormone therapy can be started immediately after surgery—even if RAI is going to be given.

Once thyroid hormone is started, use **suppressive doses** of **thyroxine** in higher-risk cancers. Most **differentiated** thyroid cancers remain **responsive** to TSH, so keeping the TSH suppressed slightly below the lower limit of normal helps prevent recurrence. Suppression of TSH can increase the risk of hyperthyroid complications (e.g., atrial fibrillation, dilated cardiomyopathy, osteoporosis); therefore, target the TSH to be around $0.1 \mu\text{U/mL}$ (0.1 mU/L) for cancers with higher risk of recurrence while maintaining a normal FT_4 .

Long-term follow-up usually involves one or more of the following: neck ultrasound, total body scans, and/or thyroglobulin levels (as long as the patient does not have antithyroglobulin antibodies to interfere with the assay). Thyroglobulin is only expressed by thyroid tissue (both cancer and noncancerous cells), so thyroglobulin levels following surgery and RAI therapy should be undetectable. Any rise in thyroglobulin levels suggests recurrent disease. Do not check the thyroglobulin immediately after surgery, as it has a long half-life (> 60 hours) and levels can be elevated up to 25 days post-op.

Thyroid **lymphoma** is associated with chronic autoimmune thyroiditis. Think about this in a patient with chronic autoimmune thyroiditis who develops a **fast-growing thyroid mass**. The most common tumor type is a diffuse large B-cell lymphoma, which is treated with chemotherapy and external beam radiation. Surgery is used only for biopsy and diagnosis.

Nontoxic Goiter

Simple, nontoxic goiter is a diffuse enlargement of the thyroid gland with a normal TSH and FT_4 . It can be caused by a lack of iodine or ingestion of a goitrogen (e.g., cassava root, Brussels sprouts, cauliflower, cabbage), but many cases are idiopathic. Diagnose nontoxic goiter with thyroid function tests; FT_4 and TSH are normal.

Treatment: Remove any goitrogens from the diet. If the cause is low iodine, iodine supplements help.

Multinodular Goiter — Nontoxic and Toxic

Nontoxic multinodular goiter (MNG) is fairly common and occurs more often in **women**. Cause is multifactorial. Nodules of varying sizes are distributed throughout the gland, but patients are generally asymptomatic and euthyroid with a normal TSH. They come to attention because of the size of their gland or because (rarely) the gland gets large enough to compress surrounding structures.

Suspect this diagnosis when various-sized nodules are palpated in a goiter. After obtaining a normal TSH, perform U/S to look for any nodules with features suspicious for malignancy. If concerning features are present, do a biopsy (see the U/S criteria for FNA biopsy under **Nodule Workup** on page 1-17). If no biopsy is needed or the results of the FNA are benign, then nontoxic MNG is generally managed conservatively but has 2 main indications for treatment:

- 1) Symptomatic compression of key structures (e.g., trachea or esophagus)
- 2) Cosmetic: surgical correction of a disfiguration

Standard surgical treatment of nontoxic MNG, if indicated, is bilateral subtotal thyroidectomy. If the patient is not a surgical candidate, radioiodine therapy can be used for goiter shrinkage. These nodules are typically **benign**. Benign nodules remain benign, and they do not change size. Thyroxine suppressive therapy is **not** used because it is not very effective and long-term thyroxine therapy increases the risk of osteoporosis and atrial fibrillation.

Toxic MNG refers to an MNG with **thyrotoxicosis**. TSH is suppressed, and FT_3 and FT_4 are often increased. The thyroid scan (see **Figure 1-4** on page 1-10) usually shows ≥ 1 **hot** nodule.

Toxic MNG can be treated with antithyroid medications (e.g., methimazole) in urgent or emergent clinical situations to control the hyperthyroidism, but 1st line treatment is usually ablative therapy with radioactive iodine since it is curative. This does not destroy all the nodules, but it does destroy those that are hyperfunctioning. Most patients end up euthyroid after RAI. Surgery is used in cases that are refractory or in symptomatic cases when compression symptoms are present.

ADRENAL GLAND

PREVIEW | REVIEW

- Name 3 different hormones that are produced in the adrenal cortex. (Also see [Figure 1-8](#).)
- What is produced in the adrenal medulla?
- What do mineralocorticoid hormones do?
- What are the mineralocorticoid effects of excess cortisol?
- How does a woman who overproduces adrenal androgens present?
- Which gene defect is most commonly associated with congenital adrenal hyperplasia?
- What is the difference between Cushing syndrome and Cushing disease?
- What is the adrenocorticotropic hormone (ACTH) level in Cushing disease?
- What are your choices for initial tests to evaluate a patient who may have Cushing syndrome?
- In which clinical situations does pseudo-Cushing syndrome occur?
- How does adrenal insufficiency (both primary and secondary) present?
- Abnormal K^+ levels occur in which type of adrenal insufficiency? Why?
- How do aldosterone levels affect serum Na^+ and K^+ ?
- Which syndrome should you be concerned about in a patient with difficult-to-treat hypertension and low K^+ ?
- What is the best screening test for primary hyperaldosteronism? How do you interpret it?
- Hypoaldosteronism is usually due to which acquired problem?
- Which screenings are employed to test for pheochromocytoma?
- What are the 1st steps in working up adrenal incidentalomas?

OVERVIEW

Cortisol, adrenal androgens, and aldosterone are made in the cortex of the adrenal gland from cholesterol.

The adrenal **cortex** has 3 zones (remember “**GFR**” as the sequence and “the deeper you go, the sweeter it gets”):

- 1) The outer zona **glomerulosa** (aldosterone = salt)
- 2) The middle zona **fasciculata** (cortisol = sugar)
- 3) The inner zona **reticularis** (androgens = sex)

The adrenal **medulla** makes **epinephrine** in chromaffin cells.

Hypothalamic corticotropin-releasing hormone (CRH) is secreted in response to a low serum cortisol, stress, and circadian rhythm. CRH causes the release of adrenocorticotropic hormone (ACTH) from the anterior pituitary, which stimulates the adrenal gland to release glucocorticoids (**cortisol** and precursors), adrenal androgens (mainly dehydroepiandrosterone sulfate [**DHEA-S**]), and to a lesser extent, mineralocorticoids (**aldosterone** and precursors), because aldosterone production is mostly regulated by the renin-angiotensin system. ACTH has **no effect** on epinephrine production from the adrenal medulla. See [Figure 1-7](#).

Figure 1-7: HTH-pituitary-adrenal (HPA) axis

STEROID SYNTHESIS

Refer to the adrenal steroid synthesis diagram ([Figure 1-8](#)). It gives you all you need to know for those mind-boggling conditions of congenital adrenal hyperplasia.

Remember: In response to ACTH, the adrenal gland takes cholesterol and forms 3 products—**mineralocorticoids** (aldosterone), **cortisol**, and **androgens** (DHEA-S)—through a series of enzyme actions.

In [Figure 1-8](#), the solid green line represents normal pathways of steroid synthesis. The ovals are the genes that code for important enzymes:

- *CYP17* → 17 α -hydroxylase
- *CYP21A2* → 21-hydroxylase
- *CYP11B1* → 11 β -hydroxylase

An “X” over the oval represents a defect in the gene, with subsequent impairment of the enzyme for that step of synthesis. The color of the X matches the color of the pathway that increases if that enzyme is blocked. For example, a defect in either *CYP11B1* or *CYP21A2* results in increased DHEA-S and decreased aldosterone and cortisol. Not only that, but it causes a buildup in the hormone right before it. For example, a defect in *CYP11B1* causes a buildup of 11-deoxycortisol, and a defect in *CYP21A2* causes a buildup of 17-hydroxyprogesterone.

Recognize that whenever a pathway is blocked, precursors to the blocked point build up. Levels of these precursor hormones are measured clinically to diagnose the particular enzyme deficiency. If you know the effects of the final product of each pathway, then you can easily deduce the clinical presentation of deficiencies and excesses that arise when any pathway is blocked and rerouted into other pathways.

Now, let's go over the actions of the 3 ultimate products and their effects:

- 1) Mineralocorticoids (e.g., **aldosterone**) increase renal Na^+ reabsorption and K^+/H^+ excretion, so high levels cause hypertension, hypokalemia, and metabolic alkalosis. Although ACTH does stimulate aldosterone production, the major regulator is **angiotensin II**.
- 2) Glucocorticoids (e.g., cortisol) stimulate lipolysis and gluconeogenesis by the liver, and they release amino acids from the muscles. They also weaken bones by decreasing the protein matrix. Cortisol inhibits all stages of the inflammatory process. Its immunosuppressive effect is on T cells and their associated cell-mediated immunity and delayed hypersensitivity. Excess cortisol can also stimulate mineralocorticoid receptors with the clinical appearance of aldosterone excess (i.e., hypertension, hypokalemia, and alkalosis) even though the aldosterone level is low!
- 3) The main androgen produced by the adrenals is DHEA-S.
 - In normal males, adrenal androgens are overshadowed by the production of **testicular** androgens.
 - Normally, in females, the adrenals **contribute half** of the **circulating testosterone** (ovaries contribute the other 50%). Together with adrenal DHEA-S, these androgens slightly virilize the normal female

(e.g., pubic and axillary hair). In excess, the clinical effects depend on whether exposure occurs in utero (causing ambiguous genitalia in females) or postnatally (causing virilization, hirsutism, and abnormal menses). Bottom line: Anytime virilization is noted in a female, think about overproduction of androgens by either the **adrenals** or **ovaries**. You can tell where androgens are coming from by the DHEA-S level because DHEA-S is only produced by the adrenal gland; this is unlike testosterone, which can be from either adrenals or ovaries. So, high DHEA-S = adrenal origin!

Virilization is the development of male secondary sex characteristics (e.g., male hair growth, male pattern baldness, increased muscle bulk) in a female.

Refer again to the synthesis diagram (Figure 1-8) and note the following:

- With defective *CYP21A2* and *CYP11B1*, the increased precursors force the reactions along the purple line with enhanced production of adrenal androgens (DHEA-S).
- If *CYP17* is defective, the reaction is forced along the pink line, and more mineralocorticoids are produced.

CONGENITAL ADRENAL HYPERPLASIA (CAH)

CAH is a congenital, autosomal recessive mutation that causes a decrease in cortisol production. CAH is caused by defects in 1 of the 3 genes previously mentioned:

- *CYP21A2* (enzyme = 21-hydroxylase)
- *CYP11B1* (enzyme = 11 β -hydroxylase)
- *CYP17* (enzyme = 17 α -hydroxylase)

Figure 1-8: Adrenal steroid synthesis pathways

95% of all CAH is due to mutations in **CYP21A2**, causing a deficiency of 21-hydroxylase such that 17-OH progesterone is not converted to 11-deoxycortisol (and thus 17-OH progesterone accumulates and is the screening test). This mutation/deficiency blocks **cortisol** (and aldosterone) production and the high precursors lead to increased androgen production. These mutations have variable expression and can result in severe, moderate, or mild clinical syndromes. The elevated ACTH that occurs in response to the low cortisol causes adrenal hypertrophy ("hyperplasia"). Note: These patients will require long-term glucocorticoid and mineralocorticoid therapy.

Severe 21-hydroxylase deficiency causes the classic "salt-losing" form of CAH. The newborn can present in **adrenal crisis** with hyponatremia and hyperkalemia. Females with this salt-losing type are born with **ambiguous genitalia**. This occurs because the impairment of 21-hydroxylase during gestation forces an increase in DHEA-S and testosterone (purple line on diagram), which causes not only the ambiguous genitalia in newborn girls but also subsequent virilization in boys and girls.

Moderate 21-hydroxylase deficiency causes the classic "simple virilizing" form of CAH. These patients have 1–2% of normal 21-hydroxylase enzyme activity. This is just enough to make sufficient cortisol and aldosterone, but there is still a buildup of precursors that cause an elevated DHEA-S so females have **prepubertal** virilization and males have precocious puberty.

Mild 21-hydroxylase deficiency causes the nonclassic "late onset" form of CAH. Females have **postpubertal** virilization. Labs show an **early morning elevation** of blood **17-hydroxyprogesterone**, and increased blood DHEA-S. Late-onset CAH must be differentiated from polycystic ovary syndrome (PCOS). Confirm with a markedly elevated, 17-hydroxyprogesterone level after ACTH stimulation. Combination estrogen-progesterone oral contraceptive pills (OCPs) are first-line therapy, similar to polycystic ovary syndrome (PCOS) management. Spironolactone can be added. Glucocorticoids are effective but are not used as first-line agents for late-onset CAH, due to the need for long-term therapy and the possible side effects of long-term glucocorticoid use. However, glucocorticoids can be used for a short time to assist with infertility/anovulation in late-onset CAH when fertility is desired.

Less commonly, CAH is due to a genetic defect in **CYP11B1** with 11 β -hydroxylase deficiency. This leads to elevated **11-deoxycortisol** and **11-deoxycorticosterone** (DOC). DOC is a mineralocorticoid precursor but it also has its own mineralocorticoid activity. As with 21-hydroxylase deficiency, cholesterol is shunted along the purple line of the diagram into producing excess DHEA-S and testosterone. As a result, patients with 11 β -hydroxylase deficiency have both virilization and signs of mineralocorticoid excess, even though aldosterone levels are low! Thus, the clinical presentation is hypertension, hypokalemia, and metabolic alkalosis due to DOC; and hirsutism and menstrual irregularities from the elevated DHEA-S.

Mutations in **CYP17** are the rarest of all, accounting for < 1% of all CAH. Here, deficiency in 17 α -hydroxylase pushes the pathway into formation of only mineralocorticoids (primarily DOC). Clinical features are hypertension, hypokalemia, alkalosis (due to DOC), and hypogonadism (due to androgen deficiency). Aldosterone is suppressed by the hypokalemia and renin is low, due to the hypervolemic state. Diagnose with a high DOC and corticosterone, with low cortisol, androgens, and estrogens.

CUSHING SYNDROME

Cushing syndrome occurs when there is an **excess of glucocorticoid in circulation** causing easy fatigability, proximal muscle weakness, easy bruising, weight gain, and emotional lability (sometimes frank psychosis). In women, it additionally causes amenorrhea, hirsutism, and acne. Physical exam reveals facial plethora (a.k.a. moon facies; i.e., a round, red face); thin skin; thick (at least 1.0 cm), bright **purplish** striae (**Figure 1-9**); cervicodorsal fat pad ("buffalo hump"); and truncal obesity. Cortisol in high concentrations can stimulate mineralocorticoid receptors, leading to edema, hypertension, hypokalemia, and metabolic alkalosis in some patients. Comorbid diagnoses include insulin resistance (20% have Type 2 diabetes) and osteoporosis.

Figure 1-9: Abdominal striae in Cushing syndrome

Causes of Cushing syndrome:

- Iatrogenic glucocorticoid administration (e.g., prednisone); the most common cause
- ACTH-secreting **pituitary** adenoma (Cushing **disease**); the most common cause of ACTH-dependent cortisol excess
- **Ectopic ACTH-secreting tumor**: bronchogenic, pancreatic, or thymic carcinoma (Small cell lung cancer is the most common cause of **ectopic** Cushing's syndrome in patients > 60 years of age!)
- Bilateral adrenal hyperplasia
- Adrenal adenomas or carcinomas

Cushing **syndrome** caused by pituitary adenomas is termed Cushing **disease**. Next to exogenous steroids, Cushing disease is the **most common** cause of Cushing syndrome.

Know the following:

- The ACTH level is elevated or inappropriately normal in Cushing disease.
- Recall that ACTH increases the synthesis of not only **cortisol**, but also **adrenal androgens** (Figure 1-8 on page 1-21). So, in Cushing disease (pituitary disease) and ectopic ACTH production, elevated ACTH stimulates production of adrenal DHEA-S, and females can present with hirsutism, virilization, and acne. This is in contrast to non-ACTH-mediated cortisol excess, in which the ACTH and DHEA-S are both low.

In clinical practice, Cushing's can have subtle nuances, but typical exam question scenarios are straightforward when you use the following workup.

Cushing Syndrome Workup

The suspicion of Cushing syndrome comes from recognizing the typical clinical features (i.e., moon facies, buffalo hump, and central obesity).

Before starting the following workup for hypercortisolism, be sure to exclude exogenous glucocorticoid administration, including factitious (i.e., surreptitious) ingestion. Patients on glucocorticoids should not be worked up for Cushing syndrome because you cannot assess for endogenous cortisol excess while on glucocorticoids. All glucocorticoids, including steroid inhalers, topical steroids, and injectable steroids will suppress ACTH and endogenous cortisol secretion.

Step 1: Document the presence of cortisol excess with one of the following initial tests:

- 24-hour urinary free cortisol (**UFC**),
- late-night **salivary cortisol**, and/or
- **low-dose (1 mg) dexamethasone** suppression test (DST).

Confirm an abnormal test either by repeating it or with one of the other 2 tests. A random cortisol is affected by multiple factors and is not useful to evaluate for cortisol excess.

The majority of plasma cortisol is bound to cortisol-binding globulin (CBG), and < 5% is free and physiologically active. Be aware that estrogen (OCPs) raises CBG, which raises serum cortisol and can give a false-positive DST. The urinary and salivary cortisol tests measure free cortisol and do not result in false-positives with estrogen use.

If the patient is depressed, obese, alcoholic, or has uncontrolled diabetes, think **pseudo-Cushing's** before attributing the clinical scenario to true Cushing syndrome. Identify pseudo-Cushing's with the low-dose DST or salivary cortisol levels. Patients with pseudo-Cushing's usually have normal cortisol suppression after treatment

with dexamethasone, and they maintain their diurnal rhythm on salivary cortisol testing. Do not use a UFC because it can often be elevated in pseudo-Cushing's. If a screen for excess cortisol production is abnormal, make an endocrine referral.

Remember: Cushing **syndrome** is the general description for any state of excess cortisol and includes the specific diagnosis of Cushing **disease**, which refers to an ACTH-secreting pituitary tumor.

Step 2: Determine if the Cushing syndrome is ACTH-dependent or ACTH-independent.

Once you have identified a patient with true Cushing syndrome with a Step 1 test, check the **ACTH** level. Normally, a high cortisol state completely suppresses ACTH production. Thus, **any** measurable **ACTH** indicates ACTH-dependent Cushing syndrome—either Cushing disease or ectopic ACTH production. Go to Step 3a.

A suppressed ACTH indicates ACTH-independent Cushing syndrome—**adrenal** hyperplasia, adrenal nodule, or adrenal carcinoma. Go to Step 3b.

Step 3a (ACTH-dependent Cushing syndrome):

ACTH-dependent Cushing syndrome means the cause is either a pituitary tumor (Cushing disease) or an ectopic, ACTH-secreting tumor. Again, ACTH level is elevated or inappropriately normal in both, but Cushing disease is much more common.

See the algorithmic approach for ACTH-dependent vs. ACTH-independent workup (Figure 1-10 on page 1-24).

As Cushing disease is more common than ectopic secreting tumors in ACTH-mediated cortisol excess, the next step is to image the **pituitary** with a **gadolinium-enhanced MRI** and refer the patient to a neurosurgeon if you see a pituitary tumor.

Some ACTH-producing microadenomas are not visible on MRI due to their very small size, so pituitary etiology of cortisol excess is verified with inferior petrosal sinus venous sampling (**IPSS**; detects local production of ACTH). If the IPSS does not confirm a pituitary source, the patient likely has an ectopic ACTH-producing tumor, such as primary lung or carcinoid tumor; look for these with **high-resolution CT** of the **chest** and **abdomen**.

Step 3b (ACTH-independent Cushing syndrome):

When the patient has a high cortisol and low ACTH, there is most likely an **adrenal tumor** (hyperplasia, adenoma or carcinoma) that is secreting cortisol. Image the adrenals with a contrast-enhanced CT. If a mass is found, refer to a surgeon for adrenalectomy.

Consider ordering DHEA-S concentration. Since patients with cortisol-producing adrenal **adenomas** have **low** ACTH, the DHEA-S level will also be low. In contrast, **carcinomas** can make all adrenal products, and they can have **high** DHEA-S, cortisol, aldosterone, and **urine 17-ketosteroids** despite a low ACTH.

Figure 1-10: Cushing syndrome workup

ADRENAL INSUFFICIENCY (AI)

AI can be **primary** (i.e., Addison disease = dysfunction of the adrenal gland itself) or **secondary** (pituitary) disease. When AI presents acutely, it is an endocrine emergency (adrenal crisis).

In industrialized countries, **primary** AI is most often the result of autoimmune adrenalitis (which is sometimes seen in polyglandular autoimmune syndromes 1 and 2), but it can also be caused by granulomatous and infiltrative diseases, (e.g., HIV/AIDS, CMV, TB, amyloidosis, sarcoidosis). The most common cause of **secondary** AI is rapid withdrawal of chronic exogenous glucocorticoids.

Polyglandular autoimmune syndrome 1 is autosomal recessive (defective *AIRE* gene). Key manifestations include chronic mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency. Other findings can include malabsorption/pernicious anemia, hepatitis, alopecia, chronic autoimmune thyroiditis, and premature gonadal failure.

Polyglandular autoimmune syndrome 2 includes ≥ 2 of the following: Addison disease, chronic autoimmune thyroiditis, premature ovarian failure, and Type 1 diabetes. Less common findings include pernicious anemia, vitiligo, alopecia, sprue, and myasthenia. Schmidt syndrome is the Type 2 syndrome with primary adrenal insufficiency and autoimmune thyroid disease (and often Type 1 diabetes). Know that you must **replace cortisol first** because giving thyroid replacement prior to glucocorticoid replacement can precipitate an adrenal crisis.

Remember that autoimmune diseases often occur together.

Signs and symptoms of AI: The preeminent symptom of adrenal insufficiency is **weakness**. As the disease worsens, patients can become bed-bound. Other symptoms include anorexia, weight loss, N/V, vague abdominal pain, hypoglycemia, and moodiness. Hypercalcemia occurs in 20% of patients (mechanism is unknown). Eosinophilia is unusual but, if present, can be a clue.

Since primary AI affects the entire cortex in addition to cortisol deficiency and low DHEA-S level, there is aldosterone deficiency leading to hyperkalemia, a. Hyponatremia is often seen in primary AI. **Hyperpigmentation** may be evident on physical exam and is due to cosecretion of ACTH and melanin precursor.

Secondary AI (disease of the **pituitary**; e.g., postpartum hypopituitarism [a.k.a. Sheehan syndrome]): **Low ACTH** is **not** due to diseased adrenal glands; thus, because aldosterone is normal and hyponatremia and hyperkalemia are not seen, the zona glomerulosa can still make aldosterone in response to the renin-angiotensin system. The renin-angiotensin system is the major regulator of aldosterone production, not ACTH. It is not associated with hyperpigmentation. Here, the DHEA-S is low due to lack of ACTH stimulation.

Diagnosis and treatment of AI: If the patient has **acute adrenal insufficiency**, it needs to be **treated immediately**. Your first task is simply to recognize that AI exists and treat it. You can sort out etiology later.

Treatment of adrenal crisis: If the patient is in **shock** and you suspect adrenal shock, check a random cortisol, give IV fluids with glucose if the patient is hypoglycemic and dexamethasone. Perform an ACTH stimulation test **after** the patient **stabilizes**. **Dexamethasone** is potent, does **not interfere** with the cortisol assay, and does not cause endogenous adrenal suppression for a few hours, so the ACTH stimulation test is reliable. Dexamethasone does suppress the ACTH level, so if you have time, draw a serum ACTH prior to instituting treatment.

Treatment of stable patients with AI: In patients who are hemodynamically stable, perform an ACTH stimulation test: First, draw a baseline cortisol and ACTH level, then give **cosyntropin** (synthetic ACTH) 0.25 mg IM/IV, and recheck cortisol at 30 and 60 minutes. Normally, the cortisol level increases with cosyntropin stimulation. If the stimulated cortisol is $< 18\text{--}20\text{ }\mu\text{g/dL}$ ($496\text{--}552\text{ nmol/L}$), your patient has AI. The ACTH level determines whether the disease is in the adrenals (primary; high ACTH level) or the pituitary (secondary; low ACTH level).

You may not need the cosyntropin (ACTH) test in 2 types of patients when AI is suspected: those whose 8 a.m. cortisol is $< 3\text{ }\mu\text{g/dL}$ (83 nmol/L) with clear-cut clinical findings of adrenal insufficiency and those with chronic glucocorticoid use or recent high-dose glucocorticoid therapy, because the test is impossible to interpret.

Note: The cosyntropin stimulation test is abnormal (lower than expected increase in cortisol) in **both** primary and secondary adrenal insufficiency. In primary AI, endogenous ACTH levels are already high and administration of cosyntropin has little effect. In longstanding secondary/tertiary AI (disease in pituitary or hypothalamus), the adrenal glands do not respond to

ACTH stimulation even though they are not diseased (because they are atrophied).

If the cosyntropin test is abnormal, you can check an ACTH level and a serum aldosterone. In primary AI, the ACTH level is high while the serum aldosterone is low.

Summary of interpretation of labs in AI:

- **Primary AI** = **abnormal** cosyntropin stimulation, **high** ACTH level, and **low** aldosterone (because multiple layers of adrenal are affected by the disease process). Hyperkalemia occurs in $> 20\%$ of cases, but its absence does not rule out primary AI. Low DHEA-S.
- **Secondary/Tertiary AI** = abnormal cosyntropin stimulation, low or low-normal ACTH level, and normal aldosterone. Low DHEA-S. Image the pituitary (sella) with MRI if no history of steroid use.

Although longstanding secondary/tertiary AI causes an abnormal cosyntropin stimulation test, acute causes of central adrenal insufficiency (e.g., after pituitary surgery, intracranial trauma/bleeding) can have a normal cosyntropin test because the adrenal glands haven't had time to atrophy (so they respond normally to ACTH stimulation). Consider treating empirically and wait several weeks before checking the cosyntropin test in these patients.

After the acute phase of treatment of AI, these patients need long-term glucocorticoid therapy. Remember to instruct the patient about stress dosing (doubling their baseline steroid therapy in case of illness), and the importance of having a medical ID form with them at all times describing their disease. Also, remember that in **primary AI**, there is usually an associated **mineralocorticoid deficiency**, so for long-term care you need to also replace mineralocorticoids with fludrocortisone.

MINERALOCORTICIDS

Aldosterone is discussed extensively in the **Nephrology** section. It increases Na^+ resorption and, hence, K^+ and H^+ excretion in the distal tubules, causing hypokalemia and a metabolic acidosis. Increased Na^+ resorption means increased water retention and the tendency for hypertension. The release of aldosterone is mainly controlled by both the renin-angiotensin system and the K^+ level, but ACTH does have some effect.

To recap, renin is released by the **healthy** kidney from the juxtaglomerular apparatus in response to at least 3 independent factors:

- 1) Perceived volume depletion, as measured by the juxtaglomerular cells. These are specialized myoepithelial cells cuffing the afferent arteriole.
- 2) Decreased levels of filtered Na^+ , as measured by the efferent macula densa cells
- 3) Sympathetic nervous system stimulation, which stimulates release of renin in response to assuming the upright posture

Renin converts **angiotensinogen** to **angiotensin I**, which is then converted to **angiotensin II** by the angiotensin-converting enzyme (ACE)—mainly in the lungs. Angiotensin II has pressor effects and stimulates aldosterone release from the **zona glomerulosa** in the adrenal glands.

Hyperaldosteronism

Primary hyperaldosteronism (disease in the adrenal) is associated with **low renin**, hypertension, hypokalemia, and metabolic alkalosis.

Secondary hyperaldosteronism (disease in the kidney) is a **high renin** state. Decreased renal blood flow from either renal artery stenosis or fibromuscular dysplasia → increased renin → increased angiotensin II → increased aldosterone.

Situations other than aldosterone excess that can cause hypertension and hypokalemia are licorice ingestion and Cushing syndrome.

See the **Nephrology** section for more on when and whom to screen for hyperaldosteronism.

Figure 1-11 summarizes the screening and confirmatory tests and how to determine the source of the aldosterone.

The best **screening test** for primary hyperaldosteronism is a paired plasma aldosterone concentration (PAC) and plasma renin activity (PRA). This is often presented as a PAC:PRA ratio. Know that aldosterone blockers (i.e., spironolactone, eplerenone) interfere with the PAC:PRA ratio **and must be stopped 4 weeks prior to performing this test**. All other antihypertensive medications can be continued. Low K^+ decreases the aldosterone production and can give a false-negative PAC:PRA ratio, so correct hypokalemia with oral K^+ before the test. Interpret the results this way:

- **Primary hyperaldosteronism:** aldosterone (PAC) elevated and renin (PRA) suppressed → elevated PAC:PRA ratio (of at least 20:1). Think adrenal disease (aldosterone-producing adenoma or primary adrenal hyperplasia).

Suspected Primary Hyperaldosteronism

Figure 1-11: Primary hyperaldosteronism workup

- **Secondary hyperaldosteronism:** PAC and PRA both elevated, with PAC:PRA usually < 10. Think renovascular disease (common) or renin-secreting tumor (rare).
- **Cushing's** (cortisol activates mineralocorticoid receptor) and chronic consumption of **black licorice** (increases mineralocorticoid effect of glucocorticoids): PAC and PRA both low, with PAC:PRA either normal or elevated

Confirmatory tests: If the labs support primary hyperaldosteronism (PAC high, PRA low, and PAC:PRA high), **confirm** the diagnosis by **trying to suppress** aldosterone production. In saline suppression testing, give 2 L normal saline IV over 3–4 hours to the recumbent patient. Nonsuppression of PAC indicates primary hyperaldosteronism. Alternatively, you can give an oral Na⁺ load for 3 days, then measure the 24-hour urine aldosterone excretion. (Again, nonsuppression suggests adrenal disease.) These tests are not as easy as they seem. In patients with significant hypertension, giving saline or a high-salt diet runs the risk of dangerously increasing blood pressure.

Remember, if the aldosterone level is not high (at least > 10 ng/dL [277.4 pmol/L]), it is not hyperaldosteronism, even when the PAC:PRA is high. The renin activity can be very low for other reasons (e.g., high salt consumption, essential hypertension), giving a misleadingly high PAC:PRA ratio.

Once primary hyperaldosteronism is confirmed, the next step is to determine if it is due to an aldosterone-producing adenoma (APA) or primary adrenal hyperplasia (PAH). With this workup, keep in mind that while APA can be treated surgically, both APA and PAH can be treated medically. If the patient is not a surgical candidate, or surgical treatment is not preferred, you can stop here—just treat with an aldosterone antagonist!

If the patient is a surgical candidate and wishes to pursue surgical treatment, proceed as follows. First, **image** the adrenals with either high-resolution CT or MRI to see if there is an adrenal adenoma.

If there is a unilateral adrenal nodule on CT/MRI, the next step depends on the age of the patient:

- < 35 years of age: Go straight to surgical adrenalectomy. Nonfunctioning adrenal adenomas are rare in this age group.
- > 35 years of age: Perform adrenal vein sampling (AVS) to prove the adenoma is functional (i.e., an APA). If AVS is consistent with APA (lateralization of high aldosterone to the side with the tumor), proceed to surgery.

If imaging does **not** reveal an adrenal nodule, there still may be an APA that is too small to detect on imaging. Regardless of age, perform AVS. If there is lateralization of aldosterone production, you can proceed with adrenalectomy.

If AVS shows no lateralization (i.e., no APA), the primary aldosteronism is due to PAH and treatment is with aldosterone antagonists (i.e., spironolactone, eplerenone).

Hypoaldosteronism

The most common cause of hypoaldosteronism is decreased production of **renin** in **diabetic** patients with mild renal failure (**hyporeninemic hypoaldosteronism**, a.k.a. Type 4 renal tubular acidosis [RTA]). It is also seen in patients with chronic interstitial nephritis, chronic NSAID use, and heparin therapy. More severe hypoaldosteronism is seen with primary adrenal insufficiency (i.e., Addison disease).

Suspect hypoaldosteronism in patients with **hyperkalemia** and **normal** anion gap metabolic **acidosis** out of proportion to the renal disease (low aldosterone leads to failure to excrete H⁺/K⁺ in the distal tubule). Patients are unable to retain Na⁺ in states of volume contraction, and they develop **postural hypotension**.

Start the workup by excluding AI as a cause of the hyperkalemia and hypotension because, clinically, they can look similar; perform an ACTH stimulation test. Next, measure renin and aldosterone levels during upright posture and salt restriction (renin is low in this diagnosis but high in AI). Treat with a mineralocorticoid (fludrocortisone). If hypertension and edema are present, do not use fludrocortisone; treat with a low-potassium diet and a loop diuretic.

PHEOCHROMOCYTOMA

In 2014 the Endocrine Society published the 1st clinical practice guidelines for pheochromocytoma. Our discussion is based on these guidelines.

Pheochromocytoma (pheo) is a rare catecholamine-secreting tumor that arises from chromaffin tissue of the adrenal medulla. They are called paragangliomas when they arise in extraadrenal sympathetic ganglia. Symptoms are due to secretion of catecholamines: epinephrine, norepinephrine, and dopamine. Symptoms are typically paroxysmal and described as “spells.” The classic triad is headaches, sweating, and tachycardia. Rule of thumb: 10% are extraadrenal, 10% are bilateral, 10% are **malignant**, and 10% are **genetic/familial**.

The **risk of malignancy** is **higher** in **extraadrenal pheo** and in certain genetic mutations. 5–15% of patients with these tumors do **not** present with hypertension and many have sustained, not paroxysmal hypertension.

The differential diagnosis includes labile essential hypertension, anxiety, hyperthyroidism, hypoglycemia, and menopausal flushing—all are more common than pheo. Medications and drugs (e.g., cocaine, pseudoephedrine, amphetamines) can also cause similar symptoms. Carcinoid tumor can mimic pheo but is quite rare.

Suspect a pheo in patients who have **spells** of headaches, sweating, and tachycardia. The likelihood of a pheo increases with these risk factors:

- Orthostatic hypotension (volume depletion)
- Refractory HTN
- HTN in a young person without a family Hx

- Adrenal incidentaloma
- Dilated cardiomyopathy of unknown cause
- HTN during procedures or with ingestion of tyramine-containing foods
- Paroxysmal HTN
- Atypical results when using certain classes of medications (e.g., MAO inhibitors, sympathomimetics, opioids, dopamine receptor antagonists, β -blockers)
- Family Hx of pheochromocytoma (particularly high risk)
- Family Hx of MEN2, neurofibromatosis (NF), or von Hippel-Lindau (VHL) disease (particularly high risk)

Start the pheo workup with the following biochemical screening tests:

- **24-hour urinary fractionated metanephrines:** This screening test is very sensitive and specific but cumbersome. It's usually the best test in patients with low pretest probability of pheo. Wean patients off tricyclic antidepressants and cyclobenzaprine 2 weeks before testing because these meds interfere with the results. (SSRIs are okay.)
- **Plasma free metanephrines:** Simple to do, and sensitivity is high, so a negative test excludes disease. However, specificity is lower, and false-positive results are common, especially in patients with low pretest probability of disease. Plasma free metanephrines is most appropriate in high-risk patients: those with MEN2/NF/VHL, incidentaloma with characteristics of pheo, or family history of pheo.
- Do not measure plasma catecholamines or vanillyl-mandelic acid (VMA)—these tests have proven to be less accurate than the above tests.
- If screening test confirms pheo ($> 3 \times$ ULN) then image; if not, then confirmatory testing needs to be done with a clonidine suppression test.

If the biochemical tests confirm a pheo, perform CT or MRI to localize the tumor.

If imaging does not show a tumor and you still suspect one given the screening tests and history, look for the tumor using a PET scan, total body MRI, or radioactive tracer (^{123}I , metaiodobenzylguanidine [MIBG] scintigraphy, a norepinephrine analog that concentrates in adrenals and pheos).

Discuss genetic testing with all patients with pheochromocytoma, but prioritize the following patient groups:

- Young age (< 45 years)
- Paranglioma: familial paragangliomas due to germline mutations of genes encoding succinate dehydrogenase subunits B, C, and D (SDHB, SDHC, SDHD), which increase malignancy risk
- Those with a family Hx of pheo or paraganglioma
- Those with multifocal, bilateral, or metastatic disease

Always treat pheos with surgical resection. Laparoscopic adrenalectomy is usually appropriate, but open resection

should be considered for large (> 6 cm) or invasive tumors. Treat all patients with preoperative α -adrenergic receptor blockade (phenoxybenzamine or doxazosin) for at least 7–14 days prior to resection. A CCB or β -blocker can be added if blood pressure cannot be controlled with α -blockade alone.

Remember to **never** use a β -blocker without first treating with an α -blocker, because it leads to unopposed α stimulation, which can cause hypertensive crisis. Patients with pheo tend to have depleted intravascular volume; replace preoperatively using intravenous saline or a high-sodium diet.

Although most pheos are benign, approximately 10% are malignant. For those with malignant, metastatic disease and positive ^{123}I -MIBG scintigraphy, treatment with ^{131}I -MIBG can be effective. For rapidly expanding lesions or those with negative ^{123}I -MIBG scintigraphy, a chemotherapy regimen of cyclophosphamide, vincristine, and dacarbazine can provide up to 50% tumor regression.

Patients with an undiagnosed pheo who go to surgery for an unrelated condition have a high mortality rate. Severe adverse reactions to anesthesia include hypertensive crisis, cardiac arrhythmia, and death.

OTHER ADRENAL MASSES

Many adrenal masses are “incidentalomas”—masses > 1.0 cm and discovered by accident on an imaging study done for another reason, such as abdominal pain. Prevalence of incidentalomas increases with age and can reach 10%. Up to 15% of patients with an incidentaloma have bilateral masses.

90% of incidentalomas are nonfunctioning adenomas. $< 3\%$ are cancerous unless the patient has a known diagnosis of malignancy, in which case the mass has a 50% chance of being malignant.

Without a history of malignancy, the 2 questions to ask yourself are:

- 1) Is it making hormones?
- 2) Is it cancerous (primary adrenocortical carcinoma [ACC] or metastatic)? ACC is suspected with lesions > 4 –6 cm.

All patients with adrenal incidentaloma should have the following tests:

- **Low-dose overnight dexamethasone suppression test** for all patients; this test evaluates for subclinical Cushing syndrome, the most common hormonal abnormality.
- **Plasma free or urinary fractionated metanephrines** for all patients; this test evaluates for pheochromocytoma, the most dangerous hormonal abnormality.
- **Blood pressure and serum K^+** for all patients. Only check PAC:PRA if hypertension or hypokalemia is present. These tests evaluate for primary hyperaldosteronism.

- Only check adrenal sex hormones if females have virilization (DHEA-S) or males have feminization (estradiol).

If the results of these tests are normal and the mass is < 4 cm, observation is appropriate with repeat imaging in 6–12 months and repeat hormonal testing for cortisol excess yearly for a few years, depending on the clinical setting. Know that FNA is **never** used to determine whether an adrenal mass is an adenoma or an ACC because cytologic features may not distinguish between them. However, FNA **may** be used to differentiate an adenoma from **metastatic** disease. Remember to rule out pheochromocytoma before doing any procedure on an adrenal mass!

There are 3 indications for **adrenalectomy** of an incidentaloma:

- 1) Tests indicate a functioning tumor (namely cortisol or catecholamine production, because aldosterone excess can be treated medically or surgically).
- 2) Mass is > 4–6 cm.
- 3) Imaging characteristics are suspicious for malignancy (e.g., irregular margins, calcifications, inhomogeneous density, growth over time).

HORMONES OF REPRODUCTION

PREVIEW | REVIEW

- What is the definition of primary amenorrhea, and what are the common causes?
- A female patient with short stature, primary amenorrhea, and little or no breast development probably has which genetic defect?
- What is the definition of secondary amenorrhea, and what are the common causes?

FEMALES

Normal Physiology

Follow along in [Figure 1-12 on page 1-30](#).

The menstrual cycle is a complex series of changes required for the production of an oocyte, and for the preparation of the uterus for pregnancy. The cycle is divided into two phases: follicular and luteal. The follicular phase begins with the onset of menses (day 1 of the menstrual cycle) and ends at ovulation (some say it ends on the day before the LH surge). The follicular phase can last 14 to 21 days. The luteal phase, which consistently lasts 14 days, begins after ovulation (some say on the day of the LH surge) and ends at the onset of the next menses.

The hypothalamus secretes gonadotropin-releasing hormone (GnRH) in a pulsatile fashion (60- to 90-minute cycle), which stimulates the anterior pituitary to then pulse out two gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

LH stimulates androgen formation within the theca cells. FSH regulates the new ovarian follicle granulosa cells to produce 2 hormones: **estrogen** from the androgen precursors (builds up the lining of the uterus) and **inhibin** (suppresses secretion of FSH). Estrogen normally **inhibits** FSH and LH production; however, at **midcycle**, estrogen has a **positive** feedback effect causing a **surge** in the LH and FSH, which then stimulates ovulation.

After ovulation, the follicle becomes a corpus luteum that secretes estradiol (main estrogen) and progesterone. Progesterone, in turn, prepares the lining of the uterus for possible implantation and **suppresses** gonadotropin release.

In women, the ovaries and adrenals share the task of producing testosterone—each producing 50%. Differentiate where androgen excess is from by checking a DHEA-S, because sulfation of DHEA only occurs in the adrenal glands (not the ovaries). The major effect of testosterone in females is androgenization with normal hair development in the pubic and axillary regions.

Amenorrhea

Amenorrhea is the absence of menses and can be intermittent or permanent, depending on the etiology.

Primary Amenorrhea

Primary amenorrhea is the absence of menses by 16 years of age in the presence of normal growth and secondary sexual characteristics. It is commonly the result of a genetic cause or an anatomical problem.

To determine etiology, think of the organs affecting the menstrual cycle:

- Hypothalamus (e.g., anorexia, constitutional delay of puberty, GnRH deficiency)
- Pituitary (e.g., hypopituitarism, hyperprolactinemia, hypothyroidism)
- Ovary (e.g., PCOS, Turner syndrome gonadal dysgenesis)
- Uterus (e.g., Müllerian agenesis)
- Vagina (e.g., transverse vaginal septum)

Figure 1-12: Menstrual cycle

An abnormality at any one of these locations can cause primary amenorrhea.

Primary amenorrhea is **rare**, and evaluation is often undertaken by pediatricians; however, know the following important diagnoses:

- If a patient with primary amenorrhea has short stature, widely spaced nipples, little breast development, webbed neck, and decreased pubic and axillary hair, think of **Turner syndrome** (karyotype 45,X).
- If you see a female with **no palpable cervix** and **no uterus**, but there are normal secondary sex characteristics, including breasts and pubic and axillary hair, consider congenital absence of the uterus.
- If you see a female with **no palpable cervix**, **no uterus**, and **no pubic and axillary hair**, but there are **breasts**, consider androgen insensitivity syndrome (an insensitivity to androgens in a **karyotypic 46,XY**). In this condition, testosterone levels are in the normal male range.

Secondary Amenorrhea

Secondary amenorrhea is the absence of menses for:

- ≥ 3 months in a woman who previously had regular menstrual cycles or
- ≥ 6 months in a woman who has had irregular menses.

The most common causes of secondary amenorrhea are pregnancy, PCOS, and functional hypothalamic amenorrhea.

Know that erratic menstrual cycles are common in the first years after menarche and in the last years prior to menopause. Secondary amenorrhea is most often caused by **pregnancy**; once that is excluded, think about the other causes.

In initial labs, include a pregnancy test (always!), FSH, LH, prolactin (PRL), and thyroid-stimulating hormone (TSH). If the woman is hirsute, and particularly if she is virilized (e.g., deepening voice, balding), measure serum total testosterone and DHEA-S. Also consider 17-OH progesterone.

Increased FSH and LH levels in the amenorrheic woman tell you that there is ovarian failure. See [Figure 1-13](#). If the woman is < 40 years of age, this is called primary ovarian insufficiency (POI), and, if the woman is > 40 years of age, it is called menopausal ovarian failure. (The median age of menopause is 51 years.) In POI cases, consider mosaic Turner syndrome (get a karyotype), fragile X, or autoimmune polyglandular syndrome. Note, though, that POI does occur idiopathically in many women.

Figure 1-13: HTH-pituitary-gonadal axis in women

Low FSH and LH levels in the amenorrheic woman tell you that the pituitary is not making the hormones, either because it is diseased or because the hypothalamus is not sending out GnRH. This is called “**hypogonadotropic hypogonadism**,” and it has several causes. Etiologies include hyperprolactinemia, hypothyroidism, infiltrative disorders, celiac disease, and **functional** hypothalamic amenorrhea.

Functional hypothalamic amenorrhea (FHA) is caused by **stress** from an eating disorder and/or prolonged, intense exercise; e.g., long-distance running. **FSH/LH** and **estrogen** are **decreased**. Measure PRL and TSH to exclude hyperprolactinemia and hypothyroidism before making this diagnosis.

So, check the following for the secondarily **amenorrheic** woman with **low FSH and LH**:

- Prolactin level
- TSH level
- MRI of the pituitary gland

If there is a question as to the estrogen status (LH and FSH are “normal” with secondary amenorrhea), a progesterone challenge test can be done. If withdrawal bleeding occurs, it signifies the presence of endogenous estrogen exposure—consider adding progesterone for endometrial protection. Absence of menses after progesterone withdrawal confirms a low or absent estrogen state. Order a brain MRI and consider starting estrogen to prevent long-term complications.

Amenorrhea with Hirsutism

The **amenorrheic** woman with **virilizing** signs needs a good history (duration of symptoms), physical exam, and labs: **DHEA-S**, **testosterone**, and **17-OH progesterone** levels.

The major diagnoses that cause **amenorrhea** and **virilization** are **polycystic ovary syndrome (PCOS)**, congenital adrenal hyperplasia, and, rarely, **tumors** of the **adrenal** or **ovary**. Recall from the discussion in [Steroid Synthesis on page 1-20](#) that, in the female, both the ovaries and the adrenals contribute to androgen production, almost equally. Usually, normal androgen production causes only growth of pubic and axillary hair. **Excess** growth of hair in these areas and/or other “masculinizing” signs prompt concern about either PCOS or adrenal/ovarian tumors.

Polycystic Ovary Syndrome

For a discussion of polycystic ovary syndrome, see the [Women's and Men's Health](#) section.

Hirsutism

This topic is simply a more targeted discussion of hirsutism—a specific virilizing sign ([Table 1-3](#)). Hirsutism is when a woman grows coarse hair in places they typically either do not grow hair or only have very fine hair (e.g., moustache area, chin, torso, back). The history and physical exam are keys to evaluating a hirsute woman. Rapid onset and progression are always more worrisome for a tumor. Always ask the patient about the hair distribution in family members (mother/sister) to distinguish from normal ethnic/genetic hirsutism. Objectively assess hair growth and distribution during the physical.

Idiopathic hirsutism refers to hirsutism with no identifiable cause in a woman with no other signs of virilization (e.g., clitoromegaly, deepening of the voice, male-pattern

Table 1-3: Hirsutism Workup — Laboratory Findings

Disorder	Testosterone	DHEA-S	LH:FSH Ratio	17-OH Progesterone
Adrenal carcinoma	Normal/↑	↑↑↑	Normal	Normal/↑
Ovarian carcinoma	↑↑↑	Normal	Normal	Normal
Congenital adrenal hyperplasia	Normal/↑	Normal/↑	Normal	↑↑↑
Polycystic ovary syndrome	Normal/↑	Normal/↑	> 2	Normal

balding, increased muscle mass) and with normal menstrual cycles, hormone levels, and weight. The best treatment to slow hair growth is spironolactone, which is an aldosterone and androgen receptor antagonist. Birth control pills may also slow hair growth and should be used in conjunction with spironolactone (since spironolactone is contraindicated in pregnancy!).

A scoring system (**Ferriman-Gallwey**) can be useful to determine whether a patient truly has worrisome features. The scale shows photos of hair growth in parts of the body subject to androgens: upper lip, chin, chest, abdomen, pelvis, upper arms, thighs, upper back, and lower back. For each location, the amount of hair is assessed and graded on a scale of 0 to 4. A score > 8 merits further evaluation, especially when the hirsutism is associated with other virilizing signs/symptoms (e.g., deepening of the voice, increased muscle bulk).

In truth, the scoring system is not used much in practice, as hirsutism is not typically pathologic. It's the presence of virilization and rapidly worsening hirsutism that are concerning.

The workup for the **virilized female** includes evaluation of ovarian and adrenal androgens: **testosterone**, **DHEA-S**, the **LH:FSH** ratio, and **17-OH progesterone** (Table 1-3 on page 1-31).

Recognize the lab results below, which are seen in the **virilized woman**:

- **Mild** elevations of DHEA-S and/or testosterone are consistent with **PCOS**.
- **Elevated** testosterone and **very high** DHEA-S are consistent with an **adrenal carcinoma**.
- **Very high** testosterone with normal DHEA-S is consistent with an **ovarian stromal tumor** (e.g., Sertoli-Leydig tumor = < 1% of ovarian cancers).

Remember that hirsutism can also be due to **late-onset, partial congenital adrenal hyperplasia**, which is usually caused by a **CYP21A2** gene defect (→ 21-hydroxylase deficiency). Labs show elevated blood 17-hydroxyprogesterone and blood DHEA-S (Figure 1-8 on page 1-21).

Cushing disease (in the pituitary) and **prolactinoma** are uncommon causes of hirsutism. Drugs causing hirsutism include minoxidil, cyclosporine, and phenytoin.

MALES

In men, luteinizing hormone stimulates Leydig cells (**L stimulates L**) to produce testosterone, which in turn inhibits FSH and LH secretion. FSH stimulates the Sertoli cells to secrete inhibin B and also secrete androgen-binding protein (ABP), which in turn binds to testosterone and moves into the seminiferous tubules. ABP-testosterone is less lipophilic and concentrates within the luminal fluid of the seminiferous tubules, enabling spermatogenesis in these tubules and sperm maturation in the epididymis. Hence, both FSH and LH are required for spermatogenesis. See Figure 1-14 for the hypothalamus-pituitary-gonadal axis in men.

Figure 1-14: HTH-pituitary-gonadal axis in men

Primary hypogonadism (testicular failure) is usually due to **Klinefelter syndrome** (47,XXY or mosaic 46,XY/47,XXY). The genetic abnormality results in **defective testosterone synthesis** by the Leydig cells. The testes do not grow properly, and they fail to adequately produce androgens. Clinical features include small testes, long arms and legs, infertility, lack of virilization (sparse hair growth and muscle mass), and gynecomastia. Some patients have learning disabilities. The expression of this genetic abnormality is variable. Occasionally, mosaic individuals are fertile. Testosterone is decreased, and serum LH and FSH are markedly elevated. Diagnose with a karyotype. Treat Klinefelter syndrome with testosterone. Infertility can be addressed with in vitro techniques harvesting spermatozoa from the testes.

Secondary hypogonadism is due to an **abnormal hypothalamic-pituitary-gonadal axis**, so testosterone level is low and FSH and LH are low or inappropriately normal. Causes of secondary hypogonadism are acquired or congenital.

Acquired causes are more common and include:

- Hyperprolactinemia
- Longstanding use of exogenous testosterone or abuse of anabolic steroids
- Excessive glucocorticoids from any source
- Infiltrative disorders
- Chronic opioid use
- Aging
- Obesity

The workup for hypogonadism in men is summarized in Figure 1-15.

Kallmann syndrome is an example of a congenital gonadotropin deficiency. It is characterized by GnRH deficiency + anosmia (inability to smell). It is associated with midline

Figure 1-15: Hypogonadism workup for men

defects, such as cleft palate and horseshoe kidney. It is X-linked recessive, so male relatives on the maternal side may be affected. In Kallmann syndrome, FSH and LH levels are low (distinguishing it from Klinefelter syndrome, where LH and FSH are high).

Erectile dysfunction is discussed in the [Women's and Men's Health](#) section.

Gynecomastia results from an increased **estrogen-to-androgen** ratio. Unilateral or bilateral gynecomastia is **normal at puberty** and tends to **regress after 1-2 years**. It is found in males who have increased aromatization of circulating androgens into estrogen. Also, conditions that produce excess testosterone (such as DHEAS-secreting adrenal adenoma) can result in excess estradiol because of peripheral aromatization.

Gynecomastia is also seen in advanced age, obesity, renal failure, cirrhosis, hyperthyroidism, Klinefelter syndrome, germ cell tumors, and hyperprolactinemia. It can be brought on by certain drugs (think spironolactone!), including anabolic steroids (additional clues to anabolic steroid use include a very muscular physique, small testes, and infertility), and certain supplements. A healthy male with chronic stable nontender gynecomastia, normal history and physical exam does **not** require further workup.

Labs for gynecomastia include TSH, estradiol, prolactin, testosterone, LH:FSH, and hCG levels. In males with gynecomastia and an elevated hCG and/or high estradiol levels, check a testicular ultrasound for a tumor. Testicular cancers are discussed further in the [Oncology](#) section.

DIABETES MELLITUS

OVERVIEW

The U.S. is seeing an epidemic of metabolic syndrome and diabetes mellitus that **parallels** the epidemic of U.S. **obesity**. For those born in 2000, the lifetime risk of developing

any kind of DM is **33%** (males) and **39%** (females)! Diabetic patients have **2×** the **death rate** of nondiabetic patients from cardiovascular disease (CVD). The life span of diabetic patients is reduced by 12 years (males) and 19 years (females), as compared with nondiabetic individuals. **Early** initiation of excellent glycemic control reduces the risk of CVD and microvascular complications in patients with Type 1 and Type 2 diabetes.

Classification of diabetes is based on the **mechanism of dysfunction** (Type 1 or 2), not on whether the patient requires insulin for treatment.

The American Diabetes Association (ADA) and the American Association of Clinical Endocrinologists (AACE) have practice guidelines for management. Fortunately, they pretty much agree on the major items!

CLASSIFICATION

PREVIEW | REVIEW

- What are the categories of diabetes mellitus?
- List 3 medications that can induce diabetes or impair insulin action.
- Define maturity-onset diabetes of the young and latent autoimmune diabetes in adults.

Know these categories:

- **Prediabetes** includes both impaired glucose tolerance (IGT) and impaired fasting glucose (IFG).
- **Type 1 DM** (T1DM; < 10% of DM): previously called insulin-dependent DM (IDDM) and juvenile-onset DM. The term IDDM is **not** used anymore. T1DM is most commonly immune mediated but can be idiopathic (antibody negative).
- **Type 2 DM** (T2DM; > 90% of DM): previously non-insulin-dependent DM (NIDDM) and adult-onset DM. The term NIDDM is **not** used anymore.

- **Gestational DM:** diabetes or glucose intolerance with pregnancy
- Specific types of DM due to **other causes:**
 - Drug-induced or chemical: Certain drugs can induce T2DM in patients with insulin resistance or impair the action of insulin (especially niacin, steroids, thiazides, oral contraceptives, β -blockers, and statins).
 - Endocrinopathy-induced: Cushing syndrome, acromegaly, pheo
 - Exocrine pancreas-induced: trauma, surgery, pancreatitis, cystic fibrosis (termed cystic fibrosis-related diabetes [CFRD])
 - Posttransplant diabetes
 - Genetic defects of the β -cells: Maturity-onset diabetes of the young (MODY) is a group of rare monogenetic autosomal dominant defects that cause ineffective production and/or release of insulin by the β -cells in the pancreas. If the patient does not have evidence of T1DM (negative T1DM antibody test), consider MODY if there is a strong family history of diabetes and the patient does not have risk factors for T2DM (obesity, acanthosis, HTN).
 - Latent autoimmune diabetes in adults (LADA): A late onset of an immune-mediated diabetes mellitus, LADA is also referred to as Type 1.5 DM. These patients are generally > 30 years of age and often nonobese adults. LADA can be initially controlled on orals but will require insulin over time. Distinguish from T2DM with a positive T1DM antibody test.

DIAGNOSIS AND SCREENING

PREVIEW | REVIEW

- What are the criteria for the diagnosis of prediabetes?
- Which diseases can result in a misleading value of hemoglobin A1c?
- When are finger stick glucoses useful? When should they not be used?

The recommendations in this section are based on the 2020 American Diabetes Association “Standards of Medical Care in Diabetes,” which we refer to as the 2020 ADA guidelines.

Normal fasting plasma glucose (FPG) is < 100 mg/dL (5.6 mmol/L).

Diagnosis of prediabetes (use 1 of the following):

- 1) Impaired fasting glucose (IFG) = FPG 100–125 mg/dL (5.6–6.9 mmol/L)
- 2) Impaired glucose tolerance (IGT) = 2-hour plasma glucose of 140–199 mg/dL (7.8–11.0 mmol/L) after a 75-g oral glucose load; i.e., during an oral glucose tolerance test (OGTT)
- 3) HbA1c of 5.7–6.4%

The OGTT is more sensitive than FPG for diagnosing prediabetes and is considered the best test by the AACE, but it is rather impractical in most offices—and the screening guidelines take this into account.

Diagnosis of diabetes (use 1 of the following):

- 1) FPG $\geq$ 126 mg/dL (7.0 mmol/L)
- 2) Random plasma glucose $\geq$ 200 mg/dL (11.1 mmol/L) with symptoms (polyuria, polydipsia)
- 3) HbA1c $\geq$ 6.5%
- 4) 2-hour plasma glucose $\geq$ 200 mg/dL after a 75-g OGTT

Confirm diagnosis by **retesting** at least once unless there are clear signs of metabolic decompensation (i.e., diabetic ketoacidosis [DKA], hyperosmolar coma).

Know that the best test for diagnosing T2DM is the fasting plasma glucose (FPG). About 20% of patients screened with the HbA1c have false-negative tests, compared to using the FPG or OGTT.

Additionally, the HbA1c result can be misleading in some patient groups; e.g., those with hemoglobinopathies and thalassemias, patients with iron deficiency or hemolytic anemias, and those with hepatic or renal diseases.

Finger stick (capillary whole blood) glucoses are not equivalent to serum/plasma glucoses. Finger sticks obtain whole blood from capillaries, and capillary whole blood glucoses are subject to much variability. **Finger sticks** are acceptable for **self-monitoring** of known diabetic patients, but only use **plasma or serum** for **diagnosis** of diabetes.

Screen **all** patients for DM at **3-year intervals**, beginning at 45 years of age, and screen younger patients if overweight (2017 ADA guidelines define overweight as a BMI $\geq$ 25 kg/m² or BMI $\geq$ 23 kg/m² in Asian Americans) with any of the following risk factors:

- 1st degree relative with diabetes
- CVD
- Acanthosis nigricans, PCOS, nonalcoholic fatty liver disease
- Sedentary
- High-risk ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
- Metabolic syndrome
- HTN or on therapy for HTN
- Dyslipidemia (HDL < 35 mg/dL [0.9 mmol/L]; triglycerides [TG] > 250 mg/dL [2.8 mmol/L])
- Hx of gestational diabetes or of delivery of infant > 9 lb
- Antipsychotic therapy (for schizophrenia or bipolar disorder)
- Chronic glucocorticoid exposure

PREDIABETES

PREVIEW | REVIEW

- What is the significance of diagnosing prediabetes?

Prediabetic patients have a **6-fold increased risk** of developing overt T2DM; 1/3 of them do, 1/3 stay prediabetic, and 1/3 normalize. The condition is quite important to discover because some prediabetic patients **develop microvascular disease**. Also, overt diabetes increases a patient's risk of CVD by 50%!

Goals and Types of Treatment

Promoting a “healthy lifestyle” is your best bet for helping the prediabetic patient. Weight loss of 5–10% decreases the risk of developing overt diabetes by 50%, as do regular exercise (30–60 minutes, moderate intensity, 5 days/week) and a low-sodium/high-fiber diet (low in saturated and trans fats) with moderation of alcohol.

No drugs are FDA approved yet for the treatment of prediabetes, although metformin, acarbose, glitazones, and GLP-1 agonists have been studied, with strong evidence in their favor. Per the ADA and other experts, metformin is indicated in high-risk patients to decrease the rate of progression to T2DM by 30%. (Note: There was a 50% decrease with 5–7% weight loss!)

Lipid and blood pressure goals and aspirin therapy should be the same as for the diabetic patient (see [Ancillary Management on page 1-41](#)).

The 2020 ADA guidelines recommend yearly screening of patients with prediabetes for the development of diabetes and assessment of modifiable CVD risk factors.

TYPE 1 DM

PREVIEW | REVIEW

- Which autoimmune diseases are associated with Type 1 diabetes mellitus (T1DM)?
- What is the primary treatment for T1DM?
- Explain the honeymoon effect and the dawn phenomenon.
- What is the best way to treat morning hyperglycemia?

T1DM accounts for 5–10% of diabetes and is caused by cell-mediated β -cell destruction that leads to an absolute insulin deficiency. **90%** of patients have **autoantibodies** against:

- islet cells,
- insulin,
- glutamic acid decarboxylase [GAD], and/or
- tyrosine phosphatases IA-2 and IA-2 β .

Test patients with prediabetes, IGT, or IFG yearly.

95% of patients with T1DM have HLA DR3 or DR4, indicating a genetic predisposition. Certain environmental factors, such as viruses, may also be important.

The rate of β -cell destruction is quite variable, being rapid in some individuals (mainly infants and children)

and slow in others (mainly adults). When there is slowly progressive autoimmune diabetes with an adult onset, it is often called latent autoimmune diabetes in adults (LADA).

T1DM patients are prone to ketosis, depending on how much insulin is being produced or taken. Do not forget that T1DM is associated with other autoimmune diseases. Autoimmune diseases associated with T1DM include Hashimoto thyroiditis, primary adrenal insufficiency, celiac disease, vitiligo, pernicious anemia (B_{12} deficiency due to autoantibodies), and myasthenia gravis. (Note: In T2DM, screen for B_{12} deficiency if on long term metformin.)

Treatment of T1DM

Treatment of hyperglycemia in T1DM reduces micro- and macrovascular complications.

Treat with **insulin**. Oral hypoglycemics are ineffective. See [Table 1-4 on page 1-36](#).

Multiple daily injection (MDI) insulin regimens include agents in 2 main groups:

- 1) Basal—**long-acting insulin** to cover fasting needs (about 50% of the daily insulin):
 - Glargine
 - Detemir (Levemir)
- 2) Bolus or prandial—**short-acting insulin** to cover meals (about 50% of the daily insulin):
 - Regular (HumuLIN R, NovoLIN R)
 - Lispro (Humalog)
 - Aspart (NovoLOG)
 - Glulisine (Apidra)

Intermediate-acting insulin can also be used to cover fasting and meals: NPH (neutral protamine Hagedorn; HumuLIN N, NovoLIN N) is not used as much as the basal and bolus insulins in the above list. It is generally only used when cost is an issue. Timing of the evening NPH dose can be tricky and is generally given with dinner. If there is nocturnal hypoglycemia or early morning hyperglycemia, the evening NPH dose can be changed from dinner to bedtime to shift the insulin peak from overnight to morning.

Premixed insulin combinations (e.g., “70/30” of NPH/R) are generally **not** recommended to treat patients with T1DM.

Fixed daily doses of each type of insulin do not always correct hyperglycemia, especially in patients whose intake of carbohydrates varies dramatically. The approach is to use nutritional counseling to teach patients how to effectively **carbohydrate count** (i.e., estimate the grams of carbohydrate in their next meal). Then, they use a preestablished insulin:carbohydrate (I:C) ratio to calculate the dose of their premeal short-acting insulin. For example, if using rapid acting insulin and the patient's individualized I:C ratio is 1:15, then when the intake is estimated at 60 g of carbs, the dose is 60/15, or ~ 4.0 units of short-acting insulin premeal. This dosing method gives patients a little

Table 1-4: Insulin Preparations

Type	Duration of Action	Drug (Brand Name)	Onset	Peak	Duration	Relative Cost	Miscellaneous
Human insulin preparations	Intermediate	NPH (Humulin N, NovoLIN N)	2 hours	4–10 hours	10–16 hours	\$	Peaks and duration do not simulate natural basal and post-meal insulin activity as well as insulin analogs.
	Short	Regular (Humulin R, NovoLIN R)	30–60 minutes	2–4 hours	5–8 hours	\$	
Insulin analogs	Long	Glargine	2 hours	None!	20–24 hours	\$\$\$	Less nocturnal hypoglycemia compared to NPH
		Detemir (Levemir)	2 hours	3–9 hours	6–24 hours*	\$\$\$	
	Short	Lispro (Humalog)	5–15 minutes	30–75 minutes	3–5 hours	\$\$\$	Less hypoglycemia compared to Regular
		Aspart (NovoLOG)	5–15 minutes	30–75 minutes	3–5 hours	\$\$\$	
		Glulisine (Apidra)	5–15 minutes	30–75 minutes	3–5 hours	\$\$\$	

*Duration of action for detemir is dose-dependent.

more dietary flexibility and still prevents hyperglycemia. The counseling aspect is important because it is difficult to estimate the carbohydrate content of most meals. The use of mobile device apps has greatly improved patients' ability to accurately count carbohydrates.

Alternatively, patients can be treated with a continuous pump that provides rapid-acting insulin at a basal rate throughout the day. Patients then enter a premeal glucose level and the amount of carbs to be eaten. The pump then delivers a bolus that provides an appropriate insulin correction and the meal dose of insulin. The pumps appear to slightly improve glucose control over MDI injections, decrease hypoglycemic events, and allow for greater flexibility in timing of meals.

Pumps and intensive insulin regimens carry a danger of **hypoglycemia**, and this can be fatal if it occurs at night or is otherwise unrecognized. Malfunction of the pump can result in quick ketoacidosis. Sensor-augmented therapy with continuous glucose monitoring can be useful in decreasing the number and severity of hypoglycemic events.

Know that **nocturnal hypoglycemia** is a problem, not only because it is potentially lethal, but also because episodes lead to feeling poorly the next day with marked fatigue and a measurable decrease in productivity.

Notes for T1DM

Labile DM: T1DM is a difficult condition, because so many factors impact glucose levels (e.g., food, exercise, stress, sleep). Labile DM (a.k.a. brittle diabetes) reflects very hard-to-control diabetes with marked variability in glucose reading, which leads to overt hyper and hypoglycemia. Labile DM is so unstable that patients are often unable to maintain a normal life and have frequent hospitalizations.

Female patients tend to have complicated pregnancies. **Labile T1DM** occurs in 3/1,000 patients with T1DM, most of whom are young women. Hypoglycemia and DKA seem unpredictable. Contributing causes include defective insulin action or delayed food absorption. For example, increased growth hormone in puberty causes increased insulin resistance. An important cause is delayed gastric emptying (a.k.a. gastroparesis; from autonomic neuropathy). Malabsorption, antipsychotic meds, and alcohol use can also contribute to labile diabetes. Factitious (i.e., self-induced) lability is sometimes seen, resulting from some combination of cognitive, behavioral, and psychosocial factors. Management depends on etiology, but those with profound recurrent hypoglycemia without a modifiable cause may benefit from pancreas transplantation.

The **honeymoon effect** refers to an improvement of hyperglycemia after diagnosis and institution of treatment. Sometimes, patients can be removed from insulin entirely for a short while. Eventually, however, they require reinstitution of treatment. The **dawn phenomenon** refers to increased blood glucose between 4:00 and 7:00 a.m. with no preceding hypoglycemia. It also can occur in healthy nondiabetic people. The cause is transient, mild insulin resistance due to the normal early-morning rise in cortisol and growth hormone (GH).

In diabetic patients, early-morning hyperglycemia can also be due to the evening long-acting insulin dose wearing off. Increase the basal (long-acting) insulin in the evening to target a normal fasting glucose level.

The **Somogyi effect**: It was hypothesized that nocturnal hypoglycemia causes early morning hyperglycemia, and the suggested treatment had previously been to decrease the evening insulin to prevent the nocturnal hypoglycemia. This theory has been disproven! Thus, it is **incorrect to reduce** the evening basal insulin in patients with morning hyperglycemia.

TYPE 2 DM

PREVIEW | REVIEW

- Which mechanisms lead to the development of Type 2 diabetes mellitus (T2DM)?
- Which conditions are associated with acanthosis nigricans?
- What are the initial drugs used to treat newly diagnosed T2DM?
- What are the mechanisms of action of the main classes of oral hypoglycemics?
- What are the metformin side effects and contraindications? Thiazolidinediones?
- In which T2DM situations should patients be prescribed insulin early in treatment?

Etiology

More than 90% of diabetes cases are due to T2DM. T2DM is characterized by impaired glucose handling at many sites. The disease has a strong **hereditary** component (multifactorial and polygenic), and several candidate genes have emerged in various populations. Concordance of T2DM in monozygotic twins is 70–90%. Obesity increases insulin resistance, and ~ 80% of patients with T2DM are obese. T2DM patients with central obesity, HTN, and dyslipidemia are said to have **metabolic syndrome**. For more information, see **Obesity** on page 1-46.

Know the mechanisms that lead to T2DM:

- Insulin resistance in muscle and fat tissues
- Gradual reduction in insulin secretion by the pancreas
- Dysregulated hepatic gluconeogenesis and glucagon secretion
- Reduction in gastrointestinal incretins (glucagon-like peptide 1 and glucose-dependent insulinotropic polypeptide)

Note: Insulin resistance is also associated with **acanthosis nigricans**. This velvety, dark rash in flexural areas occurs in conditions associated with insulin resistance, such as PCOS, Cushing's, certain medications (e.g., niacin, corticosteroids), and acromegaly. Rapid onset of widespread acanthosis nigricans in the older patient suggests GI malignancy.

Treatment of T2DM

Metformin monotherapy, in addition to therapeutic lifestyle changes (**TLC**; i.e., diet and exercise, weight loss) is recommended as initial treatment for most patients with T2DM, unless there are contraindications (e.g., glomerular filtration rate [GFR] < 30 mL/minute). Agents from other classes are added later as needed to achieve glycemic control. Use a patient-centered approach to guide the choice of add-on pharmacologic agents. Consider cardiovascular comorbidities and hypoglycemia risk, as

well as impact on weight, cost, risk for side effects, and patient preferences. Management of T2DM is covered under **Approach to Drug Therapy in T2DM** on page 1-39. First we will go over the different agents and their classes. In the following, focus particularly on **metformin**, **GLP-1 receptor agonists**, and **insulin**.

Medications used to treat T2DM:

- Secretagogues (i.e., sulfonylureas, meglitinides)
- Sensitizers:
 - Biguanide (metformin)
 - Thiazolidinediones/glitazones (rosiglitazone, pioglitazone)
- α -Glucosidase inhibitors
- Amylin analogs (pramlintide)
- Glucagon-like peptide-1 (GLP-1) receptor agonists (i.e., exenatide, liraglutide, albiglutide, lixisenatide, and dulaglutide)
- Dipeptidyl-peptidase 4 inhibitors (DPP4I; i.e., alogliptin, linagliptin, saxagliptin, sitagliptin)
- Sodium-glucose cotransport (SGLT-2) inhibitors (canagliflozin, dapagliflozin, empagliflozin)
- Insulin

See **Approach to Drug Therapy in T2DM** on page 1-39 for details on when and how to initiate these agents.

For general competency and for exam questions, it is important to know the mechanisms of action of each class of oral hypoglycemic drugs. Note the maximum efficacy in lowering HbA1c for metformin and sulfonylureas is 1–2%; the efficacy is lower for the other medications.

The **sulfonylureas** and **meglitinides** are **insulin secretagogues**: they **both** increase insulin secretion but do so by different, although similar, mechanisms of action.

Sulfonylureas

2nd generation sulfonylureas include **glipizide**, **glyburide**, and **glimepiride**. Glyburide's half-life is very long, and patients (especially the **elderly**) are at risk for **severe hypoglycemia**. The use of glyburide is no longer preferred by the ADA; **use glipizide and glimepiride instead**. Sulfonylureas are rarely used, except when cost is an issue.

Sulfonylureas are approved for use in combination with most other drugs **except** meglitinides. **Weight gain** and hypoglycemia are common side effects of sulfonylureas.

Hypoglycemia can persist for several days in states of overdose or renal impairment. Severe hypoglycemia caused by an **overdose** of sulfonylureas mandates an admission to the hospital because the resultant persistent hypoglycemia may require:

- close observation for several days,
- IV dextrose initially to reverse the hypoglycemia, and
- octreotide (usually IM or SQ, q 6 hours $\times$ 24 hours).

Octreotide is a long-acting somatostatin analog that markedly inhibits insulin secretion.

Use sulfonylureas with caution in the elderly and in patients with declining renal function; glipizide has a relatively shorter half-life and is safer in these conditions.

Meglitinides

Meglitinides are also insulin secretagogues. These are rapid-acting drugs with a very short half-life. Examples are **repaglinide** and **nateglinide**. The major effect is on postprandial glucose.

As with sulfonylureas, weight gain is a common side effect of the meglitinides. As a group, there is less evidence of their effect with regard to macro- or microvascular outcomes.

Use secretagogues with caution in patients with **chronic kidney disease**. Rarely used, because they need to be taken with each meal.

Biguanides

Biguanides are insulin sensitizers and reduce hepatic glucose production.

Metformin is the only biguanide on the market in the U.S. It is the **1st line medication** in most diabetes management guidelines, unless the patient has an indication for immediate insulin (more information is under **Insulins**). Start with 500 mg bid and gradually increase to a maximum of 2,000 mg/day in divided doses. Many other formulations are available, such as extended-release metformin and metformin in combination with glyburide as a single tablet.

There are fewer side effects with metformin monotherapy than with sulfonylureas. There is no weight gain, and hypoglycemia is rare.

Also favorable: Metformin decreases LDL and TGs and may decrease cardiovascular events, according to the United Kingdom Prospective Diabetes Study [UKPDS]).

Be aware of side effects and conditions that sometimes limit the use of metformin:

- Dose-related abdominal pain and diarrhea
- Metformin is contraindicated in patients with severe **renal** dysfunction (GFR < 30 mL/minute/1.73 m²), decompensated heart failure (HF), and acute or chronic metabolic acidosis.
- In acutely **ill** patients and in those scheduled for **contrast** procedures or surgery, hold the metformin due to the increased risk of lactic acidosis. (The supposed propensity of metformin to cause lactic acidosis is not supported by evidence; however, it is still in the package insert, and you may be tested on it.)
- Potential for B₁₂ deficiency

Thiazolidinediones (TZDs)

TZDs (a.k.a. **glitazones**) are also insulin sensitizers. They act on adipose, muscle, and liver to increase glucose utilization and decrease glucose production and may help

preserve some function of pancreatic β -cells. There are 2 approved in the U.S.: **rosiglitazone** and **pioglitazone**.

Favorable effects: modest reduction in blood pressure, increased HDL, and decreased TGs.

Serious adverse effects include fluid retention, exacerbation of stable heart failure, and weight gain, so avoid thiazolidinediones in those with or at risk for HF. (There is an FDA black box warning of HF for these medications.) There is also an **increased risk of fractures** (definitely in women, probably in men). Pioglitazone may be associated with bladder cancer. Rare hepatotoxicity has been reported, so obtain baseline liver tests and monitor periodically. There is low risk of hypoglycemia.

α -Glucosidase Inhibitors (AGIs)

AGIs (**acarbose** and **miglitol**) delay carbohydrate absorption in the gut. They are not used often. The biggest effect is on postprandial glucose. Common side effects are flatulence, diarrhea, and abdominal bloating. AGIs are approved as monotherapy and in combination with sulfonylureas.

Amylin Analogs

Amylin is a hormone secreted by pancreatic β -cells, along with insulin, which regulates glucose influx by suppressing glucagon and slowing stomach emptying.

Pramlintide is an amylin analog given as an injection before meals. It is intended to be used **with prandial insulin** because it helps insulin work more effectively. Based on the complexity of the regimen, it is not used often.

Cut the insulin dose by 50% when initiating treatment with pramlintide. Gastroparesis and insensitivity to hypoglycemia are contraindications.

Glucagon-Like Peptide-1 (GLP-1) Receptor Agonists

GLP-1 drugs are called **incretin** mimetics. Incretin hormones are secreted by the gut (GLP-1 is an example) and regulate glucose by stimulating insulin release, inhibiting postprandial glucagon release, slowing nutrient absorption, and accelerating satiety.

Exenatide was the 1st GLP-1 injection approved for diabetes treatment, with a bid injection. Extended-release exenatide is available for **once-weekly injection**. It can be combined with MET, sulfonylureas, and TZDs as well as basal insulin. Other GLP-1 receptor agonists are **liraglutide**, **dulaglutide**, **albiglutide**, and **lixisenatide** injections.

Side effects include vomiting and diarrhea, which can be significant.

Acute pancreatitis has been reported in association with GLP-1 receptor agonist treatment, but there is not sufficient data to know if there is a causal relationship.

There is an FDA black box warning of the risk of thyroid C-cell tumors. All GLP-1 receptor agonists are contraindicated in patients with a family history of medullary

thyroid cancer, including MEN2 syndromes, because of C-cell hyperplasia (seen only in rodents so far and not in humans). Exenatide should not be used in patients with $\text{GFR} < 30 \text{ mL/minute/1.73 m}^2$, but other GLP-1 can be used cautiously in CKD.

GLP-1 receptor agonists are useful add-ons to metformin to promote weight loss and to minimize hypoglycemia risk.

GLP-1 receptor agonists with demonstrated cardiovascular disease benefit (liraglutide, semaglutide, dulaglutide) should also be strongly considered, independent of A1c, in those who have established atherosclerotic cardiovascular disease or indicators of high risk, established kidney disease, or heart failure.

Dipeptidyl-Peptidase 4 Inhibitors (DPP4Is)

DPP4Is slow the breakdown of endogenous **incretins**, such as GLP-1, thereby increasing its concentration. Representative drugs are: **sitagliptin**, **saxagliptin**, **vildagliptin**, **linagliptin**, and **alogliptin**. They can be used alone or in combination with metformin or TZD.

The biggest effect is on decreasing postprandial hyperglycemia. DPP4Is do not tend to cause hypoglycemia. The glycemic lowering is less than GLP-1 agonists. DPP4Is are effective in patients with chronic kidney disease; some will need dose adjustments. Rarely, these drugs cause severe skin reactions, such as blistering, angioedema, and anaphylaxis. The concerns about increased pancreatitis with DPP4Is seem not to have panned out, similar to the situation with GLP-1 agonists.

Like GLP-1 agonists, DPP4Is are **useful add-ons to metformin**, **sulfonylureas**, or **TZDs** to minimize weight gain and minimize hypoglycemia risk.

Sodium-Glucose Cotransport (SGLT-2) Inhibitors

SGLT-2 inhibitors are an important class of oral hypoglycemic agents. They block renal reabsorption of Na^+ and glucose in the proximal tubule, increasing urinary excretion of glucose. These drugs do not cause hypoglycemia, and they lead to modest weight loss.

Canagliflozin was the 1st agent in this class. It is an oral agent approved as monotherapy and in combination with metformin, sulfonylureas, glitazones, and insulin. **Empagliflozin** and **dapagliflozin** are other approved SGLT-2 inhibitors. They not approved for use in Type 1 diabetes or in patients with a $\text{GFR} < 45 \text{ mL/minute/1.73 m}^2$. Common side effects are dehydration, renal impairment, urinary tract infections, and genital mycotic infections. This class of drugs may increase the risk of euglycemic DKA in T2DM patients! There is an FDA black box warning about the risk of amputation with canagliflozin.

Strongly consider SGLT-2 inhibitors, independent of A1c, in patients who have ASCVD to reduce the risk of major adverse cardiovascular events in those with T2DM. In

patients with ASCVD, multiple risk factors for ASCVD, or diabetic kidney disease, SGLT-2 inhibitors appear to reduce risk of heart failure hospitalization and progression of kidney disease.

Insulins

Most patients with T2DM eventually require insulin therapy. The same insulins used in T1DM are used in T2DM. Although they may cause less nocturnal hypoglycemia, the **insulin analogs** (long- and short-acting) are **not** more effective at lowering HbA1c than the older human insulins (NPH and regular); however, human insulin is much less expensive for patients. The fixed insulin preparations (e.g., “70/30” of NPH/regular) are also used in T2DM patients. (See [Table 1-4 on page 1-36](#).)

As in patients with T1DM, patients with T2DM who take insulin can sometimes benefit from using the **carbohydrate:insulin ratio** to calculate premeal insulin doses.

Nocturnal hypoglycemia can lead to poor daytime functioning in patients with T2DM, just as in patients with T1DM.

According to both the ADA and the AACE, add insulin to the treatment regimen when there is persistent hyperglycemia on oral drugs, **except** in the following special situations, in which you should institute insulin **early**:

- Consistently high random plasma glucoses ($> 300\text{--}350 \text{ mg/dL}$ [$16.6\text{--}19.4 \text{ mmol/L}$])
- $\text{HbA1c} > 10\text{--}12\%$
- $\text{HbA1c} > 9\%$ with symptoms
- Severe symptoms of hyperglycemia or history of DKA

In these situations, oral agents can be added later, after the glucoses have stabilized with insulin—and, eventually, you may be able to stop the insulin entirely.

Both the ADA and the AACE suggest waiting to add insulin (meaning, use oral agents 1st), except in the above groups, because of the side effects of weight gain ($\sim 2\text{--}4 \text{ kg}$) and hypoglycemia associated with insulin use.

The ADA-preferred regimen for insulin is **basal-bolus** dosing, where patients are given a long-acting insulin that keeps glucoses controlled during the fasting state, and short-acting insulin is given preprandially (just before meals). In patients who are hospitalized, or are fasting for whatever reason, do **not** discontinue their basal insulin simply because they are not eating. Stop the rapid-acting prandial (mealtime) insulins, but **continue** the **basal insulin** because its function is to deal with the hyperglycemia that occurs regardless of whether food is present or not, though the dose might need to be reduced by 30–50%.

Approach to Drug Therapy in T2DM

Along with lifestyle changes, metformin is the preferred initial treatment in all patients with T2DM unless a contraindication exists or the patient cannot tolerate it.

Intensify treatment if the HbA1c is $\geq 7\%$ (6.5% per the AACE) after **3 months**.

The 2020 ADA guidelines recommend the following approach based on hemoglobin HbA1c at presentation:

- HbA1c $< 9\%$ = **metformin monotherapy**.
- HbA1c $> 9\%$ = **dual therapy**: metformin + one of the following: sulfonylurea, GLP-1 agonist, DPP4I, TZD, SGLT-2 inhibitor, or basal insulin.
- HbA1c $> 10\%$, blood glucose > 300 mg/dL (16.65 mmol/L), or marked symptoms = combination injectable therapy (usually basal insulin + rapid-acting insulin) + metformin.

If the HbA1c is not at goal after **3 months**, intensify therapy with an additional agent from another class. Add-on medication choice is governed by comorbidities, as well as hypoglycemia, weight gain, and cost concerns.

If ASCVD or multiple risk factors for ASCVD, choose a GLP-1 receptor agonist with demonstrated cardiovascular benefit. If CKD or heart failure, consider an SGLT-2 inhibitor with demonstrated heart failure reduction and/or CKD progression benefit.

If hypoglycemia is a concern, consider GLP-1 agonist, DPP4 inhibitor, TZD, or SGLT-2 inhibitor. To minimize weight gain or promote weight loss, consider GLP-1 agonist or SGLT-2 inhibitor. Only choose SU or TZD if cost is a major issue.

Insulin pumps are not a quick fix but are good for patients who require multiple injections and are motivated to learn carbohydrate counting. Insulins are described under [Treatment of T1DM on page 1-35](#).

Keep in mind that bariatric surgery is an option with a BMI > 35 kg/m², per the ADA.

GLYCEMIC TREATMENT GOALS

PREVIEW | REVIEW

- What are the treatment goals for glucose and hemoglobin A1c (HbA1c)?
- Describe the relationship between HbA1c and pre- and postprandial blood glucoses.

For both T1DM and T2DM, keep the glucose level as close to normal as possible while avoiding significant hypoglycemia. Recommendations between the advisory groups differ only slightly in targets. The ADA recommends a target HbA1c $< 7\%$ for many nonpregnant adults; the AACE recommends $< 6.5\%$. However, treatment targets should be individualized.

Note: Data has emerged (ADVANCE, VADT, and ACCORD studies) showing that **intensive** glycemic control (compared to standard control) may have **no** long-term benefit or actually **cause harm** in some groups of patients.

Therefore, the target HbA1c may be loosened to **$< 8\%$** for the following groups:

- History of severe hypoglycemia or hypoglycemic unawareness
- Limited life expectancy
- Advanced vascular complications
- Extensive comorbidities
- Longstanding DM with difficulty attaining low HbA1c despite optimal and aggressive management attempts.

If the HbA1c remains elevated but the FPG are controlled, start checking postprandial glucose levels.

Also know that preprandial hyperglycemia contributes more to high average blood glucose when the HbA1c is elevated. Once the HbA1c is $< 7.5\text{--}8\%$, postprandial hyperglycemia contributes more to high average blood glucose and is linked to macrovascular complications.

When using insulin to treat DM, consider checking the postprandial glucose periodically, even when the HbA1c is at a target, so you do not miss periods of hyperglycemia.

Some patients who are hospitalized get worse when their blood glucoses are tightly controlled (80–110 mg/dL [4.4–6.1 mmol/L]); therefore, these are the recommendations:

- Noncritically ill patients: Keep FPG < 140 mg/dL (7.8 mmol/L) and random glucoses < 180 mg/dL (10 mmol/L) using the patient's typical basal regimen and a titrated prandial regimen. A corrective dose of insulin is appropriate if needed to correct prandial hyperglycemia, but use of the sliding scale is discouraged.
- Critically ill patients: Keep glucose at 140–180 mg/dL using an IV insulin infusion as needed.

DIABETIC COMPLICATIONS

PREVIEW | REVIEW

- Name 3 diabetic microvascular complications and characterize their screening and treatment.
- Which microvascular complication usually occurs first in diabetic patients, retinopathy or nephropathy?
- Discuss the major diabetes studies that show a correlation between reducing blood glucoses and subsequent micro- and macrovascular complications.
- Which tests make up the annual monitoring for a known diabetic patient?

Diabetes causes **microvascular** disease (e.g., retinopathy, nephropathy, neuropathy) and **macrovascular** disease (e.g., coronary and peripheral atherosclerosis $\rightarrow$ CVD, stroke, and PAD). Tobacco use greatly accelerates macrovascular complications.

Start screening for microvascular complications immediately at diagnosis because T2DM may already have been present for 5–10 years. The following 3 microvascular complications usually appear 10–15 years after the onset (not diagnosis) of DM:

- 1) **Retinopathy** correlates with duration and control of DM. Early findings include dot hemorrhages. Macular edema and neovascularization (proliferative retinopathy) are late findings. Treatment options include intravitreal anti-vascular endothelial growth factor (anti-VEGF) and photocoagulation (laser treatment). Retinopathy can worsen transiently with initiation of tight glycemic control.
- 2) **Nephropathy** is usually heralded by persistent albuminuria (urine albumin:creatinine ratio > 30 mg/g). Note: Albuminuria in the range of 30–300 mg/g was previously called microalbuminuria. Treat with either ACEI or ARB to **decrease** the rate of nephropathy progression (by decreasing intraglomerular pressure). Retinopathy almost universally precedes nephropathy. If a diabetic patient without retinopathy develops nephrotic-range proteinuria, evaluate the patient for other causes of nephrotic syndrome.
- 3) **Neuropathy** includes autonomic neuropathy, axonal (Schwann cell) degeneration, symmetric polyneuropathy (“stocking and glove”), erectile dysfunction, and gastroparesis. Both alcohol and tobacco use increase the risk and severity of neuropathy. Diabetic mononeuropathy usually affects the 3rd and 6th cranial nerves, the peroneal nerve (foot drop), and the radial nerve (wrist drop). Strict glycemic control decreases the risk of neuropathy and improves nerve conduction. The pain associated with diabetic sensory dysfunction is difficult to treat. Recommended drugs include amitriptyline, venlafaxine, duloxetine, gabapentin, and pregabalin. Remember: Before diagnosing a neuropathy due to diabetes, check B₁₂ levels if on metformin.

Know the major diabetes studies and how glycemic control affects diabetic complications:

- Tight blood glucose control reduces **microvascular** complications in both T1DM and T2DM. This was demonstrated for T1DM by the Diabetes Control and Complications Trial (DCCT) and for T2DM by the UKPDS, the Japanese Kumamoto study, and the ACCORD study.
- A reduction in **macrovascular** complications (cardiovascular disease) has been harder to show, particularly for T2DM. A 10-year follow-up of intensively treated (HbA_{1c} ~ 7%) UKPDS and DCCT patients (the EDIC trial) showed improved cardiovascular outcomes. Although the difference was not statistically significant at the time of the original studies, the benefit emerged as the patients aged. However, ACCORD, ADVANCE, and VADT did not show any benefit of tighter glycemic control on cardiovascular outcomes in patients with T2DM.

Monitoring

All diabetic patients need **annual** evaluations for microvascular complications (5 years after diagnosis in T1DM and immediately at diagnosis in T2DM).

Be sure to do the following:

- Urine spot albumin:creatinine ratio as a test for nephropathy. Normal is < 30 mg of albumin per gram of creatinine. Moderately increased albuminuria is 30–300 mg/g. Severely increased albuminuria is > 300 mg/g.
- Check creatinine and estimated **GFR**.
- Refer patient to an **ophthalmologist** for a retinal exam and rapidly refer macular edema or proliferative retinopathy. Macular edema can lead to vision loss if not treated. It is acceptable to use fundus photography in clinical situations when experienced ophthalmologists are unavailable.
- Inspect the **feet** and perform a sensory evaluation using 10-g monofilament, pinprick, temperature, and vibration. Know that loss of vibratory sense and sensation to the 10-g monofilament predicts foot ulcers.
- Do **not** routinely screen asymptomatic diabetic patients for ischemic heart disease. Outcomes are unchanged with intervention in asymptomatic patients, provided you are treating their CVD risk factors.

ANCILLARY MANAGEMENT

PREVIEW | REVIEW

- Which antihypertensives are recommended for diabetic patients with hypertension?

Hypertension

Although blood pressure targets are individualized in hypertensive patients with diabetes, the 2020 ADA Standards of Medical Care recommends medication in addition to lifestyle changes for pressures ≥ 140/90 mmHg. For those patients at high cardiovascular risk a target of < 130/80 mmHg, may be appropriate, but only if it can be safely attained.

The 2020 ADA Standards of Medical Care in Diabetes, which are consistent with the 2019 ACC/AHA High Blood Pressure guidelines, say to treat diabetic patients with albuminuria (albumin:creatinine ratio > 30 mg/g) 1st with an **ACEI** or an **ARB**. Next, add a thiazide diuretic (e.g., chlorthalidone)—and/or dihydropyridine calcium channel blocker (e.g., amlodipine) if needed—to reach the BP target. Remember: Avoid combination ACEI + ARB! ONTARGET (2008) showed this combo increases risk of hypotensive symptoms, hyperkalemia, and acute kidney injury, with no cardiovascular benefit.

For the rare patient with DM who is not hypertensive, use an ACEI or an ARB if albuminuria is present. There is no

evidence to support the use of ACEI or ARB for primary prevention in diabetic patients without albuminuria or hypertension.

Dyslipidemia

The ADA Standards of Medical Care in Diabetes—2020 include recommendations on statin initiation. Recommendations are risk based (“statin benefit group”), not LDL based (“treat to target”).

Treat diabetic patients 40–75 years of age:

- With a moderate-intensity statin
- With a high-intensity statin if at high risk

Every 39 mg/dL (1.0 mmol/L) LDL-C decrease causes a 21% decrease in major vascular events. Treatment of dyslipidemia is discussed in detail in the Cardiology section.

Know that triglyceride levels are very dependent upon glycemic control. The worse the diabetes control, the higher the triglycerides. Also know that even if the triglycerides are high and the LDL is normal, the initial lipid therapy is a statin (“statin benefit group”).

Aspirin

Aspirin use in diabetic patients is controversial because not all diabetic patients have the same risk for heart disease, despite DM being listed as a CVD risk-equivalent. Per the 2020 ADA recommendation, aspirin therapy (75–162 mg/day) may be considered as a primary prevention strategy in those with diabetes who are at increased cardiovascular risk, after a comprehensive discussion with the patient on the benefits versus the comparable increased risk of bleeding. Give diabetic patients with known cardiovascular disease a daily aspirin as secondary prevention. ASA-allergic patients can take clopidogrel.

HYPERGLYCEMIC EMERGENCIES

PREVIEW | REVIEW

- List the symptoms of diabetic ketoacidosis (DKA).
- Which lab abnormalities occur in the patient with DKA?
- What is the formula used for correction of pseudohyponatremia due to hyperglycemia?
- When is HCO₃⁻ given to treat DKA?

Ketoacidosis

Diabetic ketoacidosis (DKA) is sometimes the initial presentation of T1DM, but it can also occur in T2DM. It is caused by a state of complete or partial insulin deficiency leading to massive lipolysis. Lipolysis causes a release of free fatty acids and ketone bodies (β-hydroxybutyrate and acetoacetate). These products, high anion gap acidosis (because ketones are acids),

and the associated hyperglycemia cause volume depletion from massive osmotic diuresis.

Symptoms include nausea, vomiting, abdominal pain, polyuria, and lethargy. Ask about symptoms of infection (e.g., pneumonia, UTI) and nonadherence with diabetes medications, the two most frequent precipitating conditions for DKA.

On clinical exam, hypotension can occur due to severe volume depletion. Fruity breath and a Kussmaul respiratory pattern suggest ketoacidosis. Severe cases are marked by confusion or obtundation.

Diagnosis: DKA is diagnosed by a high anion gap acidosis, ketosis, and, most of the time, hyperglycemia (see Table 1-5). Secondary derangements include deficits in total body K⁺ and phosphorus (even though both can be normal in serum measurements at presentation because of the acidosis and hemoconcentration). Serum Na⁺ is usually decreased because of the osmotic shift of water from inside cells to the intravascular space caused by the hyperglycemia, a phenomenon referred to as pseudohyponatremia. Correct for this by adding 2.0 mEq/L (2 mmol/L) to the measured serum Na⁺ for every 100 mg/dL (5.6 mmol/L) increase in blood glucose over 100 mg/dL.

Table 1-5: Diagnostic Criteria for Diabetic Ketoacidosis (DKA) vs. Hyperglycemic Hyperosmolar State (HHS)

Parameter	DKA	HHS
Usual glucose at diagnosis	> 250 mg/dL (13.88 mmol/L)	> 600 mg/dL (33.3 mmol/L)
Arterial pH	< 7.3	> 7.3
Serum HCO ₃ ⁻	< 18 mEq/L (18 mmol/L)	> 18 mEq/L (18 mmol/L)
Urine ketones	Positive	"Small" or negative
Serum ketones	> 3 mmol/L	< 0.6 mmol/L
Effective serum osmolality	Variable	> 320 mOsm/kg (320 mmol/kg)
Anion gap	> 10 mEq/L (10 mmol/L)	Variable
Mental status	Varies with severity	Stupor/Coma

Adapted from: Kitabchi, A. E., G. E. Umpierrez, J. M. Miles, and J. N. Fisher. 2009. Hyperglycemic crises in adult patients with diabetes. *Diabetes Care*. 32(7):1335–1343.

Treatment:

- Treat precipitating causes (e.g., infection, infarction).
- Start aggressive volume replacement; give normal saline (~ 2–3 L), then either continue the normal saline or switch to 0.45% saline if the corrected serum Na⁺ is > 135 mEq/L (135 mmol/L).
- Start IV insulin at 0.1 units/kg/hour. When glucose is < 200 mg/dL (11.1 mmol/L), add D5 (5% dextrose) to the IV fluids to avoid hypoglycemia while insulin

is infusing. Keep the IV insulin going until the acidosis is resolved and the anion gap is normal; the insulin is required to stop production of the ketoacids.

- If the K^+ is < 5.0 mEq/L (5.0 mmol/L) at the start of treatment, give potassium chloride (KCl) immediately because there is usually a several-hundred mEq K^+ deficit despite normal serum K^+ concentration.
- In cases of very low K^+ (< 3.3 mEq/L [3.3 mmol/L]), give KCl and hold insulin until the K^+ is ≥ 3.3 mEq/L.

More on K^+ : It falls with treatment of DKA because of shifting into the cells from both the reversal of acidosis and the action of insulin. This can further aggravate hypokalemia and lead to cardiac arrest or respiratory muscle weaknesses. Also monitor the heart-wave morphology and rhythm for any hypokalemic changes, such as T-wave amplitude flattening (1st change), ST-segment depression, T-wave inversions, PR-interval prolongation, and, finally, an increase in amplitude of U waves.

Bicarbonate (HCO_3^-) is controversial but can be given when pH is < 7.0 , especially if the patient is having respiratory or hemodynamic collapse.

The standard urine ketone test (and older plasma tests) react with acetoacetate, but not β -hydroxybutyrate. With severe ketoacidosis, β -hydroxybutyrate levels can be much higher than acetoacetate levels. In this situation, urine ketone testing can underestimate the presence or severity of the DKA.

If the patient is being treated for DKA and seems to be getting better but the ketones start rising, the β -hydroxybutyrate is being converted to acetoacetate as the acidosis resolves. Clinically, you can follow resolution by monitoring the pH and anion gap. The anion gap reflects both types of ketones. Plasma β -hydroxybutyrate concentration can be checked directly with point of care testing, and it is sensitive and more specific than the urine tests.

Hyperglycemic Hyperosmolar State (HHS)

HHS is one of the most serious acute complications of T2DM. It can lead to coma and death and has many precipitating factors, including volume depletion, infection, drugs (e.g., glucocorticoids), and any serious illness.

HHS is caused by partial insulin deficiency and decreased intake of fluids. The patient is usually elderly and has a preceding history of lethargy, weight loss, and polyuria.

Exam is consistent with severe volume depletion and confusion, stupor, or coma. These patients are not severely acidotic, so they do not have fruity breath or Kussmaul respirations.

Labs show severe hyperglycemia (typically > 600 mg/dL [33.3 mmol/L]) and evidence of azotemia, dehydration, and volume depletion. If an anion gap metabolic ketoacidosis is present, it is generally mild.

See [Table 1-5](#) for a comparison of diagnostic criteria in DKA vs. HHS.

Treat HHS similarly to DKA, with IV fluid resuscitation and insulin bolus + infusion. Be sure to correct the serum Na^+ for the hyperglycemia to determine if a free-water deficit exists, then replace it gradually over the next 24–48 hours. K^+ replacement is usually required.

DIABETES IN PREGNANCY

See the [Women's and Men's Health](#) section.

HYPOGLYCEMIA

PREVIEW | REVIEW

- What is the Whipple triad?
- Which laboratory tests help you determine if someone is factitiously self-injecting insulin to induce hypoglycemia?

OVERVIEW

The diagnosis of hypoglycemia is not based on a low blood glucose level alone; it requires fulfillment of the **Whipple triad**:

- 1) Signs and symptoms consistent with hypoglycemia
- 2) Associated low **plasma** glucose level (< 55 mg/dL [3.0 mmol/L])—do not measure with a home glucose monitor.)
- 3) Relief of symptoms with supplemental glucose

Symptoms are autonomic (e.g., palpitations, tremor, sweating, paresthesias) and neuroglycopenic due to CNS glucose deprivation (e.g., confusion, impaired consciousness, seizures). Usually, autonomic symptoms happen first. Signs of hypoglycemia are nonspecific (e.g., hunger, sweating, anxiety, tremor, altered mental status).

Divide your patients into 2 groups—hypoglycemic patients without diabetes and hypoglycemic patients with diabetes—and then treat accordingly. See [Hypoglycemia in Patients without Diabetes](#) next and [Hypoglycemia in Patients with Diabetes](#) on page 1-45 for details.

HYPOGLYCEMIA IN PATIENTS WITHOUT DIABETES

Etiology

Causes of hypoglycemia in nondiabetic patients include:

- **Drugs:** insulin, insulin secretagogues (e.g., glyburide), oral hypoglycemic agents, alcohol. Be sure to think about accidental, surreptitious, and malicious ingestion of sulfonylureas or insulin, especially in patients in the health care field or with a diabetic family member (see [Genetic Causes of Hypercalcemia](#) on page 1-48).

- **Hormone deficiencies:** cortisol, glucagon, epinephrine
- **Critical illness:** heart failure, renal failure, liver failure, sepsis, severe malnutrition
- **Islet cell tumors:** insulinoma, insulinlike growth factor (IGF)-secreting tumor
- **Non-islet cell tumors:** Rarely, other tumors (e.g., hepatocellular carcinoma, fibrosarcomas) can cause hypoglycemia via overproduction of insulinlike growth factor-2 (IGF-2).
- **Functional B-cell disorders:** post gastric bypass, non-insulinoma pancreatogenous hypoglycemia (usually postprandial hypoglycemia)
- **Autoimmune:** endogenous antibodies to insulin or insulin receptor (rare)

Diagnostic Approach

After the diagnosis of hypoglycemia has been established (using Whipple's triad), begin your diagnostic evaluation. First, do a careful history (especially medications) and physical exam, looking for clues to one of the causes listed in [Etiology on page 1-43](#). If the patient is seemingly well, always evaluate for exogenous, accidental, surreptitious, or malicious ingestion or administration of sulfonylureas (SUs) or insulin before doing any further testing. Consider adrenal insufficiency, even though it is rare that this would cause hypoglycemia without other clinical features. Finding an isolated low cortisol during a hypoglycemic event does not necessarily mean the patient has primary adrenal insufficiency because recurrent hypoglycemia lowers the baseline of cortisol secretion; i.e., the hypoglycemia may be causing the low cortisol. If the etiology is not apparent, proceed with laboratory testing.

There are 2 classifications of hypoglycemia: **reactive** (sometimes called postprandial) and **nonreactive** (sometimes called fasting).

Reactive Hypoglycemia

Reactive hypoglycemia (a.k.a. postprandial hypoglycemia) develops in response to a **nutrient challenge**. Significant postprandial hypoglycemia has been documented in postoperative gastric bypass patients due to islet cell hypertrophy. This must be distinguished from traditional dumping syndrome in postoperative bariatric surgery patients, where there are hypoglycemic-type symptoms but no hypoglycemia after a meal. Initial treatment for both includes small, frequent meals that are high in protein and fiber and low in carbs. Postoperative bariatric surgery patients with refractory severe hypoglycemia due to abnormal islet cells may require surgery (pancreatectomy or reversal of the bypass).

Postprandial hypoglycemia in patients without gastric bypass also needs to be evaluated. The test of choice is a nonliquid mixed meal that the patient believes will trigger the hypoglycemia. In the past, postprandial hypoglycemia was diagnosed based on hypoglycemia after an OGTT.

This diagnosis has been discredited over time due to poor reproducibility and poor correlation between hypoglycemic symptoms and documented low blood glucose. **Never** order an OGTT to work up hypoglycemia. On exams, OGTT is a typical distractor from the correct answer.

All reactive hypoglycemia requires fulfillment of the Whipple triad to be a true diagnosis warranting additional evaluation.

Nonreactive Hypoglycemia

In nonreactive hypoglycemia (a.k.a. fasting hypoglycemia), the patient is unable to maintain glucose levels with fasting. The most common causes in hospitalized patients are alcohol abuse, drugs (e.g., oral hypoglycemics, pentamidine), and sepsis.

The causes of nonreactive hypoglycemia in seemingly healthy patients (and that are most commonly tested on exams) are causes of hyperinsulinism. The workup for nonreactive hypoglycemia is summarized in [Figure 1-16](#).

Factitious Hypoglycemia

Factitious hypoglycemia is hypoglycemia in a nondiabetic patient caused by ingestion of antidiabetes medications. Insulin and insulin secretagogues are the typical culprits; other classes of antidiabetic medications do not usually cause hypoglycemia. Ingestion can be accidental, surreptitious, and/or malicious. Evaluate for and exclude this diagnosis before any imaging to look for an insulinoma. Review the patient's medication list, and search for pharmacy/medication errors. Suspect surreptitious or malicious etiologies if a patient or family members are in the health care fields or have knowledge/access to glucose-lowering medications.

Endogenous Hyperinsulinism

Endogenous hyperinsulinism is a group of diseases that includes insulinomas, β -cell disorders (such as may occur after gastric bypass), antiinsulin antibodies, and the use of secretagogues in those without diabetes.

If the patient has a spontaneous hypoglycemic event, first confirm the hypoglycemic value with a plasma glucose (capillary/fingerstick glucose values are unreliable and should not be used for hypoglycemia diagnosis), and pair the glucose with a C-peptide, proinsulin, insulin level, and a sulfonylurea (SU) screen.

If insulinoma is suspected but Whipple's triad has not yet been documented, it can be induced by a supervised fast (gold standard: 72-hour fast). The following labs should be obtained at the time of hypoglycemic symptoms (prior to treatment):

- 1) Serum proinsulin (always paired with a glucose)
- 2) C-peptide (always paired with a glucose)
- 3) Urinary/Plasma SU screen
- 4) Serum insulin (always paired with a glucose)

Figure 1-16: Nonreactive hypoglycemia workup

Proinsulin (the precursor of insulin): Insulinomas tend to cause a high ratio of proinsulin to total insulin in the serum. The normal level is 10% of total insulin. With **insulinomas** the level is > 20%, and often 30–40%. With exogenous insulin use, it is low.

C-peptide is produced in a 1:1 ratio with insulin when they are both cleaved from proinsulin. Therefore, with endogenous insulin production (sulfonylurea-induced and insulinoma), the C-peptide level parallels serum insulin values and is high or inappropriately normal during a hypoglycemic event. **C-peptide is low** with exogenous **insulin** injection.

A **urinary/plasma sulfonylurea** test rules in or out factitious hypoglycemia from SU use. Do not proceed to any imaging for insulinoma until a negative SU screen is documented.

Insulin is high or inappropriately normal during the hypoglycemic episode in the following situations:

- Exogenous insulin administration: Insulin levels can be high (sometimes > 100 µU/mL [694.4 pmol/L]) due to self-administration, but the C-peptide is low!
- SU ingestion: Insulin, C-peptide, and proinsulin levels are all high, but the SU screen is positive.
- Insulinoma: Insulin, proinsulin, and C-peptide levels are usually high during an episode of hypoglycemia; SU screen is negative.

- Autoimmune etiologies (antibodies to insulin and insulin receptors): These conditions can cause hypoglycemia **or** hyperglycemia.

HYPOGLYCEMIA IN PATIENTS WITH DIABETES

Hypoglycemia caused by medications is by far the most frequent cause of hypoglycemia in patients with diabetes. Do **not** test diabetic patients for rare causes of hypoglycemia until after extensively reviewing diabetes management and adjusting antidiabetic medications appropriately.

Remember that, in T1DM, other comorbidities (e.g., adrenal insufficiency, celiac disease) can increase the risk of hypoglycemia. In longstanding T2DM and diabetes patients with comorbidities (e.g., heart failure, renal failure, liver failure), agents that are not typically associated with hypoglycemia (i.e., biguanides, TZDs, GLP-1 analogs, DPP4 inhibitors) can still be the cause of hypoglycemia, especially if they are combined with insulin therapy.

Treatment of hypoglycemia, regardless of the etiology, is generally oral carbs (15–20 g) if the patient is able to take them. If not, options are IV dextrose if an IV is in place, or IM/SQ/nasal glucagon if the patient does not have an IV.

OBESITY

OVERVIEW

The prevalence of obesity has increased significantly in the U.S. over the last 30 years: 40% of adults in the U.S. are now obese (BMI > 30 kg/m²), and 7.7% are severely obese (BMI > 40 kg/m²). Obesity is associated with the development of diabetes, hypertension, fatty liver, dyslipidemia, cardiovascular disease, degenerative joint disease, and obstructive sleep apnea.

EVALUATION AND CLASSIFICATION

Screen every patient for obesity by measuring their body mass index (BMI, in kg/m²). Normal BMI is 18.5–24.9 kg/m², BMI 25.0–29.9 kg/m² is overweight, and BMI ≥ 30 kg/m² is obese. Note that BMI will overestimate obesity in individuals with high muscle mass (e.g., body-builders) and underestimate obesity in individuals with low muscle mass (e.g., older adults).

Measure waist circumference—it's an additional cardiovascular risk factor if > 102 cm for men and > 88 cm for women.

MANAGEMENT

Most obesity-associated diseases and complications improve with only a 5–10% weight reduction. Remember to manage the patient's weight loss expectations and focus on healthy lifestyle, not on weight loss alone.

Every patient with overweight/obesity should be offered a lifestyle management plan consisting of 3 components:

- Meal plan: Recommend a diet 500–750 kcal/day less than the daily requirement, and individualize the plan to the patient's preference and culture.
- Physical activity: Recommend aerobic exercise that progresses to 150 minutes/week on 3–5 separate days, with 2–3 resistance exercise sessions 2–3×/week.
- Behavioral modification: Recognize and control environmental cues and stimuli that promote unhealthy eating and sedentary lifestyle. Include self-monitoring, education, stress reduction, and goal setting that requires participation of others.

For obese patients, and overweight patients with ≥ 1 weight-related disease or complication, offer weight-loss medications if lifestyle management therapy has failed.

Weight-loss medications, which can be used alone or in combination, include serotonin agonists (lorcaserin), diabetes medications (liraglutide), sympathomimetics (phentermine), antidepressants (bupropion), anticonvulsants (topiramate), and inhibitors of fat digestion (orlistat). Most of them produce an average of 6–8 kg of weight loss, with around 50–60% of patients reaching a 5% weight loss. All weight-loss medications are contraindicated in pregnancy.

Consider bariatric surgery in patients with BMI > 40 kg/m² or BMI > 35 kg/m² with ≥ 1 severe weight-related diseases/complications who have not met weight-loss goals with exercise, diets, and meds.

BONE / CALCIUM DISORDERS

- What is the treatment for hypercalcemia?
- What is osteomalacia? How does it present?
- What is the most common cause of vitamin D deficiency?
- Which lab value is used to measure vitamin D levels?

NORMAL CALCIUM PHYSIOLOGY

Ca²⁺ is absorbed from the duodenum, stored in the bone, and excreted by the kidneys. Ca²⁺ levels are tightly regulated by multiple hormones to keep serum Ca²⁺ in a normal range.

When serum Ca²⁺ is low, 2 endogenous hormones are responsible for **increasing** serum Ca²⁺ levels: parathyroid hormone (PTH) and 1,25-(OH)₂-vitamin D (a.k.a. 1,25-(OH)₂-D, calcitriol).

PTH increases Ca²⁺ in the blood through the following:

- Stimulates release of bone Ca²⁺ stores by indirect stimulation of osteoclasts (c = chew bone)
- Increases renal tubular Ca²⁺ reabsorption and renal tubular phosphorus excretion
- Increases activity of kidney 1α-hydroxylase, which increases the production of 1,25-(OH)₂-D and, thereby, increases Ca²⁺ and phosphorus absorption from the gut

Vitamin D is either ingested or is made in the skin after a reaction with sunlight, but it is inert until it is sequentially hydroxylated, first in the liver to form 25-OH-D, and then in the kidney to form 1,25-(OH)₂-D. 1,25-(OH)₂-D increases Ca²⁺ and phosphorus absorption from the gut. 25-OH-D is the stored (measured) vitamin D, and 1,25-(OH)₂-D is the active vitamin D, which acts as a hormone.

High serum free Ca²⁺ feeds back to suppress PTH secretion and, subsequently, 1,25-(OH)₂-D. Low serum Ca²⁺ and vitamin D deficiency increase PTH production.

Calcitonin, from the thyroid parafollicular cells (C cells), can be considered a PTH antagonist. It slows down the osteoclasts, causing a decrease in bone resorption and increase in renal Ca²⁺ clearance (calciuria).

Other hormones also can influence Ca²⁺ levels and bone health. Normal levels of **glucocorticoids** help maintain osteoblast (b = build bone) function, but excess levels increase bone resorption, decrease bone formation, and cause calciuria.

HYPERCALCEMIA

Hyperparathyroidism

Primary hyperparathyroidism (PHPT) is often found incidentally after noting high serum Ca²⁺ on screening laboratory studies. 80% of cases are caused by solitary parathyroid adenomas. Complications of untreated PHPT include low bone density (measured in the distal radius), fractures, kidney stones, and hypercalcemia.

Although most patients are asymptomatic, the classic signs and symptoms of PHPT have been described as “bones, stones, abdominal moans, and psychic groans.”

Bones refer to both increased risk of fractures and the presence of bone aches and pains. There is an increased risk of calcium-containing kidney **stones** and nephrocalcinosis. **Abdominal moans** refer to the multiple GI symptoms (e.g., constipation, nausea, anorexia, abdominal pain, peptic ulcer) linked to hypercalcemia.

Psychic groans can include confusion, memory loss, and delirium. As helpful as this mnemonic is, remember

that most symptomatic patients have mostly vague, nonspecific symptoms, like generalized fatigue, attention/concentration deficits, depression, and weakness.

On the ECG, expect to find a shortened ST segment.

Subperiosteal bone resorption (a.k.a. osteitis fibrosa cystica) with a **moth-eaten** appearance to the radial side of phalangeal cortices on **finger** radiographs is the classic finding, indicating prolonged PTH excess. This finding is now rare, probably due to earlier recognition. If an exam question shows you radiographs of a patient's hands, think about primary hyperparathyroidism.

The diagnosis of PHPT is made by finding an **elevated** or **inappropriately normal** intact PTH (iPTH) with an **elevated Ca²⁺** (see Table 1-6). A normal iPTH in the setting of hypercalcemia is compatible with the diagnosis of primary hyperparathyroidism because, normally, high Ca²⁺ suppresses iPTH. Serum phosphorus is usually low-normal to low (see Table 1-6).

Know that patients with drug-induced hypercalcemia caused by lithium or thiazides may present with PTH levels above normal; ask about these meds, and stop thiazides for 3 months before the hypercalcemia evaluation is done.

Differentiate hypercalcemia due to PHPT from benign familial hypocalciuric hypercalcemia (FHH) by measuring 24-hour urinary Ca²⁺ and Cr excretion and calculating the Ca²⁺/Cr clearance ratio:

$$\text{Ca}^{2+}/\text{Cr clearance ratio} = \frac{[24\text{h urine Ca}^{2+} \times \text{serum Cr}]}{[24\text{h urine Cr} \times \text{serum Ca}^{2+}]}$$

Urinary Ca²⁺ excretion is very low in FHH (Ca²⁺/Cr clearance ratio < 0.01) and normal to high in PHPT. FHH does not need treatment (see [Genetic Causes of Hypercalcemia on page 1-48](#)).

Remember: If a patient with PHPT is taking hydrochlorothiazide (HCTZ) or lithium or has coexisting vitamin D deficiency, the 24-hour urine Ca²⁺ (and the Ca²⁺/Cr clearance ratio) can be low. Screen patients with PHPT for vitamin D deficiency by checking the 25-OH-D level (not 1,25-(OH)₂-D).

Table 1-6: Labs in Diseases Affecting Calcium

Calcium-Related Diseases	Ca ²⁺	PO ₄ ³⁻	Alkaline Phosphatase	iPTH	25-OH-D	1,25-(OH) ₂ -D
Primary hyperparathyroidism	↑	Normal/↓	Normal/↑	Normal/↑	Normal/↓	N/A
Hypercalcemia of malignancy due to lytic bone lesions	↑	Normal/↑	↑	↓	Normal	Normal (except in lymphoma, where it is ↑)
Humoral hypercalcemia of malignancy (i.e., due to PTHrp)	↑	Normal/↓	↑	↓ (but PTHrp is ↑)	Normal	Normal
Chronic kidney disease	Normal/↓	↑	N/A	↑	Normal/↓	Do not check (but it is ↓).
Osteomalacia from vitamin D deficiency	↓	↓	↑	↑	↓	Do not check.

PHPT is a biochemical diagnosis (made by labs); imaging is not necessary for the diagnosis but is often done to localize the adenoma. Imaging can include sestamibi scans and ultrasound.

Once the diagnosis of PHPT has been established biochemically, determine if parathyroidectomy is indicated. Indications for surgical **parathyroidectomy** include:

- Symptomatic PHPT (remember “bones, stones, abdominal moans, psychic groans”)
- eGFR < 60 mL/minute/1.73 m² (CKD Stage 3 or higher)
- Serum Ca²⁺ > 1 mg/dL (0.25 mmol/L) above the upper limit of normal
- T-score of ≤ -2.5 at lumbar spine, femoral neck, total hip, or distal 1/3 radius; Z-score of ≤ -2.0 in premenopausal women and men < 50 years of age
- < 50 years of age
- Vertebral fracture by x-ray, CT, MRI, or DEXA (dual energy x-ray absorptiometry)
- Kidney stone, either clinically or on imaging, or nephrocalcinosis
- 24-hour urine Ca²⁺ > 400 mg (> 10 mmol) and increased stone risk by urine biochemical stone risk profile

Monitoring and management of asymptomatic PHPT patients **who do not undergo surgery** includes:

- Measure serum Ca²⁺ and creatinine yearly.
- Obtain **bone density scans** every 1-2 years.
- Check 25-OH-D level, and supplement if < 20 ng/dL (480 pmol/L).
- Measure 24-hour urinary Ca²⁺. If the urinary Ca²⁺ is > 400 mg/day, then do a complete urinary biochemical stone profile.
- Diet advice is the same as for patients without primary hyperparathyroidism (i.e., goal = Ca²⁺ intake of 1,000 mg/day). Do **not** tell patients to restrict their Ca²⁺ intake—just avoid excessive supplementation.

No specific drug is recommended by the 2014 Guidelines for the Management of Asymptomatic Primary Hyperparathyroidism because long-term efficacy data are scarce. However, **cinacalcet** (Sensipar) is approved for the medical management of PHPT. Cinacalcet can be useful in patients who are not candidates for, or refuse, surgical parathyroidectomy. Note that this agent controls hypercalcemia alone and does not address bone loss or hypercalciuria. **Bisphosphonates** can be used to build bone in the lumbar spine and hips, but they do not decrease serum Ca²⁺ or urine Ca²⁺ excretion in the long term. Therefore, the clinical situation determines whether and which medication to use. A patient with fractures or severe osteoporosis requires bisphosphonates, while symptomatic hypercalcemia requires cinacalcet. If neither of these situations apply, do **not** give these medications. Hypercalciuria and kidney stones can only be addressed by parathyroid surgery.

Secondary hyperparathyroidism is the overproduction of parathyroid hormone secondary to a chronic abnormal stimulus inducing its production. Ca²⁺ is usually normal. Typically, this is due to chronic kidney disease and/or vitamin D deficiency. In chronic kidney disease, there is reduced renal 1-hydroxylation (i.e., activation) of 25-OH-D, leading to low levels of active 1,25-(OH)₂-D. This leads to lower Ca²⁺ and high PTH. Phosphate (PO₄³⁻) is high due to poor renal excretion (see [Table 1-6 on page 1-47](#) and the [Nephrology](#) section for further discussion).

Tertiary hyperparathyroidism is seen in patients with end-stage renal failure (ESRD) and chronic, poorly controlled secondary hyperparathyroidism. There is progression from 4-gland hyperplasia to autonomous PTH production. It can persist after renal transplantation if the autonomous, hypertrophied parathyroid glands continue to oversecrete parathyroid hormone, causing elevated serum Ca²⁺ levels. In the setting of ESRD +/- transplant, labs show a markedly elevated PTH and high Ca²⁺. Surgery is generally needed for severe tertiary hyperparathyroidism.

Summary: Hypercalcemic patients with elevated or normal iPTH and low phosphorus = **primary** hyperparathyroidism. If symptomatic (e.g., kidney stones, CKD, low bone density), do surgery. **Secondary** hyperparathyroidism with a normal Ca²⁺ = consider vitamin D deficiency and CKD as the cause. **Tertiary** hyperparathyroidism = ESRD or kidney transplant with hyperparathyroidism + hypercalcemia.

Other Causes of Hypercalcemia

Vitamins and Medications

Vitamin D excess, **vitamin A excess** (causes Ca²⁺ release from bones), **thiazide diuretics** (decreases Ca²⁺ excretion), and **lithium** (increases PTH threshold by requiring Ca²⁺ to be at a higher level to shut off PTH production) can cause hypercalcemia.

Genetic Causes of Hypercalcemia

Benign familial hypocalciuric hypercalcemia (FHH) is autosomal dominant with normal or slightly elevated iPTH and elevated serum [Ca²⁺].—the same laboratory pattern as in primary hyperparathyroidism. The problem is in the calcium-sensing receptor, which requires a higher Ca²⁺ level before turning off PTH secretion. FHH requires **no** treatment, so it is important to differentiate from other causes of hypercalcemia (especially primary hyperparathyroidism). If FHH is suspected, measure Ca²⁺ and creatinine in the serum and urine, then calculate the Ca²⁺/Cr clearance ratio. If the ratio is < 0.01, the diagnosis is FHH; if > 0.02, FHH is excluded, and the diagnosis is most likely primary hyperparathyroidism. Remember that this is a very rare disease, so **verify** that there are no factors that are causing a falsely low urine Ca²⁺ (especially vitamin D deficiency, malabsorption, celiac disease). Also recognize that FHH is genetic and not acquired. Thus, if there were normal calcium levels in the past, it is not FHH.

Hypercalcemia of Malignancy

Mechanisms of hypercalcemia of malignancy (non-PTH mediated) are:

- osteolytic bone lesions,
- PTH-related protein (PTHrP) production, or
- extrarenal 1α -hydroxylase production to make $1,25\text{-(OH)}_2\text{-D}$ (active vitamin D).

Types of cancer that cause hypercalcemia: myeloma, some solid tumors, tumors with bone metastases, and lymphoma.

Some solid tumors (e.g., breast, renal, squamous cell) secrete a **PTHrP**, in which the *N*-terminal (amino) end is identical to iPTH. But the mid- and carboxy-terminal portions are different, so it is not measured by the iPTH assay. The elevated Ca^{2+} inhibits production of PTH by the parathyroid glands, so PTH levels are suppressed. Make the diagnosis by measuring PTHrP levels.

Bone metastases (e.g., breast cancer and multiple myeloma) account for 1/2 of all patients with elevated Ca^{2+} and malignancy; they produce local osteoclast activation substances, causing breakdown of bone.

Lymphoma can have macrophages and lymphocytes with unregulated production of **1α -hydroxylase**, the enzyme that normally converts 25-OH-D into $1,25\text{-(OH)}_2\text{-D}$ in the kidney. This extrarenal source of 1α -hydroxylase causes an increase in $1,25\text{-(OH)}_2\text{-D}$ and hypercalcemia. Make the diagnosis by measuring $1,25\text{-(OH)}_2\text{-D}$ (**calcitriol**) levels.

More information on hypercalcemia of malignancy can be found in the [Oncology](#) section.

Granulomatous Diseases

Several **granulomatous** diseases, including sarcoidosis, tuberculosis, berylliosis, histoplasmosis, and leprosy, can cause hypercalcemia by stimulating macrophages to increase $1,25\text{-(OH)}_2\text{-D}$ production (similar to lymphoma). Macrophages (and lymphocytes) have unregulated 1α -hydroxylase activity, which converts 25-OH-D into $1,25\text{-(OH)}_2\text{-D}$. If suspected, measure $1,25\text{-(OH)}_2\text{-D}$ (**calcitriol**) levels.

Immobilization

Immobilization can cause elevated Ca^{2+} . High bone turnover states (e.g., hyperthyroidism, Paget disease, adolescence) increase the risk, but immobilization-induced hypercalcemia can occur without those comorbidities. The high Ca^{2+} level causes a **decrease in iPTH**.

Treatment of Hypercalcemia

For **severe** hypercalcemia, immediately give 3–4 L of **normal saline** to treat volume depletion (remember, hypercalcemia causes renal salt wasting and nephrogenic DI). **Calcitonin** is added to increase renal calcium excretion and inhibit bone turnover. **Loop diuretics**

should be used only if the patient develops fluid overload from saline resuscitation (monitor electrolytes and volume status).

Bisphosphonates inhibit bone resorption in areas of high turnover, such as sites of malignancy, and usually are used in conjunction with saline infusions and calcitonin to treat **moderate-to-severe** hypercalcemia.

Pamidronate and **zoledronic acid** are the bisphosphonates favored by most because of their rapid onset of action (48 hours) and intravenous formulation. Know that these drugs can cause **osteonecrosis of the jaw** in patients with multiple myeloma and metastatic bone disease.

Give glucocorticoids to treat hypercalcemia caused by sarcoidosis and other granulomatous diseases (see [Granulomatous Diseases](#)), myeloma, and lymphoma.

Mobilize patients as much as possible with physical therapy, home health assistance, and help of family.

HYPOCALCEMIA

Signs and Symptoms

Hypocalcemia can cause nonspecific symptoms, including fatigue, anxiety, and depression. The hallmark of hypocalcemia is neuromuscular irritability (i.e., tetany). Patients report paresthesias, especially in the fingers and toes and around the mouth, and muscle cramps. On physical exam, try to elicit Trousseau sign (inflate a blood pressure cuff above systolic BP for 3 minutes; the muscles of the hands will spasm) and Chvostek sign (tap the facial nerve just in front of the ear; the facial muscles will spasm).

Severe hypocalcemia can cause seizures. Know that alkalosis exacerbates hypocalcemic seizures, and acidosis is protective. In a patient with hypocalcemia and metabolic acidosis, always correct the hypocalcemia before you correct the acidosis!

Causes of Hypocalcemia

Low serum Ca^{2+} is caused by the following:

- Hypoparathyroidism—decreased PTH secretion (clue: high PO_4^{3-} + low Ca^{2+}):
 - Primary hypoparathyroidism
 - Thyroid surgery with **loss of parathyroid glands**
 - Severe **hypomagnesemia** ($\text{Mg}^{2+} < 0.8 \text{ mEq/L}$ [0.4 mmol/L]); Mg^{2+} is required for PTH release and its effect on target organs. This can be seen in patients with bowel disease or alcohol abuse.
- Vitamin D deficiency
- Severe, acute pancreatitis: precipitation of Ca^{2+} salts in the abdominal cavity
- Acute, severe **hyperphosphatemia**, whereby Ca^{2+} is chelated by the phosphorus
- “Hungry bone” after parathyroidectomy (clue: low PO_4^{3-} + low Ca^{2+} + high pre-op alkaline phosphatase)

- **Pseudohypoparathyroidism** (Types Ia, Ib, Ic, II) is due to PTH resistance. It is a rare genetic disease due to a mutation in a gene involved in PTH receptor function. These patients have an appropriately elevated PTH (in response to the hypocalcemia). In addition to hypocalcemia, patients with Type Ia have short 4th metacarpals and short stature.

When patients with shortened 4th metacarpals and short stature have a normal serum Ca^{2+} , they may have **pseudo-pseudohypoparathyroidism**. These patients are heterozygous for the Ia mutation, and have the physical phenotype of pseudohypoparathyroidism Type Ia, but normal Ca^{2+} homeostasis.

Osteomalacia

Osteomalacia is a condition of decreased mineralization of normal bone at sites of bone turnover. It typically presents with symptoms of bone pain, but occasionally presents with hypocalcemia (see Table 1-6 on page 1-47). It is most commonly caused by vitamin D deficiency. In children, osteomalacia is called rickets; it causes listlessness, irritability, and bowing of the legs. Older patients present with **bone pain** and **proximal muscle weakness**. Patients of all ages have diffuse decreased bone mineral density.

These patients have an elevated **alkaline phosphatase** due to compensatory osteoblastic activity. This is a good lab clue!

In adults, bilateral symmetric pseudofractures (i.e., narrow radiolucent lines, most commonly in the femoral neck and femoral shaft) establish the diagnosis. An iliac crest bone biopsy with tetracycline double-labeling can provide a definitive pathologic diagnosis, but usually osteomalacia is diagnosed clinically without a biopsy.

Once the diagnosis is established, work up the cause (many possibilities). Again, vitamin D deficiency is the most common case in adults. The usual cause of vitamin D deficiency is inadequate intake and/or malabsorption. It's quite common in the elderly and in northern latitudes. Vitamin D deficiency is also more typical in people who use a lot of sunscreen, have darker skin, and/or avoid sunlight.

Studies link vitamin D deficiency with falls, fractures, cancer, and CVD. Look for osteomalacia in older patients with prolonged hospitalizations, who develop bone pain with radiographs that show hairline fractures.

If you suspect vitamin D deficiency, check the 25-OH-D level, **not** the $1,25\text{-(OH)}_2\text{-D}$ level! In osteomalacia due to vitamin D deficiency (the most common cause), the 25-OH-D level will be low.

Renal osteodystrophy and adynamic bone disease are discussed in the **Nephrology** section. Osteoporosis is discussed in the **General Internal Medicine** section.

MULTIPLE ENDOCRINE NEOPLASIA (MEN)

MEN syndromes: All are autosomal **dominant** but with varying expression! See Table 1-7. The types are categorized as MEN1, MEN2A, and MEN2B.

Table 1-7: Multiple Endocrine Neoplasia Syndromes

Type	Clinical
MEN1	Primary hyperparathyroidism Pituitary adenomas Pancreatic islet cell tumors
MEN2A	Primary hyperparathyroidism Medullary thyroid cancer Pheochromocytoma
MEN2B	Medullary thyroid cancer Pheochromocytoma Developmental abnormalities*

*Marfanoid body type, skeletal deformations, mucosal neuromas (especially lips and tongue ["blubbery lips"])

MEN1: Symptoms are caused by hyperplasia, adenomas, and/or cancers of the parathyroid, pituitary, or the islet cells of the pancreas (think "**PPP**"). **Primary hyperparathyroidism** due to multiple parathyroid adenomas is typical. **Prolactinoma** is the most common pituitary tumor, and **gastrinoma** is the most common symptomatic pancreatic tumor. Suspect MEN1 in a patient with hyperprolactinemia and hypercalcemia. There is often a strong family history of peptic ulcer disease (undiagnosed gastrinoma) or primary hyperparathyroidism. Phenotypic expression within a family might be quite variable.

Aside from gastrinomas, the pancreatic tumors in MEN1 can also be insulinomas, VIPomas (which secrete vasoactive intestinal peptide), or glucagonomas. **Insulinomas** can cause hypoglycemic episodes and are diagnosed by documenting inappropriately high serum insulin levels. **VIPomas** present with secretory diarrhea. Diagnose with a high serum VIP level.

Glucagonoma is a very rare malignant tumor of pancreatic islet cells that produces glucagon and can cause a blistering dermatitis, hyperglycemia +/- diabetes, cheilitis (inflammation of the lips), diarrhea, weight loss, and cognitive impairment. The skin and tongue changes are due to a glucagon-induced amino acid deficiency. Think about it in patients with a family history of MEN1 who present with a triad of mild hyperglycemia, glossitis with a "beefy red tongue," and a distinctive blistering erythematous rash that is often found in the groin region (termed migratory necrolytic erythema).

Diagnose glucagonoma by measuring a glucagon level—one of the rare instances when it is useful to perform a randomly timed hormone assay! A level **> 500 pg/mL** (500 ng/L) is supportive. Image the pancreas with a helical CT if glucagon levels are high. In

the majority of patients, glucagonoma is metastatic (to liver, lymph nodes, bone, adrenals, kidney, and/or lung) at diagnosis.

MEN2A: **Medullary thyroid cancer** occurs in virtually all patients with MEN2A (and MEN2B) and often occurs early in life. **Pheochromocytoma** occurs frequently; **primary hyperparathyroidism** occurs in 25–50%.

MEN2B: Like MEN2A, they have **medullary thyroid carcinoma**, and 1/2 of patients have **pheochromocytoma**. Unlike MEN2A, they do not have primary hyperparathyroidism. This type is easy to differentiate from the others because of the **mucosal neuromas** seen on physical exam.

Remember: Both MEN2A and MEN2B have medullary thyroid cancer and pheochromocytoma.

Table 1-7 summarizes the classic clinical findings in MEN1, MEN2A, and MEN2B. Remember:

- **Primary hyperparathyroidism** (parathyroid hyperplasia) causes hypercalcemia but generally no symptoms.
- **Pituitary adenomas** can cause prolactinomas, acromegaly, or Cushing disease but can also be nonfunctional.
- **Pancreatic islet cell tumors** can present with hypoglycemic episodes (insulinoma) or peptic ulcer disease (gastrinoma).
- **Medullary thyroid cancer** is characterized by a high calcitonin level; diagnosis is with fine needle aspiration (FNA) biopsy.
- **Pheochromocytoma** can present with “spells” of headache, palpitations, sweating, and hypertension but usually is asymptomatic.

If a patient with an elevated iPTH has a family history of one brother having “medullary cancer” and another having a “parathyroid tumor,” what tests do you run on the patient?

Answer: Think MEN2A. Check calcitonin and free plasma metanephrines. In an exam setting, you may see only one of these in the answer choices.

The **RET protooncogene** test for hereditary medullary thyroid cancer (MTC) can also be very useful and offers the potential for prophylactic surgical intervention prior to the development of MTC in family members who are at risk. **Calcitonin** elevation correlates with **tumor burden** and may be the 1st sign of recurrent disease. Calcitonin doubling time is accurate in predicting **prognosis**. Elevated calcitonin levels can cause symptoms, such as flushing, diarrhea, and weight loss.

Treatment of MTC is surgical resection. For disease persistence or recurrence options, include observation, surgery, external beam radiation, and tyrosine kinase inhibitors.

THE MEDSTUDY HUB: YOUR GUIDELINES AND REVIEW ARTICLES RESOURCE

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub at

medstudy.com/hub

The Hub contains the **only** online consolidated list of **all** current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source. MedStudy maintains the Hub as a service to the medical community and makes it available to anyone and everyone at no cost to users.

IMMUNOLOGIC HYPERSENSITIVITY REACTIONS

PREVIEW | REVIEW

- What mediates immediate hypersensitivity reactions?
- When does the late phase of a Type 1 hypersensitivity reaction occur? Why does it occur?
- What is the difference between the late phase of Type 1 hypersensitivity reaction and the delayed Type 4 hypersensitivity reaction?
- What is the treatment for anaphylaxis?
- Which antihypertensive medication is relatively contraindicated in someone at risk for anaphylaxis? Why?
- Which diseases are mediated by Type 3 immune complex hypersensitivity reactions?

OVERVIEW

Immunologic hypersensitivity reactions reflect **immune-mediated** tissue injury seen in allergies, autoimmune disease, and other inflammatory diseases. These immune responses are the staggeringly important basis for disease prevention in the body, and are the **normal** reaction to a foreign antigen. There are 2 general dysfunctions in which these normal defense mechanisms cause disease:

- 1) An overexuberant response to a foreign antigen
- 2) Autoimmune disease develops, in which the body sees a self-antigen as foreign

So, as we go through the following mechanisms of immunologic hypersensitivity responses, remember that these are also the mechanisms of our normal immune responses to foreign antigens. We tend to forget that!

There are 4 types of immunologic hypersensitivity reactions (per Gell and Coombs):

- **Type 1:** IgE-mediated—immediate (anaphylactic, atopic)
- **Type 2:** IgG- or IgM-mediated cytotoxic
- **Type 3:** Immune complex-mediated (i.e., antibody-antigen mediated)
- **Type 4:** T Cell-mediated—delayed, 4 subtypes (a, b, c, d)

TYPE 1 — IgE-MEDIATED IMMEDIATE HYPERSENSITIVITY REACTION

The “classic” allergies are IgE-mediated Type 1 immediate hypersensitivity reactions. Almost all of these reactions are triggered by **foreign** allergens. Examples include hives/urticaria, allergic rhinitis, allergic asthma, and reactions to insect stings, drugs (e.g., penicillin [PCN]), or foods (e.g., eggs, peanuts, tree nuts, shellfish, soy).

Type 1 — Acute Response

The **acute** phase of an **immediate hypersensitivity reaction** occurs **within minutes to hours** after exposure. Mast cell degranulation (especially producing histamine) is the cause of the symptoms. This reaction is **IgE** mediated. The IgE reaction is antigen-specific and occurs only in response to **previous exposure** to the same allergen.

The base (Fc portion; see [Antibodies on page 2-22](#)) of IgE binds to a receptor on mast cells. This receptor is not specific, so there are many IgEs (each with its own antigen specificity) bound to a mast cell. Typically, no reaction occurs when IgE binds to a mast cell; however, when IgE attaches to its specific allergen, the same antigen reacts with ≥ 2 IgE molecules, interlinking them. Degranulation of the mast cell occurs with this complicated activation process, releasing histamine and stimulating the synthesis and secretion of other mediators like leukotriene, prostaglandin D₂ (PGD₂), and cytokines. Histamine is responsible for most of the acute symptoms. Mast cells also release other products that have chemotactic effects, and some of them are enzymes (e.g., chymase, tryptase). We can measure tryptase levels to confirm anaphylactic reactions because unlike histamine, which is broken down rapidly after release, tryptase is stable for up to a few hours after mast cell degranulation. See [Mastocytosis on page 2-13](#).

A quick review—histamine interacts with 4 receptors:

- **H₁** activation causes the **wheal** and flare, **bronchoconstriction**, and **pruritus**.
- **H₂** activation results in increased **gastric acid** secretion.
- **H₃** activation causes decreased histamine synthesis and release (negative feedback).
- **H₄** activation is immunomodulatory and affects eosinophil and mast cell chemotaxis.

Type 1 — Late-Phase Response

The late-phase response (LPR) occurs **3–12 hours** after the acute response in $< 25\%$ of cases and can last from **hours to days**. The LPR is caused by the initial immediate IgE reaction that stimulates the synthesis of cytokines and the subsequent cellular recruitment of eosinophils and basophils. This results in an **eosinophilic inflammatory infiltrate**.

In the airways, the LPR is a cause of airway hypersensitivity seen in asthmatic patients.

Type 1 — Anaphylaxis

Anaphylaxis is a potentially life-threatening allergic reaction that presents with symptoms such as urticaria, angioedema, abdominal pain, hypotension, and respiratory compromise. It is rapid in onset and can cause death. Anaphylaxis may begin within 5–30 minutes after antigen exposure, but can be delayed up to 2 hours.

The term “anaphylaxis” was traditionally associated only with the IgE-mediated set of symptoms we discuss under [Type 1 – Acute Response on page 2-1](#), and the term “anaphylactoid” was used for all other causes of this same set of symptoms. In 2014, the World Allergy Organization proposed new terminology that has been widely adopted. **Anaphylaxis** is now the **only** term used for this set of symptoms. Anaphylaxis, as with hypersensitivity reactions, is further categorized as immunologic or nonimmunologic.

Immunologic anaphylaxis includes:

- IgE-mediated reactions
- Complement activation with the release of anaphylatoxins C3a, C4a, and C5a

Nonimmunologic anaphylaxis includes all those previously termed “anaphylactoid,” in which the medication or substance itself directly triggers histamine and tryptase release from mast cells. Examples of **nonimmunologic** anaphylaxis are:

- Radiocontrast media (RCM) reactions
- Certain drug reactions:
 - Vancomycin (red man syndrome)
 - Opioids (especially codeine or meperidine)

Immunologic anaphylaxis is usually the result of an extreme IgE-mediated form of an immediate hypersensitivity reaction and this is the focus of the rest of this topic. IgE causes the release of the cytoplasmic granules with histamine and tryptase from mast cells (and maybe basophils). These released cytoplasmic granules cause an immediate reaction causing anaphylactic symptoms.

There are many causes of IgE-mediated anaphylaxis. The most common include:

- Drugs (especially penicillins and non-ASA NSAIDs)
- Insect stings (especially bees, wasps, and yellow jackets)
- Foods (especially peanuts, tree nuts, and shellfish)

A person may be sensitive to insect stings/bites and sustain a large, local reaction. But this does **not** increase the risk of anaphylaxis and further workup is **not** necessary. Of course, insect-sting anaphylaxis requires further evaluation with venom skin testing and serum venom-specific IgE. Refer to [Stinging-Insect Allergy on page 2-11](#).

The diagnosis of anaphylaxis is solely based on blood pressure and the patient's symptoms—as outlined in [Table 2-1](#). It involves at least 2 organ systems. Recognition and timely treatment of anaphylaxis is essential. Remember that hypotension is not necessary for the diagnosis of anaphylaxis!

Biphasic phase of anaphylaxis (late phase): Up to ~ 20% of patients experiencing IgE-mediated anaphylaxis have a 2nd episode within 1–30 hours after the initial event. This 2nd phase is believed to be caused by recruitment of inflammatory cells, including eosinophils, lymphocytes, and basophils, which is similar to

Table 2-1: Anaphylaxis Diagnosis

Anaphylaxis is diagnosed when any 1 of the following 3 criteria is fulfilled:

- 1) Sudden onset with involvement of the skin or mucosal tissue and either:
 - Sudden respiratory symptoms, or
 - Hypotension
- 2) ≥ 2 of the following occur suddenly after exposure to a likely allergen:
 - Skin or mucosal tissue involvement
 - Respiratory involvement
 - Hypotension
 - GI symptoms
- 3) Hypotension after exposure to a known allergen

the LPR of Type 1 hypersensitivity. Patients treated for anaphylaxis must be observed for the biphasic response or provided with emergency self-medications (e.g., epinephrine autoinjectors) if discharged. While difficult to predict, certain factors may increase the likelihood of the biphasic phase:

- Delayed initial epinephrine administration
- Severe initial symptoms
- Delayed resolution of initial symptoms
- Coexistence of asthma
- Oral ingestion of allergens
- β-blocker medication

Type 1 — Treatment

Treatment for immediate hypersensitivity includes avoidance of the allergen, antihistamine therapy (occasionally glucocorticoids), and allergen-specific immunotherapy (**3 As**). Advise all patients who have had prior anaphylaxis—especially those at high risk for recurrent exposure to its cause, such as **beekeepers**—to get an epinephrine autoinjection kit. Provide an anaphylaxis action plan and instructions on how/when to use epinephrine. Immunotherapy can take up to 1 year to show an effect and is not available for all causes of anaphylaxis. Effective immunotherapy causes an increase in regulatory T-cell secretion of IL-10 and blocking antibodies of the IgG isotype, among many other effects. Only IgE-mediated reactions benefit from immunotherapy treatment.

Anaphylaxis treatment:

- Administer 0.2–0.5 mL IM of epinephrine (1:1,000 dilution) in the lateral thigh muscle (fastest site of systemic absorption). The maximum dosage is 0.5 mg (0.5 cc of 1:1,000). Do not give the dose by IV due to adverse cardiovascular effects, and do not give SQ because absorption is slower compared to IM. Repeat dosing can be given every 10–20 minutes as needed. Note: Do not use the IV solution for IM treatment. Giving 0.5 mL of the 1:10,000 IV solution of epinephrine would grossly underdose the patient,

resulting in the administration of 0.05 mg (in 0.5 mL), 10× less than the intended dose of 0.5 mg.

- H₁ and H₂ antagonists (commonly diphenhydramine and cimetidine, respectively) can also be given for urticaria and pruritus.
- Give inhaled albuterol if bronchospasm develops.
- Ensure that the patient remains recumbent until they are completely asymptomatic. Deaths have occurred from patients being prematurely raised to a sitting position.
- For refractory hypotension: Administer 0.5 mg of epinephrine (5 mL of the 1:10,000 dilution) by IV every 5–10 minutes. Use caution and hemodynamic monitoring whenever using IV epinephrine due to risk of cardiac arrhythmia. Intravascular volume expansion (normal saline preferred) should also be given to patients who do not respond initially to IM epinephrine. Lastly, vasoactive agents such as dopamine, norepinephrine, and vasopressin may be needed for anaphylaxis refractory to epinephrine.

IV or PO glucocorticoids should be administered as part of the initial treatment. They are not effective for acute cases but may decrease likelihood of delayed response. Do not send patients home without making provisions for emergency self-treatment of the biphasic phase, even if they are given systemic glucocorticoids. Intramuscular epinephrine is 1st line treatment for all causes of anaphylaxis! The failure to recognize the symptoms of anaphylaxis and to promptly administer epinephrine has led to preventable fatalities.

Epinephrine affects the α- and β-adrenergic systems, resulting in bronchial relaxation, vasoconstriction, and decreased vascular permeability. The effect of epinephrine is blunted in patients on β-blockers. Therefore, in patients at risk for anaphylaxis (primary treatment is epinephrine), the use of β-blockers is relatively contraindicated. Glucagon slow infusion (5 mg slow IV bolus over 5 minutes) can be used in patients on β-blockers with anaphylaxis refractory to epinephrine; however, epinephrine should always be used first, even for patients on β-blockers. **Again:** Epinephrine is always 1st line treatment! At discharge, refer patients to an allergist, and prescribe epinephrine autoinjector.

TYPE 2 — IgG- OR IgM-MEDIATED CYTOTOXIC HYPERSENSITIVITY

Type 2 cytotoxic hypersensitivity is the main mechanism of autoimmune diseases that cause tissue or cell damage. Type 2 reactions occur when IgG or IgM binds to a fixed target tissue antigen or cell receptor, causing either dysfunction or inflammatory destruction. Most of Type 2 reactions are autoimmune—that is, directed at self-antigens. Extrinsic allergens can cause this reaction when they attach to cell surfaces. Penicillin is an example of an extrinsic agent that can cause both immediate IgE-mediated reactions and delayed IgG-mediated reactions.

The binding of the antibody results in target cell **destruction** by various means:

- Complement activation causes cells to be lysed by membrane attack complexes (MACs). This is discussed under [The 3 Complement Pathways on page 2-23](#).
- Complement activation may result in opsonization from the production of C3b. Phagocytes have a receptor for C3b and readily attack opsonized C3b-coated cells.
- Phagocytes also have a receptor for the Fc portion of the antibodies and readily attack opsonized antibody-coated cells.

Examples of target cell receptors:

- Platelets (immune thrombocytopenia [ITP], formerly known as immune thrombocytopenic purpura)
- RBCs (autoimmune hemolytic anemia)
- RBCs when penicillin binds to them, causing them to be recognized as foreign
- Foreign RBCs (hemolytic disease of the newborn)

Examples of Type 2 reactions targeting fixed tissue antigens:

- Goodpasture syndrome (basement membrane of the kidney and lung)
- Bullous pemphigoid, pemphigus vulgaris
- Rheumatic fever
- Graves disease (TSH receptor)
- Myasthenia gravis (acetylcholine receptor on muscle cells)

Do not get Type 2 cytotoxic hypersensitivity mixed up with the **T-cell-mediated** cytotoxic damage seen in Type 4 hypersensitivity reactions.

TYPE 3 — IMMUNE COMPLEX HYPERSENSITIVITY

Anytime you see a **vasculitis**, think of Type 3 hypersensitivity reactions. Type 3 reactions are seen in **autoimmune** diseases and in reactions to **drugs**. Immune complexes (ICs) form when antibodies combine with an antigen (self or foreign). A hypersensitivity reaction occurs when antibody (usually IgG) reacts with a target antigen to form ICs, which, in certain conditions, precipitate and activate complement with subsequent small vessel inflammation and necrosis.

Remember: Just because an antibody reaction occurs and ICs are formed, it does not necessarily mean there is precipitation. Significant precipitation occurs only when there is **slight antigen excess** in relation to the antibody.

Review: When the antibody response initiates, there is a **huge** excess of **antigens** compared to antibodies (Ag:Ab >> 1). The ICs that are formed are small, soluble, and are quickly **cleared**.

Within 1–2 weeks, as exceedingly more antibodies are produced, a point is reached when there is only **slight antigen excess**. This allows the ICs to interlace and become bigger and less soluble. These large ICs **precipitate** in the small vessels and activate complement, which starts a cascade—causing the release of more cytokines and the gathering of more inflammatory cells. This process ultimately results in necrosis of the small vessels in any organ. This small vessel vasculitis is also termed hypersensitivity vasculitis and leukocytoclastic vasculitis.

The pathologic hallmark skin finding in a patient with leukocytoclastic vasculitis is **palpable purpura** (Figure 2-1). See more on leukocytoclastic vasculitis in the **Rheumatology** section.

Figure 2-1: Confluent palpable purpura in severe leukocytoclastic (small vessel) vasculitis
Source: James Heilman, MD

As the antigen is cleared, there comes a point when there is **antibody excess**. The formed ICs are large, and are quickly **cleared** by circulating phagocytes (e.g., monocytes, macrophages).

There are 2 possible clinical consequences:

- 1) **Serum sickness** is a systemic reaction in which a large amount of antigen is injected into a nonimmunized host and **within 1–2 weeks**, you see a necrotic vasculitis similar to the one just discussed. Other symptoms include fever and joint pain.
- 2) **Arthus reaction** is a local reaction that occurs when a patient is first hyperimmunized (so there are many circulating IgGs) and then given a small intradermal injection of the target antigen. Many ICs are made **at the injection site** and they induce the complement cascade and inflammation. **Within 4–12 hours**, a painful, indurated lesion appears and may progress to a sterile abscess.

Serum sickness and Arthus reaction are generally self-limited, and patients usually **fully recover**. Occasionally, glucocorticoids are given.

Type 3 reactions play a role in the following autoimmune diseases and their associated antigen(s):

- SLE—nuclear materials, such as dsDNA and Smith antigen
- Chronic autoimmune thyroiditis (a.k.a. Hashimoto's) and chronic lymphocytic thyroiditis—thyroglobulin
- Pernicious anemia—intrinsic factor
- Rheumatoid arthritis—rheumatoid factor

External antigens:

- Hepatitis antigen-associated serum sickness
- Tetanus and diphtheria immunization
- Local insulin reactions
- Treat external antigen reaction by stopping the exposure to the antigen.

TYPE 4 — DELAYED T-CELL-MEDIATED HYPERSENSITIVITY

Type 4 delayed T-cell-mediated hypersensitivity is a CD4+ helper-cell-driven response and is not mediated by antibodies, unlike the other 3 hypersensitivity reactions. Previously sensitized **CD4+ helper cells** migrate to, and interact with a foreign antigen, and overproduce cytokines (signaling proteins) which initiate an inflammatory reaction with an overabundance of macrophages, eosinophils, cytotoxic T8+ cells, or neutrophils. The reaction peaks in 24–72 hours—hence, the common name of “**delayed-type hypersensitivity**.”

Gell and Coombs classification further divides **delayed cell-mediated hypersensitivity** into 4 subtypes dependent upon the effector cells that cause tissue damage and specific disease:

- **Type 4a: monocytes/macrophages** (seen in contact dermatitis and granulomatous reactions like tuberculin skin test, tuberculosis, and leprosy)
- **Type 4b: eosinophils** (seen in chronic asthma, chronic allergic rhinitis, maculopapular exanthema with eosinophilia, and drug reaction with eosinophilia and systemic symptoms [DRESS])
- **Type 4c: cytotoxic T8+ cells** (seen in contact dermatitis and skin sloughing reactions such as Stevens-Johnson syndrome/toxic epidermal necrolysis)
- **Type 4d: neutrophils** (seen in pustular exanthema reactions like Behçet disease)

Clinically, hypersensitivity reactions can be a combination of types:

- Contact dermatitis often has 4a and 4c features.
- Chronic allergic asthma and chronic allergic rhinitis can have Type 1 (i.e., IgE) and Type 4b mechanisms.
- Allergic bronchopulmonary aspergillosis (ABPA) has components of Type 1, 3, and 4.
- Hypersensitivity pneumonitis (HP) starts out as a Type 3 reaction and then becomes more of a Type 4 reaction.

Do not confuse the **delayed-type** hypersensitivity reaction of Type 4 with the **late-phase** response of Type 1!

URTICARIA

PREVIEW | REVIEW

- What is the difference between acute and chronic urticaria?
- What precipitates cholinergic urticaria?
- What is the difference between acute urticaria and urticarial vasculitis?

Acute urticaria presents as superficial, blanching, transient, pruritic wheal-and-flare reactions (hives) that last < 6 weeks (Figure 2-2). Common causes include allergies to food, insects, latex, and drugs. If the patient has isolated urticaria, treat with antihistamines. Look for other systemic symptoms (i.e., respiratory, cardiovascular, GI) that indicate more severe anaphylaxis. Allergy testing is guided by the clinical history. Refer to [Skin vs. Serum Allergy Testing](#) on page 2-12.

Figure 2-2: Urticaria
Source: john

Chronic urticaria (CU) is hives that last ≥ 6 weeks. Up to 50% of patients with CU are allergic to their own IgE receptors, 10% are allergic to their own IgE, and 10% have antithyroid antibodies. Although there is an association between CU and autoimmune disorders, routine tests to diagnose autoimmune diseases are not recommended in the absence of a clinical history suggestive of autoimmune disease.

No diagnostic testing is required for most patients with CU. However, limited routine laboratory testing can be performed to provide reassurance and to exclude underlying causes. These may include a CBC with differential, erythrocyte sedimentation rate (ESR), and/or C-reactive protein, liver enzyme, and thyroid-stimulating hormone measurement.

Treatment of urticaria involves addressing pruritus and swelling. Use H_1 antihistamines (e.g., hydroxyzine) or newer 2nd generation H_1 antihistamines (e.g., cetirizine), which are less sedating. H_2 antihistamines and glucocorticoids are reserved for refractory urticaria or angioedema.

There are also several **nonallergen-mediated** causes of urticaria:

- **Dermatographism** (a.k.a. dermatographia) simply means “writing on the skin.” Exaggerated wheals and flares arise after the skin is stroked or gentle pressure is applied (Figure 2-3).
- **Acquired cold urticaria** is mediated by either **cryoglobulins** or IgE. Shock can occur if the patient is immersed in cold water! Diagnose with a 5-minute skin ice-cube challenge.
- **Familial cold urticaria** is an **autosomal dominant inflammatory disease** characterized by urticaria, myalgias, fever, and joint pain after cold exposure.
- **Cholinergic urticaria** is precipitated by **heat** (e.g., hot showers, a hot day, exercise). It usually presents as punctate lesions that are very pruritic. The exact etiology is unknown, but mast cell hypersensitization is most likely. Treat symptoms with a 1st generation antihistamine, such as hydroxyzine, or a 2nd generation antihistamine, such as cetirizine.
- **Pressure urticaria** commonly causes swelling and burning of areas exposed to heavy pressure. Diagnose by placing 15 pounds (6.8 kg) of weight suspended over a patient’s shoulder for 15 minutes and monitoring for development of swelling.
- **Urticarial vasculitis (UV)** can clinically resemble acute urticaria. However, patients report hives lasting ≥ 24 hours in a fixed location (in contrast to acute urticaria, which resolves in minutes to hours or migrates to other areas). Patients often complain that the hives are nonpruritic, burn, and are painful. Other red flags include skin **ecchymosis**, **purpura**, **petechiae**, or elevated ESR, which are not seen in acute urticaria. Diagnose UV by skin biopsy. Although the mainstay of UV treatment is glucocorticoids, other agents are options depending on the severity of clinical signs and symptoms:
 - Pruritus— H_1 antihistamines
 - Arthralgia/Arthritis—NSAIDs
 - Mild/Moderate—dapsone, hydroxychloroquine, colchicine
 - Severe—methotrexate, azathioprine, cyclosporine A

Figure 2-3: Dermatographia

ATOPIC DERMATITIS (ECZEMA)

PREVIEW | REVIEW

- What is the 1st line treatment for atopic dermatitis?
- What do you do if you encounter an adult patient with new-onset recalcitrant eczema?

Atopic dermatitis occurs in ~ 1–3% of adults and is due to dysfunctions in the innate and adaptive immune systems and skin barrier abnormalities. It typically presents as a very pruritic, dry, thickened, scaly rash on the flexural skin surfaces (Figure 2-4). When severe, the rash becomes thick scaling plaques. Symptoms are lifelong and there is no known cure.

Figure 2-4: Atopic dermatitis
Source: James Heilman, MD

There is a layered treatment approach:

- **Moisturizers** are the 1st layer of therapy. There should be aggressive application of emollients multiple times a day and every time after the patient gets wet (showers, baths, sweating, and swimming). Moisturizers are less effective if applied to dry skin.
- **Immunomodulatory creams** are the 2nd layer of therapy. Topical corticosteroids or topical calcineurin inhibitors (i.e., pimecrolimus, tacrolimus) should be applied to problem areas of the skin to decrease inflammation. Although topical corticosteroids are the 1st line antiinflammatory agents, they can cause skin atrophy. Use on the face, axilla, and genitalia should be avoided. Topical calcineurin inhibitors do not cause skin atrophy.
- **Antihistamines** are the 3rd layer of therapy. 1st generation antihistamines are more effective than the later generations, but they have some degree of sedation. This can be useful for patients who are unable to sleep because they are constantly scratching their skin at night. It is important to break the scratch-itch-scratch cycle. Avoidance of common irritant triggers, such as harsh soaps, detergents, wool, and chemicals is recommended.

Oral corticosteroids should only be used for temporary control of an acute flare. They should not be used for chronic control because cessation can lead to rebound disease. **Antibiotics** are used if the patient shows signs of infection. Treat these infections with topical or oral antibiotics. Most patients with atopic dermatitis are colonized with *Staphylococcus aureus*, and superinfection is fairly common.

Know! For new-onset adult eczema that is recurrent and refractory to conventional therapy, refer the patient to dermatology to rule out cutaneous T-cell lymphoma (e.g., mycosis fungoides).

For more information on atopic dermatitis, see the [Dermatology](#) section.

CONTACT DERMATITIS

PREVIEW | REVIEW

- What should you do if you have a patient with a linear itchy rash just below the umbilicus where the belt buckle touches the abdomen?

Poison oak and poison ivy cause contact dermatitis in most individuals (Figure 2-5). Other agents, such as nickel (found in some jewelry), rubber components, perfumes, hair products, and makeup can cause contact dermatitis in sensitized individuals.

Remember that contact dermatitis often has features of hypersensitivity Types 4a and 4c.

Figure 2-5: Poison ivy contact dermatitis
Source: Britannic124

Order **patch testing** if the patient has a rash in a pattern that suggests their makeup, hair product, nickel-containing jewelry, or a belt buckle caused the rash. Once the allergen or irritant is identified, recommend avoidance of the offending agent. For additional information, see the [Dermatology](#) section.

RHINITIS

PREVIEW | REVIEW

- What are the 1st line therapies for mild vs. moderate-to-severe allergic rhinitis?
- Which class of medication for the treatment of allergic rhinitis is avoided during the 1st trimester of pregnancy?
- What is rhinitis medicamentosa? How is it treated?
- What is atrophic rhinitis? How is it treated?

There are 2 broad categories of rhinitis: allergic and nonallergic. The most common type of rhinitis is **viral** rhinitis, followed by **allergic** rhinitis.

ALLERGIC RHINITIS

There are 2 main types of **allergic rhinitis**:

- 1) Seasonal—provoked by seasonally present pollens
- 2) Perennial (year-round)—provoked by dust mites, molds, or animal dander

Symptoms of allergic rhinitis include congestion, sneezing, rhinorrhea, and nasal itching. Once initiated, patients have **nonspecific** hypersensitivity to many irritating stimuli. Patients demonstrate sensitization to allergens when tested by skin prick or a serum assay for specific IgE antibodies. See **Skin vs. Serum Allergy Testing** on page 2-12.

Eosinophils appear on nasal smear only when the patient is **symptomatic**. Patients with perennial allergic rhinitis can have a high nasal eosinophil count year-round. In patients with a positive allergen testing, a nasal eosinophil count > 3/HPF is very specific but not very sensitive for allergic rhinitis.

Treatment of allergic sinusitis: Intranasal glucocorticoids are the **1st line** therapy for mild allergic rhinitis. For moderate-to-severe symptoms or symptoms not controlled with intranasal glucocorticoids alone, use an intranasal antihistamine or a combination of intranasal glucocorticoid plus intranasal antihistamine.

Other drugs include the oral form of the 2nd generation less-sedating antihistamines. Of these 2nd generation antihistamines, fexofenadine and bilastine (not available in the U.S.) do not cross the blood-brain barrier and are completely nonsedating. The other 2nd generation antihistamines (e.g., cetirizine, levocetirizine, loratadine, desloratadine) are somewhat sedating because they partially cross the blood-brain barrier.

The 1st generation antihistamines (e.g., diphenhydramine, chlorpheniramine, hydroxyzine) are generally not used and are never given to the elderly. They easily cross the blood-brain barrier and cause sedation, blurry vision, dry mouth, and urinary retention.

Cromolyn sodium is sometimes used for mild symptoms.

Treatment of allergic sinusitis during pregnancy:

- For mild symptoms not controlled by avoidance, cromolyn ophthalmic drops are the treatment of choice.
- For moderate-to-severe symptoms, an intranasal glucocorticoid spray is the treatment of choice; **budesonide** is preferred.
- If intranasal budesonide is not effective enough, chlorpheniramine is commonly added on. It has a long safety record in pregnant women. If sedation is an issue with chlorpheniramine, use 2nd generation antihistamines—especially loratadine or cetirizine.
- Allergy shots are not started during pregnancy, but if a woman has already started allergy shots and becomes pregnant, she can continue without dose escalation.

- **Avoid** oral decongestants in the 1st trimester of pregnancy! They increase the risk of congenital malformations, such as gastroschisis and atresia of the small intestine.

NONALLERGIC RHINITIS

There are many nonallergic categories of rhinitis: infectious, vasomotor [idiopathic], nonallergic with eosinophilia, medicamentosa, and atrophic. Unless there is an overlap, patients with nonallergic rhinitis do **not** demonstrate sensitization to allergen when tested by skin prick or serum assay (i.e., IgE is not involved).

Infectious rhinitis is an acute rhinitis caused by a viral, bacterial, or fungal infection. Viral infections (e.g., common cold, flu) are **by far the most common cause** of any type of rhinitis. Classic symptoms are self-limited with sneezing and a watery nasal drainage.

Vasomotor rhinitis (a.k.a. idiopathic rhinitis) is the usual noninfectious cause of nonallergic rhinitis. It tends to occur in the middle-aged. It is thought to be neurogenic—a reaction to a specific stimulus. Patients have sneezing attacks, followed by nasal congestion and rhinorrhea when exposed to cold, sunlight, certain foods, or various other stimuli. Treatment is with intranasal glucocorticoids; intranasal anticholinergic sprays are effective when rhinorrhea is the predominant symptom. As with all the other causes of nonallergic rhinitis, these patients do **not** demonstrate sensitization to allergen when tested by skin prick or a serum assay.

NARES—nonallergic rhinitis with eosinophilia syndrome—is an inflammatory rhinitis that causes year-round symptoms of rhinorrhea, sneezing, and occasionally, loss of smell. NARES is not a Type 1 hypersensitivity reaction. **Eosinophils** are found in nasal secretions. Negative allergy screening along with a nasal smear showing 5–20 eosinophils/HPF makes NARES likely.

Rhinitis medicamentosa is rebound congestion caused by prolonged use of vasoconstricting nasal drops (i.e., phenylephrine, oxymetazoline). A beefy, red nasal mucosa is the diagnostic finding in the setting of persistent nasal congestion and continued use of an α -adrenergic nasal spray. Treat by stopping use of adrenergic nasal sprays. Use intranasal glucocorticoids prn to help with recovery.

Atrophic rhinitis is characterized by **atrophy** of the nasal mucosa, **crusting**, dryness, **fetor**, and **loss of smell** (anosmia). Patients are typically **younger** and from warmer climates. Some are colonized with *Klebsiella ozaenae*. Secondary causes include excessive nasal/sinus surgeries, granulomatous disease, and exposure to radiation. Treat atrophic rhinitis initially with **nasal saline lavage**.

Note that other causes of chronic nasal congestion rhinitis include deviated septum, foreign body (typically unilateral and with malodorous discharge), tumors, and drug reactions (especially with propranolol and α -methyl dopa). Persistent nasal symptoms may accompany pregnancy, hypothyroidism, or testosterone deficiency (hormonal rhinitis).

RHINOSINUSITIS

PREVIEW | REVIEW

- What are the characteristic symptoms and the duration of acute rhinosinusitis?
- When are antibiotics used to treat acute rhinosinusitis?
- How long must symptoms last before the diagnosis of chronic rhinosinusitis can be made?
- How is chronic rhinosinusitis treated?

Note: The term rhinosinusitis is now used instead of sinusitis because inflammation of the sinuses is almost always accompanied by inflammation of the nasal mucosa. **Acute rhinosinusitis** is defined as rhinorrhea, nasal congestion, facial pain, and sinus tenderness lasting **< 4 weeks**. Diagnosis is made clinically; do not order a sinus CT or other imaging for uncomplicated acute rhinosinusitis. Sinus CT or x-rays cannot distinguish between bacterial and viral infections; the vast majority of cases are caused by viral infections, which do not require antibiotics.

Initially treat acute rhinosinusitis symptomatically with nasal saline washes and intranasal glucocorticoids. Treat pain with acetaminophen or with NSAIDs (only if not sensitive).

So, **when** are antibiotics needed? Give antibiotics only in the following scenarios:

- Severe initial symptoms with high fever ($> 102.0^{\circ}\text{F}$ [38.9°C]), purulent nasal discharge, and facial pain
- Worsening symptoms after initial improvement (a.k.a. "double sickening")
- Persistent symptoms with no improvement after 7–10 days

The 1st line treatment is **amoxicillin + clavulanic acid**. Use doxycycline for PCN allergy.

Recurrent episodes of acute bacterial sinusitis may indicate a B cell defect or selective IgA deficiency.

Chronic rhinosinusitis (CRS) occurs when symptoms last **> 12 weeks**. It can occur with or without nasal polyps and can have eosinophils, neutrophils, or both in the nasal mucosa. Depending on the H&P, workup can include evaluation for allergens, immunodeficiency, cystic fibrosis, sinus CT, and referral to ENT for possible surgery in recalcitrant cases.

CRS diagnosis requires all the following history and findings:

- Duration of disease for > 12 weeks
- Presence of 2 of the following (MOPS):
 - Mucopurulent discharge
 - Obstruction/Congestion
 - Pain over paranasal sinus areas of face
 - Loss of smell (anosmia)

- Evidence of sinusitis on CT scan or evidence of mucopurulent discharge from ostiomeatal complex (visualized by rhinoscope) in posterior area of nasal cavity

Manage CRS by restoring ostiomeatal patency/drainage of sinuses with topical glucocorticoids and nasal saline lavage.

Know! Do not obtain sinus x-rays. They are not helpful in the workup of acute or chronic rhinosinusitis.

ASTHMA

Asthma is an important disease in the Allergy & Immunology subspecialty. However, for the sake of concision, asthma is extensively covered solely in the [Pulmonary Medicine](#) section.

DRUG HYPERSENSITIVITY REACTIONS

PREVIEW | REVIEW

- When is drug desensitization indicated? Give 2 examples of when penicillin desensitization is required.
- What is DRESS syndrome? Name a few drugs that commonly cause this reaction.
- What is the difference between Stevens-Johnson syndrome and toxic epidermal necrolysis?

OVERVIEW

Here we talk about drug hypersensitivity reactions. Remember that these are quite different from drug side effects, listed on the drug information sheet, and from the effects of a drug overdose. The timing and type of reaction provide clues as to which type of drug reaction is occurring. If a drug is given intravenously and an **immediate** reaction with **urticaria** develops within **minutes to an hour**, a Type 1 immediate **IgE-mediated** reaction has most likely occurred.

If a reaction is delayed up to **24–72 hours**, a **Type 4 delayed** hypersensitivity reaction is likely. An **exanthematous** (maculopapular or morbilliform) eruption also suggests a delayed hypersensitivity reaction.

More severe skin manifestations include Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and DRESS syndrome. (See more on these three manifestations under [Stevens-Johnson Syndrome \(SJS\) and Toxic Epidermal Necrolysis \(TEN\)](#) on page 2-10 and under [DRESS Syndrome](#).) These manifestations usually appear **> 72 hours** after exposure to the drug. For more details on SJS and TEN, see the [Dermatology](#) section.

Besides skin manifestations, other problems can occur, including fever, arthritis, and vasculitis, as well as GI,

neurologic, and pulmonary findings. Prior exposure to the drug is necessary for an immunologic reaction to occur.

Laboratory testing is generally **not** helpful. Peripheral blood eosinophilia is suggestive but **not** conclusive of a drug allergy. PCN skin testing is helpful if you suspect an IgE-mediated mechanism (i.e., Type 1 hypersensitivity reaction).

Also see [Immunologic Hypersensitivity Reactions on page 2-1](#).

β-LACTAM ANTIBIOTICS

β-lactam antibiotics are the **most common** cause of drug allergy, and PCN is by far the most common of these. Despite this, PCN allergy is exceedingly overdiagnosed. About 5–10% of patients report a history of PCN allergy. However, 80–95% of patients with a reported PCN allergy are found **not** to be allergic, leaving us with an actual prevalence between 0.25% and 2%.

Confirm PCN allergy with skin testing; a negative skin test has a negative predictive value of > 95% and thus makes a future anaphylactic reaction to PCN very unlikely. For those who are confirmed PCN allergic by skin testing and require treatment with PCN, desensitization is available. (See [Drug Desensitization](#).)

PCN itself does not cause an allergic reaction. It is the degradation products when linked to self-proteins (i.e., when tissue-bound) that are allergenic. The **major** determinant used in skin testing reagents is **penicilloyl-polylysine** (PPL). 75% of those with a PCN allergy react to this reagent.

Other skin testing reagents, to which fewer people react, are called **minor** determinants. These are:

- Benzylpenicillin (penicillin G)
- Penicilloate
- Penilloate

One study suggests that those who react to minor determinants are more likely to have more severe reactions. It is ideal to include both the major and minor determinants when testing for PCN allergy. Unfortunately, in the U.S., only penicillin G is available.

A negative allergy test does **not** rule out an allergic reaction to PCN because it is only about 75% sensitive. Remember: All allergy skin testing (PCN testing included) checks only for IgE-mediated reactions (i.e., Type 1 only; not Types 2, 3, and 4).

Like PCN allergy, PCN cross-reactivity also appears to be overdiagnosed. In the past, PCN was thought to cross-react with cephalosporins at a rate of as much as 20%, but data shows that cross-reactivity between PCN and 3rd generation cephalosporins is extremely low (< 2%). Cross-reactivity between PCN and 1st and 2nd generation cephalosporins may be higher as cross-reactivity involves similarities of side chains. Cross-reactivity between β-lactams and carbapenems

is very low. Aztreonam does not cross-react with other β-lactams except for ceftazidime. (They both share a common R-group side chain.)

To treat any drug allergy, **stop** the drug. For anaphylaxis, give epinephrine without delay and ensure that the patient is in a recumbent position until recovered and asymptomatic. See [Type 1 – Treatment on page 2-2](#).

DRUG DESENSITIZATION

Following a drug desensitization protocol in the appropriate situation allows for a **temporary** state of tolerance to the drug, as long as the person continues to take the specific drug.

Desensitization can be done for any patient with a Type 1 **IgE**-mediated hypersensitivity reaction to a medication. It is effective in this group for those with immediate or late-phase reactions. Common antibiotics that can cause this reaction are the β-lactams, quinolones, and clindamycin.

Know! Desensitization is necessary if the drug is the only known clinically effective therapy or all other effective treatments are unavailable.

Desensitization is **contraindicated** for serious **non-IgE**-mediated reactions, such as SJS, TEN, or DRESS syndrome.

A typical desensitization procedure (e.g., for PCN allergy) starts with very tiny oral or IV doses of approximately 1/10,000 of the full therapeutic dose—with increased dosage every 15 minutes. After 4–8 hours, a full dose is reached, and a temporary tolerance to the drug is achieved. The patient can then be given the full course of the antibiotic. This tolerance is rapidly lost once the drug is stopped, so the procedure must be repeated if the drug is ever given again.

Note: Generally, oral doses are the preferred method—but even with oral doses, the patient must be in a monitored setting where treatment for anaphylaxis (injectable epinephrine and other drugs) is available at the bedside.

Scenarios where drug desensitization is required:

- A **pregnant woman** with syphilis who has a PCN allergy
- A patient with **neurosyphilis** who has a PCN allergy

Both cases require desensitization because PCN is the only known effective therapy. After desensitization, give PCN for the duration of therapy. Again, if PCN is required in the future, desensitization therapy must be repeated.

DRESS SYNDROME

DRESS stands for drug rash with eosinophilia and systemic symptoms. DRESS syndrome is a Type 4b (i.e., with eosinophils) hypersensitivity reaction. Patients typically develop a polymorphic drug rash, peripheral eosinophilia, and systemic symptoms—which include

fever, lymphadenopathy, and multiorgan involvement (e.g., liver, kidney, heart). It commonly occurs 2–8 weeks after exposure to the offending drug, usually aromatic antiseizure medications, minocycline, and allopurinol. Reactivation of human herpesvirus 6 and other viruses has been implicated.

Treat DRESS by **stopping** the offending drug. (Symptoms may initially worsen or persist.) Treatment is with glucocorticoids and IVIG. The disease may be progressive even after discontinuation of the offending agent. When there is organ involvement, such as cardiac myopathy, corticosteroids must be weaned with extreme caution. These patients are at risk for cardiac failure and should be managed by clinicians experienced with DRESS syndrome.

STEVENS-JOHNSON SYNDROME (SJS) AND TOXIC EPIDERMAL NECROLYSIS (TEN)

SJS and TEN are part of a single disease spectrum. It is a Type 4c (i.e., with cytotoxic CD8+ T cells) hypersensitivity reaction. There is **severe sloughing** of the skin, equivalent to a 3rd degree burn! **Mucosal** involvement of the eyes, mouth, and lips almost always occurs (Figure 2-6).

Figure 2-6: Stevens-Johnson syndrome
Source: Thomas Habif, MD

Nikolsky sign is positive and refers to the removal of the epidermis with slight tangential pressure.

Diagnosis depends on the extent of epidermal detachment according to body surface area (BSA):

- SJS (< 10% BSA)
- Overlap syndrome (10–30% BSA)
- TEN (> 30% BSA)

Treat SJS and TEN with supportive care in a burn unit. Of course, stop the offending drug. **IVIG** may be beneficial. **Glucocorticoids** are **contraindicated in TEN**; use of glucocorticoids in SJS is controversial. Mortality is high.

For more information on SJS and TEN, see the **Dermatology** section.

RADIOCONTRAST MEDIA (RCM) REACTIONS

RCM reactions are almost always **nonimmunologic** reactions to parenteral iodine or gadolinium contrast media. These reactions are caused by the **direct** interaction of contrast with mast cells; i.e., they are not immunoglobulin-mediated or cell-mediated. Incidence of this reaction has decreased recently with the use of nonionic and hypoosmolar contrast media. Symptoms are usually mild (but can be severe) and range from flushing, hives, and laryngeal edema to angioedema and outright anaphylaxis. Onset of symptoms can occur quickly (within 1 hour) or be delayed for days.

Immediate, severe symptoms are indistinguishable from those of an IgE-mediated anaphylactic reaction and are termed **nonimmunologic anaphylaxis** (for more on this recent change in terminology, see [Type 1 – Anaphylaxis on page 2-1](#)). Rather than an IgE mediation of effects, this nonimmunologic anaphylactic reaction is caused by the media **directly activating** mast cells, basophils, or both. The resulting release of mediators such as histamine and tryptase cause the severe clinical reaction. Rarely, RCM causes an IgE-mediated immediate allergic response.

Know that RCM reactions are **not** associated with seafood or iodine allergies. Risk factors for RCM reactions include female gender, asthma, and prior reaction to RCM. Use of β -blockers or underlying cardiovascular disease increases the risk for more serious RCM reactions.

Decrease the likelihood of RCM reactions by giving **nonionic** or **hypoosmolar** radiocontrast and pretreat with the following regimen:

- Prednisone (50 mg): 13, 7, and 1 hour prior to procedure
- Diphenhydramine (50 mg): 1 hour prior to procedure

The nonimmunologic anaphylaxis category includes all those previously termed “anaphylactoid” in which the medication or substance itself directly triggers the release of histamine and tryptase from mast cells.

Other causes of nonimmunologic anaphylaxis are **vancomycin** (red man syndrome) and **opioids** (especially codeine and meperidine). For a dermatologic discussion of radiocontrast media cutaneous drug reaction, see the [Dermatology](#) section.

VANCOMYCIN HYPERSENSITIVITY

Vancomycin hypersensitivity (a.k.a. **red man syndrome**) is a common adverse drug reaction due to **nonimmunologic, direct mast cell degranulation**. Treat by decreasing the infusion rate, not by decreasing the dose.

Although vancomycin can also cause an IgE-mediated immediate hypersensitivity reaction, this is rare.

STINGING-INSECT ALLERGY

Insect stings from the order Hymenoptera (e.g., bees, wasps, yellow jackets, hornets, fire ants) are the most common cause of insect allergy. These allergic reactions are a Type 1 IgE-mediated immediate hypersensitivity reaction.

A large local reaction to a sting or bite is not an allergic reaction and needs no workup. Even generalized hives do **not** increase the risk of anaphylaxis and need no workup. Of course, anaphylaxis itself does require workup with allergy skin tests and serum allergy tests. Identifying the correct stinging insect by history is notoriously unreliable.

Give venom immunotherapy (venom allergy shots) to **patients with anaphylaxis** with confirmed positive insect allergy tests. This treatment has a success rate of 98%! Prescribe an epinephrine autoinjector and recommend insect avoidance.

FOOD ALLERGY

The prevalence of food allergies is about 4% in the adult population. The most common food allergens are peanuts, tree nuts, fish, shellfish, and soy. Food allergies are a Type 1 IgE-mediated immediate hypersensitivity reaction.

Patients need to learn how to avoid the food(s) they are allergic to. Teach patients how to ask the right questions in restaurants and how to read food labels to avoid exposure. Patients with severe food allergies should receive an epinephrine autoinjector and receive training on its proper administration.

LATEX ALLERGY

Latex is natural rubber tapped from the sap-like fluid of rubber trees. Latex allergy is due to sensitization to highly allergenic proteins—primarily **hevein**—on the surface of the latex products. This is a true allergic reaction, like those to stinging insects and food, and is a Type 1 IgE-mediated immediate hypersensitivity reaction.

Before latex alternatives were available, latex allergy was a frequent cause of **anaphylaxis** in patients in hospitals and among health care workers. Now, development of latex allergy is uncommon unless patients have a condition that gives them an increased exposure to latex-containing products (e.g., spina bifida, urologic problems).

The main risk factors for development of latex allergy in patients with spina bifida are the number of surgeries, total serum IgE, presence of a ventriculoperitoneal shunt, and a personal history of atopy. The greatest risk factor for patients (not just those with spina bifida) is multiple surgeries at an early age.

Interestingly, several fruits and vegetables have proteins that are **cross-reactive** with latex allergens. While these patients can show a high IgE level to multiple fruits, vegetables, and nuts, the main ones that show clinical relevance are **PKB PACT** (peekaboo PACT):

- Papaya, kiwi, banana (fruits)
- Potato, avocado, chestnut, tomato (vegetables, fruits, and nuts)

Patients with spina bifida have more cross-reactivity to potatoes, and health care workers have more cross-reactivity to kiwis, bananas, and avocados.

Evaluate for latex allergy by inquiring about a history of prior reactions and getting a latex-specific IgE antibody immunoassay. A negative immunoassay essentially rules out latex allergy.

Skin test reagents (for skin prick tests) are not commercially available in the U.S. They are used successfully in many places outside the U.S.

Treat by providing a latex-free environment, which many hospitals and clinics have adopted.

HYPERSENSITIVITY LUNG DISEASE

Both allergic bronchopulmonary aspergillosis (ABPA) and hypersensitivity pneumonitis (HP) are discussed in more detail in the [Pulmonary Medicine](#) section.

HYPERSENSITIVITY PNEUMONITIS (HP)

HP (a.k.a. extrinsic allergic alveolitis) is a very complex disease with variable presentation that can be caused by many organic agents—as suggested by its many common names, including ventilation pneumonitis, farmer's lung, bird fancier's lung, maltworker's lung, and mushroomworker's lung. **Thermophilic actinomyces** species are thought to be the culprit in many instances, especially farmer's lung. HP is initiated by a **Type 3 immune complex-mediated** hypersensitivity reaction, with an IgG precipitin developing against a specific allergen, and eventually develops a **Type 4 cell-mediated** hypersensitivity reaction (again, HP = Types 3 and 4).

Presentation of HP is acute, subacute, or chronic:

- Acute: Symptoms start within hours of exposure and include chest tightness, dyspnea without wheezing, fever, and chills.
- Subacute: gradual onset of cough and dyspnea with fatigue and weight loss
- Chronic: insidious onset of cough and dyspnea with fatigue and weight loss

Diagnosis of HP is usually made with a suggestive history, an HRCT of the lung that reflects the presentation, and results of antigen avoidance. Occasionally bronchoalveolar lavage (BAL) or lung biopsy is done. Note that skin tests are **not** a helpful diagnostic test (this is not an IgE-mediated reaction!). HRCT findings:

- Acute: infiltrates with a ground glass pattern of attenuation (may be fleeting)
- Subacute: ground glass infiltrates, centrilobar nodules, darker lobar areas due to decreased attenuation and vascularity
- Chronic: spotty ground glass infiltrates, centrilobular nodules, larger upper lobe decreased attenuation (darker areas) mainly due to air trapping. Eventually HRCT looks more like idiopathic pulmonary fibrosis.

Treatment of HP is mainly allergen avoidance. Consider a trial of glucocorticoids in chronic disease with an inflammatory component (ground glass infiltrates or BAL with > 20% lymphocytosis).

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS (ABPA)

ABPA is almost exclusively limited to patients with **asthma** (prevalence 1–2%) or **cystic fibrosis** (CF; prevalence 2–9%). There are 3 hypersensitivity reactions involved in the reaction of atopic individuals to aspergillus: Type 1 IgE-mediated, a **Type 3 immune complex-mediated (with IgG)**, and **Type 4 cell-mediated** (again, ABPA = Types 1, 3 and 4).

ABPA manifests as asthma symptoms with recurrent, sometimes severe exacerbations. Early symptoms are mild fever, wheezing, dyspnea, and coughing up sputum with brownish flecks. With severe exacerbations, the patient can have fever, bronchial plugging, dyspnea, hemoptysis, and coughing with expectoration of the brownish bronchial plugs.

Treatment for severe exacerbations includes glucocorticoids and antifungal therapy with itraconazole or voriconazole. A typical dosing regimen with prednisone is 0.5 mg/kg/day for 2 weeks followed by gradual tapering over 4–6 weeks.

Immunotherapy treatments (allergy injections) do not work with ABPA; they actually worsen it. APBA involves multiple types of hyperreactivity to multiple proteins of *Aspergillus fumigatus*, and can also involve IgE to other related allergens—so specific immunotherapy can’t hit all the targets.

SKIN vs. SERUM ALLERGY TESTING

PREVIEW | REVIEW

- What are the benefits of skin testing?
- When is serum antigen-specific IgE testing indicated?

Skin testing is quicker and has a slightly better negative predictive value (NPV) than serum-specific IgE testing. When testing for **food allergens**, both serum and skin tests have only 50–60% positive predictive value (PPV). A positive test only demonstrates sensitization to a particular allergen and does not guarantee clinical reactivity. Therefore, only order food allergy testing when there is a compatible history of food allergy.

For the serum specific IgE test, scoring is done with either a radioallergosorbent assay (RAST) or the newer fluorescent enzyme immunoassay (FEIA), which uses the College of American Pathologists scoring scheme. There are cut-off levels that have a high PPV for a limited number of foods (Table 2-2).

Table 2-2: Serum-Specific IgE Cut-Off Levels

Food	IgE Concentration (kU/L)	PPV
Egg	7	95%
Milk	15	95%
Peanut	14	100%
Codfish	20	100%
Soy	30	73%
Wheat	26	74%

Regarding inhalant allergens, skin testing has high PPV and NPV, especially when combined with positive history of reactions to inhalants. There is less data on accuracy of using antigen-specific serum IgE tests for inhalant allergies; they have good PPV, but their NPV is not as good as skin testing.

Serum testing is often done in lieu of skin testing for both food and inhalant allergens when there is:

- Extensive skin disease
- Dermatographism
- Anaphylactic sensitivity to the allergen
- Ongoing antihistamine use that cannot be withheld for 1–2 weeks (Antihistamines depress the skin test response.)

Remember: Positive results on both allergy skin testing and a serum allergy testing only **suggest** sensitivity to a potential allergen, but a **negative test** is strong evidence **against** allergy to that substance.

VACCINES

PREVIEW | REVIEW

- What should be done if your patient needs the influenza vaccine but gets hives with egg ingestion?
- Which vaccines are contraindicated in pregnancy? Which should be given?
- How long should you wait to give the measles, mumps, and rubella vaccine after your patient has received a transfusion of packed red blood cells?

INFLUENZA VACCINE AND EGG ALLERGY

Large trials have proven that even confirmed egg-allergic patients can safely receive the injectable inactivated influenza vaccine (IIV) as a single dose. The recommendation is the same for those with an egg allergy and for everybody else. The previously recommended staggered dosing of 10% then 90% is no longer done; nor is vaccine skin testing; nor is the 30-minute postvaccination observation period.

IMMUNODEFICIENCY AND LIVE VACCINES

Live viral vaccines include the following:

- Rotavirus
- Measles, mumps, rubella (MMR)
- Live attenuated influenza vaccine (LAIV)
- Varicella
- Zoster
- Yellow fever (YF)
- Smallpox
- Oral polio vaccine (OPV)
- Live oral typhoid vaccine (LOTV)
- Bacille Calmette-Guérin (BCG)

Live vaccines are **contraindicated** in the following conditions:

- HIV: CD4 < 200 cells/ μ L (0.20×10^9 /L)—all live vaccines
- B-cell deficiency: all live vaccines
- T-cell deficiency: all live vaccines
- Complement deficiency: no vaccine contraindications
- Phagocyte dysfunction: LOTV and BCG (the live bacterial vaccines), LAIV, OPV, YF, MMR
- Chemotherapy or high doses of immunosuppressive therapy: all live vaccines
- Chronic glucocorticoid use (i.e., prednisone > 20 mg/day)

PREGNANCY AND VACCINES

Vaccines should be given before conception when possible. When administered during pregnancy, vaccine

benefit to the mother and fetus should outweigh any risk. Most toxoid, inactivated vaccines are safe, while live virus vaccines may be harmful and are contraindicated.

Know:

- Vaccines recommended in pregnancy: **Tdap** (tetanus, diphtheria, and acellular pertussis); **inactivated influenza** vaccine—give with each pregnancy
- Vaccines contraindicated in pregnancy: All live attenuated vaccines including **varicella**, **MMR**, **zoster** live virus vaccine, intranasal live influenza vaccine, rotavirus, and yellow fever. Note that Shingrix (an inactivated vaccine) has replaced zoster live vaccine, but because sufficient testing has not been done, the CDC recommends that pregnant patients who have had shingles wait until after pregnancy and breastfeeding to take the vaccine.

IMMUNOGLOBULIN THERAPY AND LIVE VACCINES

Only 2 vaccines have been shown to have a significant interaction with immunoglobulin products:

- 1) Measles-containing vaccines (MMR and MMRV)
- 2) Varicella-containing vaccines (varicella and MMRV)

The following are the recommended intervals between administering measles or varicella vaccine and immunoglobulin-containing products:

- IVIG: 8–11 months, depending on dose
- Whole blood: 7 months
- Plasma, platelets, packed red blood cells (PRBCs): 6 months
- Measles immunoglobulin: 6 months
- Varicella immunoglobulin: 5 months
- Rabies immunoglobulin: 4 months
- Tetanus, hepatitis A, and hepatitis B immunoglobulins: 3 months

MASTOCYTOSIS

PREVIEW | REVIEW

- Which physical finding is pathognomonic for urticaria pigmentosa?

Mastocytosis is a rare disorder characterized by abnormal mast cell proliferation and accumulation in various organs. The degree of involvement determines the extent of the disease.

There are 3 types of mastocytosis:

- 1) **Cutaneous mastocytosis** results from increased mast cells only in the **dermis**. There are characteristic brownish macules called **urticaria pigmentosa**. Formation of a wheal upon gentle stroking of the macule (**Darier sign**) is pathognomonic.

- 2) **Systemic mastocytosis** is caused by increased mast cells in tissues, organs, and skin. These patients have generalized symptoms dependent upon the degree of involvement.
- 3) **Malignant mastocytosis** causes severe systemic symptoms but often **no** skin changes. Physical exam may reveal hepatosplenomegaly and lymphadenopathy.

Screen with **elevated tryptase ≥ 20 ng/mL**. Remember that mast cells secrete tryptase. Therefore, if you have a lot of mast cells, the tryptase levels are high. Diagnosis of systemic mastocytosis is based on the presence of the major criterion plus 1 minor criterion, or the presence of 3 out of the 4 minor criteria (Table 2-3).

Table 2-3: Diagnosis of Systemic Mastocytosis

Major Criterion (plus 1 minor)	Minor Criteria (3 out of 4 required)
Mast cell aggregates in bone marrow and/or extracutaneous organs	1) Atypical/Spindle-shaped cells in bone marrow or other extracutaneous tissue 2) Tryptase level > 20 ng/mL 3) Presence of <i>c-kit</i> gene point mutation 4) Expression of surface markers CD2, CD25, or both

Patients who have typical episodic clinical symptoms accompanied by transient elevations in serum tryptase but do not meet the diagnostic criteria for mastocytosis have mast cell activation syndrome.

Advise patients to stay away from cold, heat, alcohol, ASA, and opiates. Oral cromolyn may help GI symptoms. Various chemotherapy regimens have been used in the treatment of systemic and malignant mastocytosis. Unfortunately, chemotherapy has not been particularly successful.

EOSINOPHILIC ESOPHAGITIS (EoE)

EoE is characterized by persistent eosinophil infiltration of the esophagus. **Solid food dysphagia** and **food impaction** are the most common presenting symptoms. Other symptoms include chest pain, heartburn, and upper abdominal pain. Patients often have other allergic conditions, including asthma, allergic rhinitis, and atopic dermatitis.

Diagnose by endoscopy and biopsy of the esophagus looking for > 15 eosinophils/HPF.

Treatment is individualized and involves ≥ 1 of the following:

- Proton pump inhibitors
- Swallowed inhaled glucocorticoids
- 6-food elimination diet: milk, eggs, soy, wheat, fish/shellfish, and peanuts/tree nuts

For additional information on EoE, see the [Gastroenterology](#) section.

HUMAN LEUKOCYTE ANTIGEN (HLA) DISEASES

PREVIEW | REVIEW

- Which rheumatologic disorders have a positive human leukocyte antigen B27?

There are many diseases associated with certain HLAs; this makes sense, as the HLA complex is the **backbone** of immune surveillance. Autoimmune disease arises when there is immune dysfunction. Many **rheumatic** disorders are accompanied by HLA-B27; they include ankylosing spondylitis, acute anterior uveitis, reactive arthritis, **psoriatic spondyloarthropathy**, and **juvenile idiopathic arthritis** (but **not** adult rheumatoid arthritis [RA]).

RA is associated with the HLA-DR4 antigens. See the [Rheumatology](#) section.

IMMUNODEFICIENCIES

PREVIEW | REVIEW

- Which immune deficiency has no mature B cells? What are its symptoms?
- What is the most common Ig deficiency? How frequently does it occur?
- With what disorders do symptomatic IgA deficient patients present?
- What is Wiskott-Aldrich syndrome?
- Know the infections associated with solid organ transplants and when each is likely to occur.
- Name some factors that affect whether a patient with neutropenia develops an infection.

NOTE

The most important thing when thinking of immunodeficiency is to remember that HIV is not the only cause. If you see a patient with severe, recurrent, or atypical infections who does not have HIV, you are not done with your workup. Consider other diagnoses, such as common variable immune deficiency (CVID), uncontrolled diabetes, cystic fibrosis, and 22q11.2 deletion (DiGeorge) syndrome.

Also see [Complement Deficiencies](#) on page 2-24.

IMMUNOGLOBULIN DEFICIENCIES

Immunoglobulin (Ig) deficiencies can be inherited (e.g., agammaglobulinemia, CVID, IgA deficiency) or acquired (e.g., multiple myeloma, acute lymphocytic leukemia [ALL], chronic lymphocytic leukemia, HIV/AIDS, asplenia).

Inherited Immunoglobulin Deficiencies

Congenital agammaglobulinemia (a.k.a. Bruton's or X-linked agammaglobulinemia [XLA]) patients have **increased susceptibility** to pyogenic and encapsulated organisms (e.g., *Staphylococcus*, *Streptococcus*, meningococcus, *Haemophilus*); hence, they have recurrent **sinopulmonary** and ear infections. Some may also develop bacteremia with *Ureaplasma*, *Mycoplasma*, *Helicobacter*, *Campylobacter jejuni*, and *Pseudomonas* species. Enteroviral infections with echovirus is suggestive of agammaglobulinemia.

Diagnosis: Ig assay shows very low or no Igs. There are also no B cells (i.e., no SmIg+ cells, CD19+ cells).

Prognosis is good if the condition is caught early. Test all the patient's brothers and male cousins on the mother's side.

Treatment: exogenous IVIG or SQIG. Prophylactic antibiotics are required for some patients.

Common variable immunodeficiency (CVID) is the most clinically significant immunodeficiency in adults after HIV, yet it is highly underdiagnosed! CVID is a deficiency of IgG accompanied by deficiencies of IgA and/or IgM. Like XLA, patients have increased susceptibility to **encapsulated** organisms (e.g., *S. pneumoniae*, *H. influenzae*). Patients have recurrent **sinopulmonary infections** and **bronchiectasis**; they also tend to get **giardiasis** and **enterovirus infections**. Multiple pulmonary symptoms are common and are the leading cause of death in patients with CVID. Diarrhea is the most common presenting symptom for related GI disease. Giardiasis and enteritis with *Campylobacter jejuni* and salmonellosis are common enteric infections.

There is an **increased** incidence of autoimmune disease and malignancy, especially lymphoma.

Diagnosis: Ig assay shows low IgG with low IgA and/or low IgM. Unlike XLA, CVID patients have mature **B cells present** (CD19+).

Treatment: exogenous IVIG or SQIG. Some patients may require prophylactic antibiotics. Monitor for signs of disease-associated autoimmune complications and malignancy.

Selective IgA deficiency is the **most common Ig deficiency**, with an incidence as high as 1/300! Fortunately, ~ 2/3 of patients are asymptomatic. The ~ 1/3 with symptoms present with 1 or more of:

- Autoimmune disorders (e.g., rheumatoid arthritis, lupus, celiac disease, chronic autoimmune thyroiditis)
- Allergies
- Recurrent sinopulmonary infections (e.g., rhinosinusitis, pneumonia; often caused by encapsulated organisms [e.g., *S. pneumoniae*, *H. influenzae*])
- GI infections (especially giardiasis)
- Celiac disease

Know these 4 important facts about selective IgA deficiency:

- 1) Women can have false-positive serum pregnancy tests. (Urine pregnancy test is normal.)
- 2) In patients with celiac disease, IgA deficiency can cause false negative results in the 2 standard serologic tests for celiac disease—tissue transglutaminase (TTG) IgA antibody and antiendomysial IgA antibody. Thus, it is essential to also order a total serum IgA level at the same time either of these markers is checked. If the patient is IgA deficient, check for IgG TTG antibody.
- 3) Blood transfusion is associated with a higher-than-normal risk of **anaphylaxis** and should be avoided if possible. These patients have anti-IgA antibodies, and transfused blood contains small amounts of IgA. For more on anaphylactic reactions to transfused blood, see the **Hematology** section.
- 4) IVIG and plasma infusions are contraindicated for the same reason as blood transfusion.

Treat patients who have recurrent infections with prophylactic antibiotics.

Wiskott-Aldrich syndrome (WAS) presents with low IgM and IgG, elevated IgA, and elevated IgE. The triad of findings is eczema, immunodeficiency, and thrombocytopenia. Remembering that it is **X-linked** makes for a nice mnemonic: "Wisk" through the **EXIT**. Leukemia and B-cell lymphoma (associated with Epstein-Barr virus) are malignancies found in young males with WAS. Infection with bacteria having polysaccharide capsules (e.g., *Streptococcus pneumoniae*) is dangerous in patients with WAS. Bone marrow transplantation may be a successful cure.

Acquired Immunoglobulin Deficiencies

Acquired Ig deficiencies secondary to **malignancy**, **collagen vascular disease**, and **chemotherapy** (such as rituximab) are common clinical scenarios for the general internist. Infections arise because either effective antibodies are not produced, or B and T lymphocytes are not communicating effectively with one another. Most of these diseases are associated with **hypogammaglobulinemia** (reduction in levels of specific IgA, M, and G) but with a relative polyclonal increase in the gammaglobulin fraction. That is, patients produce an excess of fairly useless antibodies that are **not** specific for an antigen, are usually ineffective, and may cross-react with normal body components, such as RBCs and platelet surface receptors.

Patients with acquired **humoral** deficiencies are predisposed to infections with **encapsulated** organisms and **giardiasis**. See **The Adaptive Immune System** on page 2-18 for more information.

The spleen clears out bacteria and is the site for **formation of opsonizing antibodies**. Opsonizing antibodies are important in defending the host from infection with **encapsulated** organisms, especially **pneumococcus**.

Splenectomy and functional asplenia increase the risk of overwhelming **pneumococcal**, **malarial**, and **babesial** infections. The latter 2 are intra-RBC protozoan parasites.

IgA blocks viral attachment to mucosal surfaces, and IgG blocks viral attachment to host cells.

Other secondary immunodeficiency states to consider include diabetes mellitus, liver failure, renal failure, chronic glucocorticoid use, and malnutrition.

T-CELL DEFICIENCIES

Etiology

T-cell-deficient patients have decreased cellular immunity. These patients present with **opportunistic infections** (OIs; infections that do not usually present in immunocompetent patients), such as *Pneumocystis jirovecii* pneumonia, CMV colitis, and cryptococcal meningitis. Patients are found to have either low T-cell levels or poor T-cell function.

T-cell defects occur in the following:

- HIV/AIDS
- 22q11.2 deletion (DiGeorge) syndrome
- Hodgkin lymphoma (if T-cell derived)
- T-cell variant of ALL
- Prolonged glucocorticoid use
- Solid organ transplantation (because of immunosuppressant medications)

Associated Infections

Patients with T-cell defects are more susceptible to routine **community-acquired** bacteria and viruses (e.g., pneumococcus, *Mycoplasma*, *Legionella*, *Listeria*, *Salmonella*, influenza, respiratory syncytial virus [RSV]), as well as **OIs** with the following pathogens:

- Bacteria (e.g., *Nocardia*, *Rhodococcus equi*, mycobacteria)
- Viruses (especially new infections with cytomegalovirus [CMV], herpes simplex virus [HSV], or varicella-zoster virus)
- Fungi (e.g., *Pneumocystis*, *Cryptococcus*, *Aspergillus*, endemic fungi)
- Parasites (e.g., *Strongyloides*)

Patients also frequently reactivate protozoal and viral diseases that they have previously held in check (for example, *Toxoplasma gondii* and HSV, respectively).

HIV/AIDS is an acquired T-cell deficiency, discussed in the **Infectious Disease** section.

22q11.2 deletion syndrome (a.k.a. DiGeorge syndrome, congenital **thymic hypoplasia**) is a T-cell deficiency due to an early intrauterine malformation of the embryo that can affect several tissues and organs, including the thymus, parathyroids, heart and great cardiac vessels, and face.

A mnemonic for these findings is “**CATCH-22**” (cardiac, abnormal facies, thymic hypoplasia, cleft lip, hypocalcemia, chromosome 22).

There is a wide range of symptoms and variable decrease in T-cell function related to the variable decrease in thymic tissue. In many patients, a microdeletion in chromosome 22q11.2 is demonstrated. In rare circumstances, severely affected infants (complete DiGeorge syndrome = no thymus and no T cells) receive thymic transplantation. Note that some patients reach adulthood, although most adults with DiGeorge have fewer cardiac anomalies but more craniofacial defects and psychiatric illnesses.

Solid Organ Transplantation

Patients who have received a solid organ transplant are at risk for infections carried by the donor organ, as well as nosocomial infections. Additionally, they can reactivate infections that had been previously controlled by their immune system. Some of these infections are mentioned in **Associated Infections** but also include endemic fungi and mycobacteria.

Infections caused by immunosuppressive drugs tend to arise predictably, based on the length of treatment.

Know the following **classic 3** posttransplantation time periods and their associated infection risks:

- **Month 1:** infections from the donor; nosocomial infection (i.e., specific to the type of surgery performed)
- **Months 2–6:** Immunosuppressant medication is starting to take effect, and patients are at risk for the OIs described in **Associated Infections** (e.g., CMV from donor+ and recipient– solid organ transplant recipients).
- **> 6 months:** community-acquired infections

However, the use of routine prophylaxis with trimethoprim/sulfamethoxazole (TMP/SMX) and valganciclovir has shifted the time of onset for some OIs. For instance, CMV may not occur until after valganciclovir is stopped in these patients.

COMBINED T- AND B-CELL DEFICIENCIES

Combined T- and B-cell deficiencies present with infections—usually opportunistic infections. It is difficult to separate this group from the **T-Cell Deficiencies** because you cannot have normally functioning B cells without normally functioning T cells. These patients are found to have both low Ig and low T-cell numbers (or low T-cell function). These defects usually present in infancy and are universally fatal without stem cell transplantation.

Severe combined immunodeficiency (SCID) is a deficiency in both T- and B-cell numbers or function. SCID is either autosomal recessive or X-linked. It is always fatal in infancy unless treated with stem cell transplantation.

Ataxia-telangiectasia is an **autosomal recessive** disorder that causes both **cellular** and **Ig deficiency**. This results in recurrent sinopulmonary infections, bronchiectasis, and progressive telangiectasias. Patients also have a progressive **neurologic** deterioration of uncertain etiology, characterized by cerebellar ataxia and progressive mental deterioration. Survival into adulthood is not common.

NEUTROPENIA

In neutropenia, the absolute neutrophil count (ANC) is $< 1,500$ cells/ μ L (1.5×10^9 /L). Neutropenia occurs in the following scenarios:

- Normal low-variant populations who are asymptomatic (Only 4% of African Americans have ANC $> 1,500$.)
- Decreased bone marrow production due to medications, nutritional deficits, collagen vascular disease, or malignancy
- Congenital neutropenias, such as neutrophil elastase and HAX1 deficiency, usually present in childhood but may be seen in adults during initial presentation (in rare cases).
- A shift from general circulation to other organs like the spleen (e.g., hypersplenic conditions)
- Immune destruction of neutrophils (e.g., in autoimmune disease)

Neutrophils help to fight disease by disrupting or consuming disease-producing cells and microorganisms. Neutropenia can hinder the body's ability to fight disease, resulting in infection. Most often, sepsis is caused by flora that colonize the patient and enter the bloodstream across disrupted gut mucosa (via an IV catheter) or through the oropharynx into the lungs and/or sinuses. Neutropenic infections can be caused by both gram-negative and gram-positive bacteria.

The most common gram-positive organisms causing neutropenic infections are *S. aureus*, *S. epidermidis*, and streptococcal species. More and more infections are caused by the less common gram-positive organisms, such as *Corynebacterium* species, *Cutibacterium acnes* (previously known as *Propionibacterium acnes*), *Bacillus* species, and *Leuconostoc*. These are important to remember because some are **not** effectively treated with **vancomycin**.

Common gram-negative infections include *Pseudomonas* species and Enterobacteriaceae (e.g., *E. coli*, *Klebsiella* species, *Enterobacter*).

Fungi, including yeasts such as *Candida* and molds such as *Aspergillus* species, are important pathogens in patients with prolonged neutropenia. Infections with *Fusarium* species and agents of mucormycosis are especially **deadly** and are being seen more frequently. Not all fungi are equally susceptible to all antifungal drugs. When a patient with neutropenia develops fever and/or an infection while receiving an empiric antifungal drug, it is very important to know which organisms are resistant to that antifungal. (See the discussion of antifungal agents in the **Infectious Disease** section.)

The risk for infection in the patient with neutropenia is directly proportional to the degree and duration of neutropenia.

Other factors that increase risk are:

- Comorbidities
- Presence of catheters
- Concomitant use of immunosuppressive drugs, such as monoclonal antibodies and glucocorticoids (increases risk of *Pneumocystis* and tuberculosis)

A patient with severe neutropenia (< 500 neutrophils) is at a much higher risk than a patient with mild neutropenia (500–1,500 neutrophils); however, **function** of cells is as important as **number** of cells in resisting infection. Even with an adequate number of cells, patients can develop infection if the granulocytes that are present do not function properly. Suspect granulocyte **dysfunction** (e.g., **chronic granulomatous disease**) if the patient has an adequate ANC but has a history of recurrent staphylococcal skin infections, lung infections, and/or lymphadenitis. The duration of neutropenia is also key: An ANC < 500 for > 7 days greatly increases the risk of infection.

For febrile neutropenia, see the **Infectious Disease** section.

HIGHLIGHTS

Know the associations of the following inherited and acquired immunodeficiencies.

Inherited humoral deficiency:

- Recurrent sinopulmonary infections with encapsulated organisms
- Enteroviral infections
- Giardiasis
- Risk of autoimmune disease
- Risk of malignancy

Inherited selective deficiency of IgA:

- Mostly asymptomatic
- Food and inhalant allergies
- False-positive **serum** pregnancy tests
- Anaphylaxis with blood transfusion and IVIG
- Association with autoimmune diseases

Acquired humoral deficiencies can be seen in patients with splenectomy, leukemias, lymphomas, myeloma, HIV/AIDS, and encapsulated organisms.

Classical early complement deficiencies can be found in patients with sinopulmonary infections with encapsulated organisms and C2 deficiency associated with SLE.

Terminal complement deficiencies are associated with infections with encapsulated organisms and *Neisseria meningococcus*.

T-cell defects are associated with patients with HIV/AIDS, after transplantation, treatment with glucocorticoids, and infections with fungi, acid-fast bacteria, viruses, and parasites.

THE IMMUNE SYSTEM

PREVIEW | REVIEW

- What is the 1st line of defense of the immune system?
- Which part of the immune system is rapid and nonspecific?
- Which part of the immune system is slow and specific?
- How is cellular messaging used oppositely in innate and adaptive immunity?

THE INNATE IMMUNE SYSTEM

The innate immune system is the 2nd line of defense against pathogens, after the skin (which is the 1st line).

Characteristics of the innate immune system include:

- Rapid acting
- Nonspecific
- No memory

Its components include:

- Complement
- Macrophages
- Natural killer (NK) cells

THE ADAPTIVE IMMUNE SYSTEM

The adaptive immune system is the 3rd line of defense against pathogens and is activated by the innate immune system. Unlike the innate immune system, the adaptive system is:

- much slower to get started,
- very specific, and
- has memory.

The adaptive immune system can be broken down into 2 main components:

- 1) **Humoral:** B cells, plasma cells, and immunoglobulins (Igs). Activated B cells become plasma cells, which make Ig.
- 2) **Cell-mediated:** T cells

INNATE vs. ADAPTIVE IMMUNITY

The innate immune system is the foundation on which the more sophisticated adaptive immune system sits. The innate system not only protects the body while the adaptive system gears up, but it also helps direct the response. The innate immune system, in general, needs messages to **prevent** it from killing pathogens, while the adaptive immune system needs messages (usually from the innate immune system) to **allow** it to kill pathogens.

The key difference between the 2 systems can be found in their receptors:

- **Innate** immune system receptors are generic, ready-made receptors (e.g., toll-like receptors). These receptors allow a quick but nonspecific response—one that is rapid but does not recognize distinct pathogens. Think of these as the “first responders” to a new attack. The cells that carry out most innate immune functions are myeloid cells.
- **Adaptive** immune system receptors are custom-made receptors (T-cell receptors [TCRs] and Igs) that are refined to be as **specific** as possible for the pathogen. They provide the immune system with the ability to recognize a seemingly infinite variety of pathogens. Once these custom-made receptors have served their purpose, the body keeps a few of them around in case it needs them again in the future, enabling a quicker reaction based on memory. The cells that carry out most adaptive immune functions are lymphoid cells.

Summary: The innate immune system provides a quick, generic response, while the adaptive provides a slower—but more powerful and specific—response to the foreign pathogen. Thanks to immunologic memory, if the pathogen is encountered again in the future, the adaptive system can mount a quicker and more robust response.

INNATE AND ADAPTIVE OVERLAP

There is significant overlap between the innate and adaptive immune systems:

- The classical pathway of the innate complement system requires C1 to bind to an immune (antibody-antigen) complex formed by the adaptive immune system to initiate its activity.
- C3b, made by all pathways of the innate complement system and continuously generated by the alternative pathway, opsonize pathogens and immune complexes—coating and tagging them for phagocytosis. Phagocytes like macrophages and dendritic cells are also professional antigen presenting cells (APCs) and present these antigens to the T-helper cells, which in turn initiate or accelerate the adaptive immune response of B cells. (Whew!)
- Macrophages and NK cells initially function as part of the innate system; when they become further activated by T cells, they can subsequently act as part of the adaptive immune system.

INNATE-LIKE CELLS

There are cells that are part of the adaptive immune system but are innate-like. They show overlap because they are more rapid-acting and less specific than the other lymphocytes. Examples of innate-like immune cells are:

- $\gamma\delta$ T cells
- Natural killer T (NKT) cells
- B-1 cells (an innate-like version of B cells)

CELLS OF THE IMMUNE SYSTEM

There are 2 major cell types in the immune system:

1) Lymphoid cells

- Lymphocytes
 - T cells
 - $\alpha\beta$ T cells
 - CD4+ T cells (a.k.a. helper T cells, T-helper cells [Th cells])
 - CD8+ T cells (a.k.a. cytotoxic T cells)
 - $\gamma\delta$ T cells (innate-like)
 - NKT (natural killer T cells; innate-like)
 - B cells
 - B-1 cells (innate-like, found mainly in peritoneal and pleural cavities)
 - B-2 cells (a.k.a. conventional B cells; the workhorses of the immune system that produce all Igs)
 - Marginal B cells (innate-like, found mainly in the spleen)
- NK cells (natural killer cells; do not confuse with the similarly named T cells!)

2) Myeloid cells

- Granulocytes
 - Neutrophils
 - Eosinophils
 - Basophils
- Professional antigen-presenting cells (APCs)
 - Monocytes/Macrophages
 - Dendritic cells
 - B cells are APCs that are not myeloid
- Other
 - Mast cells
 - Erythrocytes
 - Megakaryocytes/Platelets

HUMAN LEUKOCYTE ANTIGENS (HLAs)

PREVIEW | REVIEW

- What are Class I human leukocyte antigens (HLAs)? What type of cells do they appear on?
- What are Class II HLAs? What type of cells do they appear on?
- What is major histocompatibility complex restriction?

The HLA complex is a group of genes that code for unique proteins, specific for that individual, that are expressed on cell surfaces. The immune system uses a class of these proteins (Class I) to determine if the cell is self (okay) or

nonself (not okay—terminate!). It uses another class, Class II, to make sure that a cell presenting foreign antigen is a professional antigen presenting cell (APC). Many species have this system, and it is identified as the major histocompatibility complex; human leukocyte antigen (HLA) complex is the same system in humans. The HLA gene complex is located on the short arm of chromosome 6. There are 3 classes of HLA. In the following, remember only the **class**—not any of the subclasses.

Class I HLAs (HLA-A, -B, and -C) are expressed on **all** nucleated cells and are used to determine if the cell is self or nonself. The Class I HLA protein on these cells complex with and present foreign antigens to the cytotoxic **CD8+ (killer) T cells**. Class I HLAs play a major role in **transplant rejection, neoplasms, and viral infections**.

In contrast to these “generalist” APCs, there are other specialized cell types that present antigen as a main function. These are called **professional** APCs.

Class II HLAs (HLA-DP, -DQ, and -DR) are expressed on the surface of the professional APCs, which include monocytes/macrophages, dendritic cells (including Langerhans cells), and B cells. The expressed Class II HLAs complex with foreign antigens and present them to **CD4+ (helper) T cells**. Class II HLAs mediate the reactions among macrophages, T cells, and B cells.

Class III HLAs code for peptides involved with inflammation such as tumor necrosis factor (TNF), heat shock proteins, and certain complement proteins.

T cells can recognize antigens only if the antigen is complexed with the proper HLA protein. HLA I presents antigen to CD8+ T cells, and HLA II presents antigen to CD4+ T cells (mnemonic: $8 \times 1 = 8$ and $4 \times 2 = 8$). This is the key concept of MHC restriction.

LYMPHOID CELLS

PREVIEW | REVIEW

- What are the functions of T cells?
- Which antigens do CD4+ helper T cells recognize? CD8+ T cells?
- What is the important distinction between the way natural killer cells and natural killer T cells kill other cells?
- Which immunoglobulins are present on the surface of mature B cells?

LYMPHOCYTES

T Cells

Clusters of differentiation (CD) markers are like “ID tags” that can be identified by monoclonal antibodies in labs.

They are useful in immunophenotyping lymphocytes, which allows us to differentiate one immune cell from another. For example:

- CD45+: all leukocytes (i.e., granulocytes, monocytes, lymphocytes)
- CD3+: T-helper cells and cytotoxic T cells
- CD4+: T-helper cell only
- CD8+: cytotoxic T cells only
- CD19+ and CD20+: mature B cells
- CD16+ and CD56+: NK cells

Interleukins (IL) are the “language of the immune system” and allow immune cells to communicate with one another. For example:

- Secretion of IL-7 causes an inflammatory response.
- Secretion of IL-4, IL-5, and IL-13 causes an allergic response.
- Secretion of IL-10 causes immune suppression.

Functions of T cells:

- Destroy intracellular and other bacteria (especially gram-negatives), viruses, fungi, parasites, and mycobacteria
- Regulate Ig production by B cells
- Activate other immune cells, such as macrophages, by secreting cytokines

All T cells have T-cell receptors (TCRs), which are antigen-specific binding sites composed of 2 subunits (the majority being alpha and beta, and a minority being the innate-like gamma and delta). The TCR is always complexed with CD3, which allows intracellular signaling.

Again: CD4 cells recognize antigen **only** if it is presented along with a Class II HLA antigen. CD8+ T cells recognize an antigen only if it is presented with a Class I HLA, whereas CD4+ T cells recognize an antigen only if it is presented with a Class II HLA. This is the key concept of MHC restriction.

CD4+ T Cells

CD4+ T-helper (Th) cells are the primary defense against extracellular threats. They are divided into several subsets:

- **Th1** activates macrophages and CD8+ cytotoxic T cells, leading to a **cell-mediated** immune reaction.
- **Th2** activates mature B cells to produce antibody, resulting in a **humoral** immune reaction.
- **Th17** induces local inflammation by secreting IL-17 which stimulates local tissue cells to express chemokines and attract inflammatory cells.

Again: Th cells are activated **only** by antigen presented in association with Class II HLAs, which only appear on professional APCs, such as B cells, monocytes/macrophages, and dendritic cells (including Langerhans cells).

How are CD4+ T cells **activated**? An APC, such as a macrophage, ingests an extracellular foreign pathogen. This foreign particle is ingested, processed, and presented

along with the Class II HLA to CD4+ helper T cells. These T cells, after being activated, **induce** B cells to convert to plasma cells and produce specific antibodies against that foreign particle.

How does HIV affect the immune system? **HIV** targets all **CD4+** cells, including CD4+ T-helper cells, macrophages, monocytes, and microglial cells. By targeting and attacking CD4+ cells, HIV severely weakens the immune system, allowing opportunistic infections to occur.

CD8+ T Cells

The CD8+ cells are **cytotoxic** T cells (CTLs) and are important in the defense against intracellular threats such as viruses and neoplastic cells. When a cell is infected by a virus or becomes neoplastic, these viral or neoplastic antigens are processed by the infected cell and presented on its surface in combination with **Class I** HLAs. This marks the cell for destruction by the CTLs. All nucleated cells have Class I HLAs, so **most** cell types can present antigen to CD8+ T cells!

T Regulatory Cells

T regulatory (Treg) cells are a specialized subpopulation of T cells that modulate the activity of the immune system. The expression of the transcription factor **FOXP3** controls the development and function of Treg cells. These cells secrete **immunosuppressive cytokines**, such as IL-10 and transforming growth factor β (TGF- β). Treg cells can down-regulate both Th1 and Th2 responses, thereby, reducing allergic inflammation and inducing tolerance against self-antigens. Genetic mutations in **FOXP3** cause an overwhelming systemic autoimmunity known as **IPEX** (immune dysregulation, polyendocrinopathy, enteropathy, **X**-linked).

Natural Killer T Cells

Name alert! Do not confuse natural killer T (NKT) cells with NK cells—the **innate** lymphoid cells with a very similar name.

NKT cells are so named because they share several features with NK cells, such as granzyme production and **CD16** and **CD56** expression. Yet, unlike NK cells, NKT cells have TCRs and require a signal to kill. They are restricted to a type of MHC-like molecules called **CD1**, which primarily recognizes **lipids** and glycolipids (in contrast to the MHC molecules, which primarily recognize protein antigens).

B Cells

B cells not only produce all the immunoglobulins in the body, but also use these same antibodies as receptors bound to the surface of the B cell. These are called B-cell receptors (BCR). In a naive, mature B cell (one that has never seen antigen), these receptors are ready to interact with antigen presented by a T-helper cell or with an antigen itself. A single B cell has about 100,000 of each class of surface Igs that cover its surface.

Progenitors to B cells develop in the bone marrow and become immature B cells (with surface IgM; **IgM only = immature**) which then migrate from the bone marrow to the lymph nodes, where they express surface IgD in addition to the surface IgM—and now are naive mature B cells (**IgM + IgD = naive mature**). These naive, mature B cells wait to become activated by T-helper cells presenting an antigen, or by an antigen itself. The activated B cell—now with a B-cell receptor (**BCR = activated B cell**) whose variable region contains changes due to the antigen DNA—then moves to the germinal center of the lymph node and starts proliferating wildly, while continuously mutating and producing different variable regions to the BCR. Most of the resulting BCRs have low affinity for the antigen and the B cell dies (apoptosis). Occasionally, one will have a receptor with increased affinity for the antigen, and this “high-affinity” BCR+ B cell survives.

When a Th cell connects to this high-affinity BCR on this mature B cell, it will induce the B cell to transform into:

- a **plasma** cell that will then produce the antigen-specific IgM antibodies at a rate of thousands per second or
- a **memory** B cell that will “**class-switch**” the receptors on its surface (e.g., to IgG, IgA, IgE) but keep the same variable region. It (or its clones) hangs around for years. When a memory B cell meets that same antigen, it will immediately proliferate and differentiate into plasma cells that will produce that new class of antibody.

B cells can be stimulated to convert to plasma cells by activated CD4+ T cells or, if there are sufficiently large quantities, by antigen alone. Plasma cells produce specific antibodies that coat the surface of a particular foreign organism. This coating identifies it as edible to the macrophages (**opsonization**) and initiates the complement cascade. Specific antibodies can also **neutralize** bacterial toxins and viruses.

B cells are also APCs and have Class II HLAs on their surfaces, enabling them to present foreign antigens to CD4+ Th cells. The activated T cells can then induce other B cells to convert to plasma cells and produce antibodies.

NATURAL KILLER CELLS

Name alert! Do not confuse these cells of the innate immune system with NKT cells.

Natural killer (NK) cells are lymphoid cells that play a major role in the immune system response to tumors and viruses. They express **CD16** and **CD56** but not TCRs or their associated CD3 molecules. This is an important difference between NK and NKT cells!

NK cells are called natural killers because they are **always in kill mode**. Cells encountered by the NK cells must present themselves appropriately to avoid getting killed. For example, all cells (except mature RBCs) must display Class I **HLA-E** on their cell surfaces in order to **avoid getting killed** by NK cells. This is in contrast to T cells and NKT cells that require a signal in order to kill.

NK cells are an important component of the immune system because some viruses have evolved to reduce Class I HLA expression on the host cell, protecting them from recognition and destruction by T cells. It is precisely this absence or reduction of Class I HLA expression that causes the NK cell to kill the infected cell (typically by inducing apoptosis), which would have been missed by the T cells.

MYELOID CELLS

Granulocytes are WBCs with identifiable granules within their cytoplasm.

Neutrophils are also known as polymorphonuclear leukocytes, polys, PMNs, segs (mature), and bands (immature). They have a multilobed nucleus with 3–5 lobes. PMNs phagocytize microorganisms, especially those coated with antibodies. If PMNs are absent, patients get overwhelming **pyogenic** infections.

Eosinophils are involved in the pathology of **allergic** reactions and in the immunologic defense against **parasites**.

Basophils are involved with the late-phase response of IgE-mediated Type 1 hypersensitivity. See [Type 1 – IgE-Mediated Immediate Hypersensitivity Reaction](#) on page 2-1.

Professional antigen-presenting cells (APCs) are cells that express Class II HLAs, and, like all nucleated cells, also express HLA I. This is an exclusive group of cells consisting of 3 cell types:

- 1) **B cells**: the **most specific** APCs
- 2) **Monocytes/Macrophages** phagocytose opsonized microorganisms, process and present antigens, and secrete interleukin-1 (IL-1; stimulates T cells).
- 3) **Dendritic cells** are scavengers; they change conformation (when they ingest a pathogen), travel to a lymph node, and activate lymphocytes.

Note that phagocytic cells consist of neutrophils, monocytes/macrophages, and dendritic cells. The monocytes/macrophages and dendritic cells together form the **mononuclear phagocyte system**.

Others:

- Mast cells are involved with the early-phase response of IgE-mediated Type 1 hypersensitivity. See [Type 1 – IgE-Mediated Immediate Hypersensitivity Reaction](#) on page 2-1.
- Erythrocytes directly participate in the immune complex reaction (bacteria, complement, and antibody) for enhanced phagocytosis; their primary functions are in oxygenation, balancing blood pH balance, and transporting nutrients and electrolytes. More information on RBC function is in the [Hematology](#) section.
- Megakaryocytes/Platelets are recognized for their clotting properties, but also are active participants in immune defense (with recruitment of neutrophils and cytokine signaling in the lysis of microorganisms). Refer to the [Hematology](#) section for more information on megakaryocyte and platelet functions.

ANTIBODIES

PREVIEW | REVIEW

- Characterize the various immunoglobulins: G, A, M, E, and D.
- Which antibody crosses the placenta?
- Which antibody is produced 1st during an infection?

All antibodies (a.k.a. immunoglobulins [Igs]) have the same basic structure (Figure 2-7). Each monomer is composed of 2 heavy and 2 light chains that are held together by disulfide bonds. There are 5 immunoglobulin isotypes: G, A, M, E, and D. These isotypes are determined by differences in the structure of the constant regions of the heavy chains. All antibodies have 1 of 2 types of light chains, kappa or lambda.

Figure 2-7: Antibody structure

Remember the following key points about immunoglobulins G, A, M, E, and D:

- **IgG** is simplest, smallest, and most abundant Ig in the serum. It is the smallest antibody and the only Ig that can pass through the placental barrier. About 75% of Igs in the serum are IgG. Mechanisms used by IgG to fight pathogens:
 - Immobilize pathogen by mediating their agglutination
 - Opsonize pathogens, making them more susceptible to phagocytosis
 - Activate the classical complement pathway
 - Bind and neutralize bacterial exotoxins and viruses
- A single plasma cell can make IgGs tailored to a specific antigen at a rate of thousands per second! IgG antibodies can cross the placental barrier and provide passive immunity to the fetus (and for the infant's first 6 months of life). IgG is involved with Type 2 IgG-mediated cytotoxic hypersensitivity and Type 3 immune complex hypersensitivity reactions.

- **IgA** is the most abundant Ig produced in the body. It is produced by surface IgA+ plasma cells and is the main Ig in secretions. It is considered our 1st line of defense against pathogens. IgA also is about 15% of Ig in the serum. It is usually in a dimer configuration (2 Igs) with a J (joining) chain connecting the two bases. This dimer configuration automatically attaches to a secretory component, which allows IgA to exit the body via exocrine glands and become part of seromucous secretions. IgA is found in tears, saliva, sweat, and in secretions of the sinuses, respiratory tract, digestive tract, and GU tract. It is the main Ig secreted in breast milk, and is especially high in colostrum. IgA works with the same mechanisms as IgG, but does **not** activate complement.
- **IgM** is the 1st immunoglobulin to develop in the fetus, appearing at ~ 20 weeks. IgM is also the first surface Ig on a developing B cell and the first Ig released by B cells when converted to plasma cells after the initial encounter with a pathogen. IgM is secreted as a pentamer (5 immunoglobulins) in which each monomer is connected at its base by a J chain. Checking for IgM can be useful in diagnosing a current illness and can help distinguish acute vs. chronic infection. IgM has the same mechanisms as IgG, but it is the most effective Ig for complement activation.
- **IgE** is the Ig with the lowest concentration in normal serum (0.05% of Igs) but is a major factor in many allergic conditions, including asthma, allergic rhinitis, atopic dermatitis, and food allergies. It is also used to fight off parasitic infections. In all these cases, plasma IgE levels can be elevated.
- **IgD** is a surface Ig found on B cells, and identifies a B cell as mature. It is involved with the formation of B-cell receptors on B cells that are fundamental in their activation. A tiny amount is found in the serum (~ 0.25% of Igs), but its function in this expressed form is uncertain.

The **variability** in Ig specificity is responsible for the immune system's ability to encounter and then remember an almost limitless number of pathogens. The rearrangement of several regions within the antibody gene makes this possible. Most of the variability is located in the complementarity determining regions, also known as hypervariable regions.

Igs bind specific antigens in the Fab region and then activate either cells or complements (see [Complement Cascade](#)), by means of the Fc region, to destroy the antigen-bearing material.

COMPLEMENT CASCADE

PREVIEW | REVIEW

- What is the cause of hereditary angioedema (HAE)?
- What is the clinical presentation of HAE?

- Which infection is most often seen with terminal complement deficiency?
- What does the CH50 assay measure, and when is it used?

OVERVIEW

The 3 Complement Pathways

The complement system (follow along with [Figure 2-8](#)) is a group of about 30 known plasma factors important in host defense. It has 3 pathways: classical, lectin, and alternative. Through these different pathways, they ultimately perform the same functions:

- Opsonizing target cells with C3b
- Inducing more inflammation with anaphylatoxins C3a, C4a, and C5a
- Building and activating the C5b–C9 membrane attack complex (MAC)

Classical Pathway

IgM and IgG immune complexes (Ig + antigen) activate the **classical pathway**. In this system, we have both the innate (complement) and adaptive (Ig) systems working together. The C1 complex is activated when it attaches to the antibody of an immune (Ag-Ab) complex. Activated C1 cleaves **many** C2s and C4s, subcomponents of which (C4b and C2a) combine and form C4b2a (a.k.a. a C3 convertase). C4b2a, in turn, cleaves **many** C3s.

One IgM pentamer can initiate the classical pathway, but it generally takes at least 2 IgGs or even greater quantities of antigen to perform the same initiation process.

Lectin (or Mannose-Binding) Pathway

Lectins bind mannose on the surface of pathogens. Lectins are also called “mannose-binding lectins” (MBLs) or “mannose (mannan)-binding proteins.” These MBL complexes are produced by an acute phase response and

are fairly nonspecific. Associated proteases then cleave many C2s and C4s, and subsequent steps are similar to the classical pathway.

Alternative Pathway

The alternative pathway is very nonspecific, but acts extremely fast when it is activated by a pathogen or dead tissue to make more C3b to opsonize the pathogen. C3b goes on to stimulate the production of the terminal complement components (C5–C9) which form the membrane attack complex (MAC) on the cell surface of the pathogenic bacteria. C3, the pivotal piece of the complement system, slowly dissociates due to protein factors in the alternative pathway that combine with C3b to make a C3 convertase. The newly produced C3b feeds back into the alternative pathway to repeat the process. This process loop is like an idling motor, and is called **C3 tick-over**—keeping just enough C3b around to immediately opsonize an invading pathogen.

Common Terminal Pathway — C3b Opsonization

Opsonins coat pathogens and mark them for destruction by the immune system. This is typically carried out by macrophages like the Kupffer cells in the liver. The 2 most important opsonins are IgG of the adaptive immune system and C3b of the innate. So, while the slower and more specific adaptive immune system's IgG takes days to mount an appropriate response, the quicker and less specific C3b fulfills this important role more rapidly.

Membrane Attack Complex

C3, when combined with either C4b2a or Factor B, activates C5 and forms the C5-6-7-8-9 **MAC**. This complex forms transplasma membrane channels on the surface of pathogenic bacteria, causing lysis.

Figure 2-8: The complement cascade

COMPLEMENT DEFICIENCIES

Hereditary Angioedema (HAE)

HAE is an autosomal dominant disorder characterized by recurrent attacks of angioedema caused by a decrease in C1 esterase inhibitor (C1-INH; a.k.a. C1 inhibitor) production or function. While C1-INH is a key inhibitor of the 1st complex in the complement cascade, it is also the principle regulator of bradykinin expression. Lack of C1-INH results in unchecked production of **bradykinin**, the key mediator in HAE attacks. Patients can have either a **decreased C1-INH level** (Type I; 85% of HAE patients) or a nonfunctioning C1-INH (Type II; 15% of HAE patients). Anything that causes an increase in kinins/bradykinins unmasks HAE and precipitates angioedema. Drugs such as ACEIs are recognized causes of angioedema due to the accumulation of bradykinin.

Patients have recurrent angioedema with each episode, lasting 1–3 days. Unlike angioedema/urticaria caused by immediate hypersensitivity reactions, hereditary angioedema is **not** associated with urticaria or itching. Even minor trauma from dental procedures can precipitate attacks! Most patients experience facial swelling, especially lip swelling. The cutaneous symptoms can also affect extremities (Figure 2-9) and genitalia and are rapid in onset. Attacks can include laryngeal swelling with possible stridor and potentially life-threatening obstruction. GI tract attacks are caused by bowel wall swelling and can produce severe abdominal pain, often leading to inappropriate surgeries.

Figure 2-9: Swollen hand during a hereditary angioedema attack
Source: LucyHAE

Diagnosis: Screen by checking for low C4 levels. A normal C4 level during an acute episode of angioedema rules out HAE. A C1-INH functional assay provides definitive diagnosis of HAE:

- If the C1-INH level is low, then it is **Type I HAE**.
- If the C1-INH level is normal, then it is **Type II HAE**.

Treat acute attacks as early as possible with one of the following (in order of preference):

- C1-INH (plasma-derived or recombinant)
- Bradykinin receptor antagonist (icatibant; competes for the bradykinin B receptor)
- Kallikrein inhibitor (ecallantide; decreases bradykinin production)

Trigger avoidance is the first step to prevent acute attacks. Common triggers are trauma to facial and throat areas, oral and dental infections, and certain medications—especially ACEIs and estrogens. If this is not sufficient, then one of the following is given:

- IV or SQ plasma-derived C1 inhibitor replacement (best overall; best if pregnant or lactating)
- Tranexamic acid (limited effect but often tried first because it is given orally)

Note that epinephrine, glucocorticoids, and antihistamines are **not** effective in any HAE therapy.

Acquired Angioedema

Acquired angioedema is clinically similar to HAE, but is defined by low C1-INH (as in HAE) and also a **low C1q**. Synthesis of complement components in the liver and macrophages are inhibited by myelo- and lymphoproliferative diseases like lymphoma. In addition, autoimmune disease can result in the formation of C1-INH autoantibodies. Both instances result in decreased C1-INH and C1q levels. Again, C1q levels are normal in HAE. Acquired angioedema is found in older patients with underlying disease, and treatment is similar to HAE.

C1, C2, and C4 Deficiencies

C1, C2, or C4 deficiencies cause **decreased activation** of complement via the **classical** pathway. C2 deficiency is the most common complement deficiency in North American Caucasians. Most of the complement proteins are inherited as **autosomal recessive** genes. Although the alternative pathway takes up some of the slack, these patients are likely to have recurrent sinopulmonary disease due to **encapsulated** bacteria (such as *Streptococcus pneumoniae*, *Haemophilus influenzae* Type b, and *Neisseria meningitidis*). Patients must undergo prophylactic vaccinations against encapsulated organisms. In patients with 1 abnormal gene, serum complement levels are about 1/2 normal. In these patients, there is an increased incidence of rheumatoid diseases—**especially SLE!**

C3 Deficiency

C3 deficiency (complete absence of its function) is heritable and results in **severe pyogenic** (bacterial) infections.

C5–C9 Deficiency

C5–C9 deficiency (a.k.a. **terminal complement deficiency**) is an autosomal recessive disorder that affects the MAC.

A very rare deficiency of Factor D or properdin in the alternative pathway also decreases the production of terminal complex components and the MAC.

It results in increased *Neisseria meningococcal*/gonococcal infections (especially meningitis or septicemia). Screen for terminal complement deficiency with a CH50 assay. Specific diagnosis is made by assay of these complement components.

CH50 ASSAY

The CH50 (a.k.a. CH100) screening assay measures the total complement activity of the classical pathway. A normal test shows that all factors of the classical pathway (C1–C9) are present. A CH50 is done on a meningococemia patients as a screen for terminal complement deficiency (C5–C9). CH50, C3, and C4 are sometimes used to follow the disease activity of SLE. If the CH50 is very low, check individual complement components (C1–C9 levels) for specific deficiencies. Know that CH50 activity can be normal even when an individual component is 50–80% decreased. For this reason, if the index of suspicion is high for a complement disorder and the CH50 is normal, it may still be necessary to measure individual components.

Immune complexes activate complement to form C3b, which attaches to the Fc portion of IgG. This maintains the solubility of the complexes in the serum and prevents them from cross-connecting and precipitating. IgA does not activate the classical complement pathway and is therefore more susceptible to precipitation. This causes ICs to deposit in small blood vessels and tissues when high levels build up.

See [Type 3 – Immune Complex Hypersensitivity on page 2-3](#).

THE MEDSTUDY HUB: YOUR GUIDELINES AND REVIEW ARTICLES RESOURCE

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub at

medstudy.com/hub

The Hub contains the **only** online consolidated list of **all** current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source. MedStudy maintains the Hub as a service to the medical community and makes it available to anyone and everyone at no cost to users.

IMMUNE COMPLEXES

Immune complexes (ICs or antigen-antibody complexes) form during normal day-to-day immune surveillance and are then removed from the serum. As they form, complement is **usually** activated and a C3 component (C3b) attaches to the complex.

The C3b-IC entity is recognized by and attaches to the complement receptor (CR). The main CR1 is found in abundance on RBCs.

Immune complexes are scrubbed off the RBCs by the Kupffer cells in the liver. (Remember that Kupffer cells also remove and destroy C3-coated gram-positive and gram-negative bacteria; see [Common Terminal Pathway – C3b Opsonization on page 2-23](#).) If there are any defects in this elimination process, ICs increase in the serum, as in the following conditions:

- **Hepatic vein thrombosis** (a.k.a. Budd-Chiari syndrome) and cirrhosis cause a decreased clearance of ICs.
- **Paroxysmal nocturnal hemoglobinuria** (PNH) causes decreased binding of ICs; for more information, see the [Hematology](#) section.
- **SLE** causes a decreased amount of CR1 on RBCs.

Note that each of these disorders causes an **increase in ICs** in the serum.

COMMON SKIN PROBLEMS

PREVIEW | REVIEW

- What bacterium most commonly infects patients with atopic dermatitis? What virus?
- What is the clinical presentation of seborrhea?
- What is the clinical presentation of intertrigo?
- Allergic contact dermatitis is an example of what type of hypersensitivity reaction?
- What are the serious side effects of isotretinoin?
- How do you distinguish rosacea from acne vulgaris?
- What inflammatory scarring disease affects the axilla, groin, and perianal areas?

OVERVIEW

As the largest organ of the human body, it is no surprise that the skin serves numerous functions that are essential in the maintenance of human health. More specifically, the skin functions to prevent infection using both innate and adaptive immunity, repair injury, protect the integrity of DNA, provide circulation, maintain a barrier for water and temperature regulation, provide sensory communication, and provide nutrition.

The skin is composed of 3 main layers: the epidermis, the dermis, and the subcutaneous tissue. The epidermis is the body's first line of defense and comprises a semipermeable, laminated surface that acts as a barrier to chemical penetration, microbiologic invasion, and fluid and solute loss. The dermis provides structural and nutritional support and is populated by nerves and vasculature. At the dermal-epidermal interface is the basement membrane, which is an area of great interest, because genetic defects of this zone may lead to significant disease. It is also a target of autoimmune attack. The subcutaneous tissue provides thermoregulation and cushioning to prevent injury to underlying structures, such as bone and muscle. Any failure of the skin to function in these capacities can lead to substantial morbidity and mortality.

MedStudy Skin Signs (available at medstudy.com/products/skin-signs-1) provides additional images and examples of various dermatologic conditions.

ATOPIC DERMATITIS (AD)

AD (a.k.a. eczema) is a chronic inflammatory skin condition with a relapsing and remitting course (Figure 3-1). Typically, 60% of cases present in infancy, with > 90% of all cases presenting at < 5 years of age; in 10–30%, the condition persists to adulthood. Onset is rare after 30 years of age, and the disease generally becomes less severe with increasing age.

AD is characterized by **dry skin** and **pruritus**. Subsequent scratching leads to more inflammation and **lichenification**

Figure 3-1: Antecubital fossa with atopic dermatitis
Source: Kimberly Salkey, MD

(i.e., thickening and hardening of the skin, with exaggeration of its normal markings), as well as more itching and scratching (i.e., “itch-scratch” cycle). In adults, the most commonly involved areas are the wrists and the antecubital and popliteal fossae. Patients can also develop erythematous and edematous pruritic patches on the head and neck, which can crust and then “weep,” at least partially as a result of scratching.

There is often a personal or family history of eczema, allergic rhinitis, or asthma, as well as laboratory findings of elevated serum IgE levels and eosinophilia. The combination of AD, allergies, and asthma is referred to as the atopic triad.

Flares can be precipitated by clothing (particularly wool), changes in weather, emotional stress, aeroallergens (dust mites and pollen), and infections. *Staphylococcus aureus* infection is often present in severe cases. Diluted bleach baths can decrease *S. aureus* colonization but have not been shown to reduce flares. Give oral antibiotics or topical mupirocin cream for secondary infections.

Most treatments for AD focus on avoiding exacerbating factors, maintaining a good moisturizing regimen, and using medications when the first 2 methods do not suffice. Hydration, moisture-trapping agents with low water content (emollients), ointments, and topical corticosteroids are the mainstays of treatment for AD. Lotions (high water content) can actually worsen the condition by drying the area through dehydration. Lotions or gels with alcohol are even more drying.

Topical steroids are the mainstay of AD treatment. Use a step-up or step-down strength method depending on the results of treatment. Use mid- or high-potency topical corticosteroids for the trunk and extremities and low-potency topical corticosteroids for the face. However, topical corticosteroids are not recommended for prolonged use on the face or intertriginous areas, because they can cause striae, atrophy, telangiectasias, pigmentary changes, and acneiform skin eruptions. Instruct patients to use steroids twice daily until their skin returns to baseline or up to 2 weeks at a time, whichever occurs first.

Tacrolimus (Protopic) and **pimecrolimus** (Elidel) are topical immunosuppressants (calcineurin inhibitors) that are effective alternatives to topical corticosteroids. Because these do not cause skin atrophy, they are especially good for facial lesions. There is a theoretical risk of skin cancer or T-cell lymphoma (black box warning due to risk with systemic use; no significant topical data yet), so these agents are 2nd line for intermittent treatment of AD. These agents should be avoided in HIV+ patients or anyone with a weakened immune system. Counsel patients about this risk; the risk of severe local side effects from topical steroids may outweigh the risk of calcineurin inhibitors for lesions involving the face.

Eczema is a chronic condition, so patients will need to follow this protocol with each flare. Because patients with AD have a defective skin barrier, they need to use a bland emollient not only during but also after flares to help prevent recurrences. Eczema can run a much more chronic and severe course, which may necessitate a referral to dermatology. Also, educate patients on the avoidance of rubbing or scratching the skin lesions.

Pruritus is a significant component of eczema, and controlling the itch tends to improve the rash. Oral antihistamines (H1 blockers) can be very helpful but generally work at night as a sedative to reduce itching.

Avoid soap, because it can be drying and strips the skin of natural oils.

Crisaborole, which is a phosphodiesterase inhibitor, can be used topically for mild and moderate AD. It is rarely used because it is expensive, but it is a nonsteroidal choice and safe for long-term use on the face and for anyone > 2 years of age. Use oral cyclosporine, azathioprine, mycophenolate mofetil, or methotrexate for severe AD that does not respond to conservative therapy. In 2017, the U.S. Food and Drug Administration (FDA) approved dupilumab (Dupixent), an injectable biologic medication that inhibits interleukin-4 (IL-4) and is indicated for severe or refractory AD. Ultraviolet (UV) light therapy is also used in this setting. Oral corticosteroids are rarely indicated for acute flares and often cause rebound flares when tapered.

Eczema herpeticum is caused by herpes simplex virus, and it can cause a severe disseminated infection. Suspect eczema herpeticum in patients who develop fever and pustular or punched-out lesions that do not respond to oral antibiotics. It is more common in patients who are taking immunosuppressants and needs to be addressed quickly to limit systemic effects. If suspected, treat with oral antivirals or, if the patient is unable to swallow, intravenous (IV) acyclovir while establishing the diagnosis.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis affects 2–5% of the population and is a chronic condition that manifests as a yellow, greasy scale overlying erythematous patches or plaques (Figure 3-2). Pruritus is variable. It affects areas where sebaceous glands are most active and especially involves the scalp (dandruff), eyebrows, paranasal area, and

external auditory canals, although the chest, axilla, and groin areas can also be involved. There is a strong association with *Malassezia furfur*, although the relationship between the resident yeast and seborrheic dermatitis is not entirely clear.

Figure 3-2: Seborrheic dermatitis

Seborrheic dermatitis is common in patients with HIV/AIDS, Parkinson disease and other neurologic disorders, and mood disorders.

Treatment of seborrheic dermatitis: frequent washing and an antidandruff shampoo. The active ingredient in these shampoos is selenium sulfide, zinc pyrithione, or salicylic acid. The antimicrobial shampoos include ketoconazole or ciclopirox.

Use low-potency topical corticosteroids in combination with ketoconazole cream for skin disease. Topical calcineurin inhibitors (**tacrolimus** and **pimecrolimus**) can be used as **steroid-sparing agents**. Sulfur/sulfacetamide cleansers or lotions are effective adjunctive or maintenance therapy for skin disease, especially for the face.

INTERTRIGO

Intertrigo is an **irritant** dermatitis found in intertriginous areas: warm and moist skin folds that rub together and have little air circulation (e.g., inframammary fold, axilla, interdigital, groin). Intertrigo presents as tender, pruritic, macerated, brightly erythematous plaques. Contributing factors include obesity, hyperhidrosis, diabetes, alcohol, and smoking. Skin microbiomes cause secondary infections (e.g., *Candida*, a yeast). Suspect *Candida* when satellite papules extend beyond the main eruption. Tinea cruris and erythrasma can mimic nonspecific intertrigo. These can be ruled out with a potassium hydroxide (KOH)

test and Wood lamp, respectively. The KOH test shows hyphae with dermatophytes and pseudohyphae with candidal infection. Wood lamp shows green with pseudomonal infection and coral red with erythrasma, which is an infection with the bacterium *Corynebacterium* that is treated with erythromycin.

Treat intertrigo with topical antifungals and drying agents (e.g., antifungal powders, aluminum sulfate products, corn starch). Avoid the use of talcum powder in the genital area of women because of the potential increased risk of ovarian cancer.

CONTACT DERMATITIS

Contact dermatitis does not have a single presentation. Its manifestations can vary from slightly dry and erythematous skin to the development of edema, oozing vesicles, or chronic eczema or dermatitis.

Contact dermatitis (Figure 3-3) can be caused by irritant contact dermatitis (80% of cases), or it can be of allergic origin (20% of cases).

Figure 3-3: Contact dermatitis of the hand
Source: James Heilman, MD

The most typical chemical irritants are soapy water, rubbing alcohol, and common household cleaners. Sufficient exposure to these irritants causes dermatitis in every individual. For irritant contact dermatitis, prior sensitization is not required. Dyshidrotic eczema is common in individuals who wash their hands frequently. The finding of highly pruritic vesicles on the sides of the fingers is helpful in making this diagnosis.

The allergic type of contact dermatitis is due to a T-cell-mediated, delayed-type hypersensitivity reaction (Type 4 hypersensitivity) in the skin. Patients must become sensitized to the antigen with 1 or many exposures. After sensitization and upon reexposure, the skin develops a pruritic lesion in 12 hours to 2 days. The most common allergens are nickel, chromium, neomycin, bacitracin, and oleoresin urushiol (poison oak, poison ivy, and poison sumac). Linear and geometric eruptions often reflect an external cause. The distribution can also provide a clue, such as an allergy to nickel in jewelry that occurs on the earlobes or an allergy to jeans buttons that occurs on the abdomen.

Identify and remove the offending allergen or irritant as 1st line treatment. Symptomatic treatment includes cool compresses, topical corticosteroids, and Burow solution (aluminum acetate dissolved in water, 1:40). If the reaction is severe or involves the face, give systemic corticosteroids, usually as a reducing dose over 2 weeks. A shorter course can precipitate rebound reaction. Patch testing is the gold standard to identify contact allergens, especially if there is no obvious precipitating exposure. In patch testing, multiple suspected allergens are applied to the patient's back under occlusive dressings. After 48 hours, the dressings are removed and the area is examined for evidence of delayed hypersensitivity reactions.

STASIS DERMATITIS

Stasis dermatitis is one of the clinical manifestations of chronic venous insufficiency of the lower extremities. Venous hypertension is exacerbated by gravity and valvular incompetence in leg veins and causes distention of capillaries. This distention allows leakage of fluid and plasma into tissue, as well as deposition of hemosiderin and erythrocyte extravasation.

Clinical features include pitting edema of the shin and calf that is more pronounced at the end of the day and resolves overnight, rusty hemosiderin deposition, and eczematous findings such as itchy and dry skin. Over time, the legs start to develop signs of lipodermatosclerosis, characterized by induration and a firm circular cuff that creates an inverted wine bottle appearance. Venous ulcers can develop and increase risk of secondary infection. Scratching may lead to oozing and crusting. Edema and superimposed contact sensitization to self-treatments may lead to blistering.

The mainstay of treatment is management of venous hypertension. Elevation of the legs and compression with stockings or bandaging can improve venous return. Encourage exercise and lifestyle changes. Surgical strategies can be pursued in more severe cases. For symptom control and management of skin changes, topical therapy such as that used for eczema is indicated, including topical corticosteroids and emollient use.

ACNE AND ROSACEA

Acne Vulgaris

Presentation

The clinical manifestations of acne vulgaris are:

- Open (blackheads) and closed (whiteheads) comedones
- Papules
- Pustules
- Cystic lesions

Comedonal acne is noninflammatory acne and develops in early adolescence. The pathogenesis involves occlusion of the follicles.

Inflammatory acne occurs as a reaction to several factors, including *Cutibacterium acnes* (previously known as *Propionibacterium acnes*) within the follicle, ruptured follicular epithelium with leaking of sebum, and the immunologic response to these factors.

Acne severity is genetic and hormonal, with an imbalance between estrogens and androgens. However, most patients with acne do not overproduce androgens. Rather, sebaceous glands that are locally hyperresponsive to androgens are more likely to explain the genetic predisposition. Very severe nodular acne with the development of sinus tracts is called acne conglobata. It usually occurs in young males on the chest and back.

In women with polycystic ovary syndrome (PCOS), however, acne is a common but nonspecific external manifestation of increased serum androgens. PCOS occurs in 5–10% of all women, and about 1/3 of women with acne have PCOS. Women with oligomenorrhea and hirsutism plus acne can be investigated for PCOS with tests for luteinizing hormone (LH), follicle-stimulating hormone (FSH), free and total testosterone, dehydroepiandrosterone sulfate (DHEAS), a lipid profile, glucose tolerance test, and insulin sensitivity. See more on PCOS in the [Women's and Men's Health](#) section.

Factors that can exacerbate acne include cosmetics, oils, repetitive mechanical trauma (e.g., scrubbing), clothing (e.g., turtlenecks, bra straps, sports helmets), humidity, and heavy sweating. Diet is a controversial cause; some studies have shown an association with low-fat milk intake (exacerbating acne). There is no reliable data on high-glycemic-load diet exacerbating acne. Stress appears to worsen acne.

Acne vulgaris differs from rosacea by the presence of comedones (not seen in rosacea) and the lack of telangiectasia (seen in rosacea).

Treatment of Acne Vulgaris

Minimize friction in acne-prone areas (e.g., chin straps, baseball caps) and discontinue aggravating factors (e.g., topical corticosteroids, industrial compounds, certain oral contraceptives, lithium, phenytoin, phenobarbital).

Comedonal (noninflammatory) acne: Topical retinoids are the drugs of choice for comedonal acne. These include adapalene, tretinoin, and tazarotene. Retinoids (except adapalene) are deactivated by sunlight, so they should be applied at night.

Side effects are mainly skin irritation and photosensitivity. Start at a low concentration and apply 2–3×/week. Note: Topical retinoids are contraindicated in pregnancy! Other agents for comedonal acne include topical salicylic acid, benzoyl peroxide, azelaic acid, and glycolic acid; all 4 have comedonal activity. In addition, benzoyl peroxide has antibacterial properties.

Mild inflammatory acne (Figure 3-4): Use benzoyl peroxide in conjunction with topical erythromycin or clindamycin to treat the *C. acnes* of inflammatory acne.

The combination therapy decreases development of resistance; combination preparations are available commercially. Topical retinoids are also useful adjuncts. Topical dapsone (Aczone), an antimicrobial agent, is also used.

Figure 3-4: Mild inflammatory acne

Moderate-to-severe inflammatory acne (Figure 3-5) requires oral antibiotics, such as tetracycline, doxycycline, and minocycline. Topical and oral antibiotics should not be used together. Oral tetracyclines should be used for ≤ 6 months. The high prevalence of *C. acnes* resistance to erythromycin has led to decreased use of this agent. Trimethoprim/sulfamethoxazole (TMP/SMX) is recommended in selected refractory cases and should be used as short-term management.

Figure 3-5: Moderate-to-severe inflammatory acne

Source: James Heilman, MD

Oral isotretinoin (1 mg/kg/day) is highly effective in severe nodulocystic, scarring, or resistant cases but is also a powerful teratogen. The use of isotretinoin is restricted to physicians who have registered with the electronic FDA iPLEDGE program and requires multiple steps to prescribe. Some of the common birth defects it causes are hearing and visual impairment, facial dysmorphism, and intellectual disabilities. Because of these risks, female patients must have 2 negative pregnancy tests before beginning the medication and must use 2 forms of birth control while taking it. Additionally, women of childbearing potential are required to undergo monthly pregnancy tests prior to obtaining their next prescription.

Patients should be counseled on these risks and advised that conception is safe beginning 1 month after the last dose of isotretinoin.

Male patients are also advised not to impregnate a woman while taking isotretinoin, although there have been no reports of fetal abnormalities in this circumstance.

In addition to teratogenicity, there are serious side effects associated with the use of isotretinoin:

- Idiopathic intracranial hypertension (formerly known as pseudotumor cerebri), especially if used in conjunction with tetracyclines
- Depression and psychosis
- Pancreatitis
- Marked hypertriglyceridemia
- Hearing loss
- Night vision loss
- Skeletal abnormalities
- Myalgias
- Arthralgias
- Hair loss

There is a controversial association between isotretinoin and depression and inflammatory bowel disease as well. Anyone prescribing isotretinoin should be well versed in these side effects and take a careful history prior to prescribing it.

Hypertriglyceridemia, if severe, warrants discontinuation of isotretinoin and levels should reduce back to normal. Fenofibrate is used to treat hypertriglyceridemia.

Isotretinoin can cause palpitations, vascular thrombotic disease, and stroke, but aspirin is not routinely recommended.

If oral isotretinoin is used, all other acne treatments must be stopped.

Oral estrogen-based contraceptive therapy is used in PCOS to decrease androgen excess and to regulate menstrual cycles. Spironolactone, which has antiandrogen effects, is also used as hormonal therapy in combination with oral contraceptives. There is potential risk of feminization of a male fetus if pregnancy develops while on spironolactone. For more on acne during pregnancy, see the [Women's and Men's Health](#) section.

Rosacea

Rosacea (Figure 3-6) is a relapsing and remitting lifelong condition that primarily affects fair-skinned, middle-aged patients and presents with erythema, phymas, telangiectasias, papules, and pustules (acne-like lesions) on the central face. It occurs more frequently in women but is more severe in men.

According to the Global Rosacea Consensus (ROSCO) Panel, rosacea is defined according to diagnostic features and major and secondary symptoms and signs. **Diagnostic features** are central facial erythema and phymatous

Figure 3-6: Rosacea

changes. **Major features** (any 2 of which make a diagnosis) include pustules and papules, flushing, telangiectasias, and ocular changes. **Minor features** are burning, stinging, swelling, and dryness.

Ocular symptoms and signs occur in 50% but may predate or occur in the absence of rosacea. Symptoms include dryness, burning and stinging, light sensitivity, blurred vision, and foreign body sensation. Signs include lid margin and conjunctival telangiectases, blepharitis, plugging of the meibomian glands, chalazia, corneal inflammation, keratitis, iritis, scarring, and loss of visual acuity.

Know how to distinguish acne vulgaris from rosacea. Again, unlike acne vulgaris, rosacea can have telangiectasias and does **not** have comedones.

Rhinophyma is more common in elderly men and may require surgical therapy.

Patients with rosacea can have a **flushing reaction** to various stimuli (e.g., alcohol, stress, spicy foods) even before the lesions appear. Once the rosacea manifests, the flush can become **permanent**. Trigger avoidance is recommended. Sun protection is important.

Treatment depends on diagnostic features, symptoms, and signs but can be topical or oral and light therapy based.

Phymas can be treated topically with brimonidine, oxymetazoline, and retinoids. Oral therapies are carvedilol, doxycycline, minocycline, tetracycline, isotretinoin, azithromycin, and TMP/SMX. Intense pulsed light and laser therapies can be used. Papules respond to topical ivermectin, **metronidazole**, azelaic acid, ivermectin, retinoids, or sulfur/sulfacetamide preparations or oral antibiotics (e.g., tetracycline, doxycycline, azithromycin, minocycline, oral isotretinoin, TMP/SMX).

Treat ocular symptoms with topical azithromycin or cyclosporine or oral cyclosporine, azithromycin, doxycycline, and minocycline, but refer to an ophthalmologist.

Telangiectasias can be treated with laser therapy or retinol; persistent erythema and flushing can be treated with brimonidine topical gel (Mirvaso) and oxymetazoline.

Steroids should be avoided as they exacerbate the disease.

Periorificial dermatitis (Figure 3-7) is a rosacea-like rash that presents with grouped superficial papulovesicular or papulopustular lesions and erythema located around the mouth, chin, nasolabial, and periocular areas with vermilion sparing. It is also referred to as perioral dermatitis. Patients report intolerance to sunlight, cosmetics, topical moisturizers, water, and soaps. Steroids can worsen the condition. Treatment is generally the same as for rosacea.

Figure 3-7: Periorificial dermatitis
Source: Jason Reichenberg, MD

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa (a.k.a. acne inversa), which affects approximately 1% of the population, is a **chronic** inflammatory scarring process involving apocrine gland-bearing areas, such as the **groin/perianal** and the **axillary** regions (Figure 3-8). It typically develops after puberty and manifests as painful, deep-seated nodules, sinus tracts, and abscesses. The presentation is symmetric. The abscesses are usually sterile but can become secondarily superinfected. Although it occurs in both sexes (women > men, 4:1), axillary and vulvar involvement is more common in women and perianal involvement is more common in men. Smoking and obesity correlate with severity of disease.

The disease process begins with dilated, occluded follicles (comedones) that often have multiple openings. Subsequently, the disease can range from mild to severe (induration, scarring, pitting, and draining abscesses). There is often an association with severe acne, dissecting cellulitis of the scalp, and pilonidal cysts, known as the follicular occlusion tetrad.

Figure 3-8: Hidradenitis suppurativa; mild vs. severe
Source: Kimberly Salkey, MD

Treatment for hidradenitis suppurativa should be guided by disease severity and often is challenging. If applicable, recommend smoking cessation and weight loss. Patients should avoid deodorants (antiperspirants are okay), tight synthetic clothing, and prolonged exposure to hot, humid environments. Treat **early** disease with 1% topical clindamycin and intralesional steroids. Treat **acute** infections with incision, drainage, and packing. Treat **late** disease with either oral tetracycline or oral clindamycin + rifampin. Corticosteroids can be injected into the nodules or used orally for severe cases. Treat more **severe** disease with immunosuppressants, such as the anti-tumor necrosis factor (TNF)- α inhibitor adalimumab (Humira), which is FDA approved for treatment of moderate to severe hidradenitis suppurativa. Infliximab (Remicade) is also effective but not FDA approved; etanercept is not effective. Oral retinoids can improve severe cases (3rd line). Antiandrogens (cyproterone acetate, finasteride) and zinc gluconate can be beneficial nonsurgical alternatives. For severe refractory lesions, definitive therapy is complete surgical excision, but laser therapy is also increasingly being used.

For females, estrogen-containing birth control pills may help, as may spironolactone. Metformin can be beneficial depending on comorbid conditions.

MOUTH FINDINGS

PREVIEW | REVIEW

- What finding on the buccal mucosa can be seen with measles? Describe and name the finding.
- What viral infection causes oral hairy leukoplakia?
- A beefy red tongue is seen with what underlying disease states?
- What are the "4 Ds" that patients with glucagonomas develop?
- If you see macroglossia, what underlying diseases should you consider?

NOTE

Know all mouth findings outlined [here!](#)

ORAL BLISTERS AND ULCERS

Recurrent aphthous stomatitis is a common and multifactorial disorder with an unclear etiology, but it is thought to be secondary to a dysfunction of the immune system. Minor aphthae are the most common presentation and are round, shallow, and painful ulcerations that heal without scarring. Major aphthae are larger and deeper lesions that are more persistent and may heal with scarring. Herpetiform aphthae are uncommon and consist of groups of small, numerous, and painful ulcerations that are mostly limited to nonkeratinized surfaces (i.e., lining of mouth), a feature that helps to distinguish these lesions from herpes simplex virus (HSV).

Herpes simplex infections consist of painful, grouped vesicles on an erythematous base that are often preceded by tingling, burning, or pain. Outbreaks are often recurrent, and recurrent lesions are commonly on the vermillion border of the lips and less commonly on the nose, perioral skin, or cheek (Figure 3-9).

Figure 3-9: HSV-1 on lips and tongue
Source: CDC

Squamous cell carcinoma is the most common malignancy of the oral cavity and is associated with tobacco and alcohol use. It can manifest as an ulcer, an exophytic mass, or an endophytic, indurated lesion. These lesions are more aggressive than their counterparts on the skin.

Pemphigus vulgaris presents as painful oral erosions that may be scattered throughout the oral mucosa but are most typically found on the buccal and palatine mucosa. The presence of ulceration can lead to decreased oral intake, and patients presenting solely with oral lesions may experience a delay in diagnosis compared to those patients with cutaneous lesions. For more information on pemphigus vulgaris, see [Blistering Lesions](#) on page 3-29.

WHITE ORAL LESIONS

Koplik spots (Figure 3-10) are small, painless, white papules on an erythematous base that are found on the buccal mucosa in patients with measles. Even though the rash is not present yet, these patients

Figure 3-10: Koplik spots
Source: CDC

are highly contagious. The oral spots usually precede the skin lesions by several days.

Oral leukoplakia (Figure 3-11) is an adherent plaque found on the mucosal surface of the mouth. It is diagnosed only after ruling out other similar lesions with an identifiable cause, such as oral candidiasis, smoker's keratosis, and oral hairy leukoplakia. These are considered precancerous lesions.

Figure 3-11: Oral leukoplakia

Oral hairy leukoplakia (Figure 3-12) is a type of leukoplakia that most commonly occurs in patients with HIV/AIDS. It is due to opportunistic Epstein-Barr virus infection in the superficial layers of the tongue's squamous epithelium. It manifests as asymptomatic, white, corrugated (or "hairy") plaques along the sides of the tongue. In contrast to *Candida*, it cannot be scraped off!

Figure 3-12: Oral hairy leukoplakia
Source: CDC

Oral candidiasis, or thrush, causes white semiadherent plaques on the tongue and mucosa. Unlike hairy leukoplakia, these **can be scraped off**.

Lichen planus (LP) can have up to 7 presentations, including erosive, bullous, and atrophic, but the most common presentation is a lacelike pattern of white, raised lines, called Wickham striae. Oral LP, particularly the erosive type, has a reported association with hepatitis C.

TONGUE LESIONS

Beefy red tongue (glossitis) is seen in pernicious anemia and various vitamin B deficiencies. B₁₂ deficiency can present with glossitis but also shows anemia, fatigue, and neurologic symptoms. Beefy red tongue can also be associated with **glucagonomas**.

Glucagonomas (pancreatic α -cell tumors) secrete excessive amounts of glucagon and can cause a **beefy red tongue** (think **GL**ucagonoma = **GL**ossitis), angular cheilitis, and a **necrolytic** migratory erythematous rash. Patients with glucagonomas may develop the **4 Ds**: diabetes, deep venous thrombosis, depression, and dermatitis. Weight loss is characteristic. Erosions of the skin primarily affecting the groin, buttocks, and lower legs and sometimes affecting the face characterize the glucagonoma syndrome. When glucagonoma syndrome is diagnosed, it is important to rule out a zinc or magnesium deficiency because the presentations can be similar. The sooner the glucagonoma is found and treated, the better is the prognosis.

Macroglossia ("big tongue") is associated with multiple myeloma, primary amyloidosis, lymphoma, hemangioma, acromegaly, hypothyroidism, angioedema, and Down syndrome. Macroglossia associated with pinch purpura (i.e., purpura and ecchymoses that develop after mild trauma, such as pressure or rubbing), especially around the eyes, strongly suggests **amyloidosis**. Amyloid deposits present as waxy nodules around the face, neck, scalp, and hands.

"Geographic" tongue is an idiopathic inflammatory condition that results in the loss of filiform papillae. It has the appearance of **migratory**, denuded, erythematous patches with serpiginous, raised, white borders that resemble a map (**Figure 3-13**). It is asymptomatic and benign but is associated with psoriasis.

Figure 3-13:
Geographic tongue
Source: Kimberly Salkey, MD

"Strawberry" tongue is due to inflamed tongue papillae and is associated with scarlet fever, toxic shock syndrome, and Kawasaki disease (a mucocutaneous lymph node syndrome typically seen in children).

"Bald" tongue is **atrophy** of the lingual papillae associated with pellagra, iron deficiency anemia, pernicious anemia, and xerostomia (dry mouth; commonly seen in Sjögren syndrome, lymphoma, mumps, and sarcoidosis; occasionally idiopathic).

CUTANEOUS DRUG REACTIONS

PREVIEW | REVIEW

- What adverse cutaneous reactions are associated with phenytoin?
- What is gadolinium? What adverse reaction can it have?
- What drug class is the most common cause of isolated angioedema?

PRESENTATIONS

DRESS syndrome (drug reaction with eosinophilia and systemic symptoms) carries a mortality rate of about 10%. Patients typically present with a morbilliform rash, facial swelling, fever, lymphadenopathy, elevated liver enzymes, and hepatomegaly. The majority of cases have associated eosinophilia. Antiseizure medications and allopurinol are the most commonly implicated drugs. Treat by removing the offending medication. Of note, corticosteroids can improve the cutaneous and visceral (e.g., liver, lung, heart) manifestations of DRESS and can be lifesaving; however, relapses are often observed when the corticosteroids are tapered. In the months following DRESS resolution, monitor for long-term sequelae, which include autoimmune diseases such as Type 1 diabetes mellitus, hypothyroidism, and anemia.

Fixed drug eruption: This is a specific type of cutaneous drug reaction that recurs in the same location every time the offending drug is given. Most often, it will present in the mucosal sites of the vulva or penis, lips, hands, face, or feet and is a round or oval erythematous patch with some swelling and/or a blister. In time, it fades to purple/brown; the blister shrinks and peels off, but it can ulcerate. Treatment consists of discontinuing the offending drug.

SPECIFIC DRUGS

The following are the most frequently seen drug-associated skin changes. **Know all of them.**

Penicillin (PCN):

- **Immediate** hypersensitivity reaction; anaphylaxis (IgE)
- **Delayed** hypersensitivity reaction; immune complex reaction, such as vasculitis or morbilliform eruption

Tetracyclines: photosensitivity (demeclocycline > doxycycline > tetracycline > minocycline). Other drugs that commonly cause photosensitivity include fluoroquinolones (e.g., ofloxacin, ciprofloxacin), sulfonamides, furosemide, thiazides, phenothiazines, amiodarone, and retinoids.

Nonsteroidal antiinflammatory drugs (NSAIDs): urticaria/angioedema in 1% and asthma in 0.5% and can cause photosensitivity or toxic epidermal necrolysis (TEN).

Phenytoin:

- Hypersensitivity syndrome—rash, facial edema, lymphadenopathy, and hepatitis
- Various skin reactions, including erythema multiforme—an eruption of well-demarcated erythematous, targetoid papules (usually without scale) that commonly appear on palms and soles. It is often associated with drugs (e.g., NSAIDs, penicillin), as well as underlying infection such as herpes simplex virus (HSV) and *Mycoplasma*.

- Gingival hyperplasia is caused by 3 groups of drugs—immunosuppressants (e.g., cyclosporine), calcium channel blockers (e.g., nifedipine, verapamil, diltiazem, amlodipine), and anticonvulsants (e.g., phenytoin); also seen in M3 and M4 subtypes of acute myeloid leukemia.
- Hirsutism

Corticosteroids: skin changes, including striae, atrophy, telangiectasia, pigmentary changes, and acne-like lesions.

Warfarin: **necrotic** patches of skin appearing 3–10 days after starting warfarin, typically occurring in patients with previously undiagnosed **protein C deficiency**. Lesions classically affect areas with the highest fat deposition, such as the breasts, buttocks, thighs, and abdomen.

Radiocontrast media: This can cause urticaria/erythema (1:15 incidence) and, rarely, a severe anaphylactoid reaction (1:1,000 incidence; **not IgE mediated**). It is caused by the release of mast cells. With a prior reaction to contrast media, there is a 30% chance of a subsequent reaction; often, the recurrence is more severe. For the prevention of radiocontrast media cutaneous drug reaction, see the **Allergy & Immunology** section.

Gadolinium is a contrast material used for magnetic resonance imaging. It can cause nephrogenic systemic fibrosis, a fibrotic disease of the skin and internal organs similar to, but distinct from, systemic sclerosis (scleroderma) in that it typically spares the face. It is a disease exclusive to end-stage renal disease. There is no good treatment, so prevention is paramount. Do not give gadolinium to a patient with Stage 4 or higher chronic kidney disease!

ACE inhibitors (ACEIs): **Angioedema** occurs in only 0.5% of patients treated with an ACEI. However, because so many patients receive an ACEI, it is one of the most common causes of isolated angioedema (i.e., no concurrent urticaria [hives] or anaphylaxis). ACEI-associated angioedema usually involves the lips, tongue, mouth, and pharynx. Angioedema can occur at any time during treatment with ACEIs. Angiotensin receptor blockers (ARBs) **rarely** cause angioedema. However, use them cautiously in patients who have a previous history of angioedema with ACEI use. Make sure that the benefit outweighs the risk (e.g., systolic heart failure, significant proteinuria).

INFLAMMATORY SKIN DISORDERS

PREVIEW | REVIEW

- Nail pitting with onycholysis is a fairly specific finding for what dermatologic disorder?
- What drugs should be added to the regimen for patients with psoriatic arthritis?

- Characterize the malar rash of systemic lupus.
- What are the manifestations of limited systemic sclerosis?
- What skin findings are associated with sarcoidosis?
- What are the skin manifestations of dermatomyositis?
- Pyoderma gangrenosum is associated with which systemic illnesses?

NOTE

Many of the disorders described here are presented in more detail in the **Rheumatology** section.

PSORIASIS

Psoriasis is a response triggered by **T lymphocytes** in the skin. The epidermis becomes **hyperproliferative**, producing skin cells at a faster rate than normal. Trauma or irritation of normal skin commonly induces lesions of **psoriasis** at the site (Koebner phenomenon).

All types of psoriasis can be precipitated/exacerbated by **β-blockers**, stress, sunburn, lithium, and infection (e.g., virus, streptococcal pharyngitis). Obesity is associated with psoriasis, and significant weight loss may lead to clinical improvement.

Types of Psoriasis

Plaque psoriasis is the **most common** type of psoriasis (**Figure 3-14**). It presents with well-defined, stable, slow-growing, erythematous skin lesions with distinctive **mica-like** (silvery) scales. Pruritus is variable (absent to severe), with patients usually having mild itching. It is typically **symmetric** and occurs on **extensor** surfaces of the knees and elbows, the sacral area, and the scalp.

Figure 3-14: Plaque psoriasis
Source: Kimberly Salkey, MD

Guttate (eruptive) psoriasis is an **abrupt** eruption of **multiple** small salmon-pink or red lesions (3–10 mm in diameter) and typically occurs on the **trunk** of children or young adults with no previous history of psoriasis (**Figure 3-15 on page 3-10**). Streptococcal pharyngitis is a known trigger of guttate psoriasis.

Figure 3-15: Guttate psoriasis

Source: Jennifer Vickers, MD

Flexural (inverse) psoriasis affects **skin fold** areas. It is called inverse because it is **not** on the extensor surfaces.

There are 2 rare, especially **severe** types of psoriasis:

- 1) Erythrodermic psoriasis
- 2) Pustular psoriasis

Erythrodermic psoriasis is an exfoliative reaction in which the entire surface of the skin becomes red, warm, and scaly—and the patient is **unable to control body temperature** (hypo-/hyperthermia is typical). Dehydration, hypoalbuminemia, and anemia of chronic disease are common sequelae. Erythrodermic psoriasis is an uncommon psoriasis subset but can be life-threatening.

In patients with stable psoriasis, erythroderma (involvement of > 90% body surface area) can be precipitated by certain medications. Potential offenders exacerbating psoriasis include β -blockers, NSAIDs, antimalarials, TMP/SMX, gold, and lithium, as well as the rebound effect of topical and oral steroids. If possible, β -blocker use should be avoided in patients with psoriasis.

Pustular psoriasis has many small pustules, often coalescing to form “**psoriatic lakes of pus**.” There are 2 forms:

- 1) The **localized** form affects only the palms and soles. It is associated with distal interphalangeal joint (DIP) joint arthritis.
- 2) The rare, **generalized** form (von Zumbusch type) is the **most severe form** of psoriasis and can occur with the erythrodermic type. Sudden withdrawal of systemic corticosteroids is a well-described inciting event.

Exfoliative dermatitis (erythroderma) is not associated with herpes simplex or herpes zoster. It is frequently seen as an allergic reaction to drugs such as sulfonamides, antimalarials, penicillin, phenytoin, and barbiturates. It has also been associated with psoriasis, atopic dermatitis, or malignancy (especially cutaneous T-cell lymphoma). Up to 30% of cases are idiopathic. No matter what the etiology, skin biopsy is often nonspecific. The course and prognosis of exfoliative dermatitis are related to the

course of the underlying process. Drug-induced exfoliative dermatitis has the best prognosis, whereas cases associated with malignancy have the highest mortality.

Nail Changes in Psoriasis

50% of patients with plaque psoriasis and 80% of those with psoriatic arthritis have fingernail changes. These can cause significant functional impairment, pain, and distress.

Psoriatic changes of the nails differ in the fingernails and the toenails. The toenail changes seen in psoriasis can be difficult to distinguish from onychomycosis.

Know the following about these fingernail findings:

- The **most common** nail change in psoriasis is “ice-pick” pitting; these pits are usually in small irregular groups on the nail (in contrast to a gridlike pattern of pitting seen in alopecia areata). Pitting is an expression of disease activity; normal nails between the groups of pits indicate disease-free activity.
- The **most specific** psoriatic nail finding is a yellow or salmon-colored “oil spot” beneath the nail plate.
- Any of these fingernail changes in a psoriasis patient are a predictor of **psoriatic arthritis**; a strong predictor is pitted nails in association with onycholysis (separation of distal nail plate from the nail bed; [Figure 3-16](#)). For more on psoriatic arthritis, see the [Rheumatology](#) section.

Figure 3-16: Pitted nail with onycholysis

Source: Kimberly Salkey, MD

Drugs Used to Treat Psoriasis

Know all of these.

Topical corticosteroids are the primary treatment for plaques. To increase their effectiveness, topical steroids can be occluded with cellophane or plastic wrap. Long-term use of high-potency steroids causes striae and thinning of the skin, and their use is especially avoided on the face and intertriginous areas (i.e., skin-to-skin areas, such as the axillae, under the breasts, the anogenital area, and between digits). **Oral corticosteroids** are not used, because they cause “rebound flares.” (See pustular psoriasis under [Types of Psoriasis on page 3-9](#).)

Tar is a traditional treatment that is safe and moderately effective. It is often combined with a corticosteroid in a compounded preparation. Application is time consuming, odorous, and messy, but tar is well tolerated and reasonably priced.

Calcineurin inhibitors: **topical tacrolimus** and **topical pimecrolimus**. These are often used for facial and intertriginous areas where high-potency steroid use is avoided.

Be aware of the FDA black box warning for a potential increased risk of lymphoma and skin malignancy with calcineurin inhibitors.

Phosphodiesterase-4 inhibitor: Apremilast (Otezla; FDA approved in 2014) is a systemic medication that suppresses inflammatory cytokines and mediators.

Retinoids (vitamin A derivatives):

- Tazarotene gel decreases the hyperkeratosis or thick scales associated with psoriasis; the main side effect is skin irritation.
- Acitretin (Soriatane), a 2nd generation oral retinoid, is used for severe psoriasis of all types. Because of its potentially toxic effects, it must be monitored closely and used with caution. Acitretin has a side-effect profile similar to that of isotretinoin, although its potential for teratogenicity can last up to 3 years after discontinuing the medication; this is in contrast to isotretinoin, which has potential teratogenicity for 1 month following discontinuation of the medication. (See moderate-to-severe inflammatory acne under [Treatment of Acne Vulgaris on page 3-4.](#))

Do not use acitretin in women with childbearing potential who use unreliable contraceptive prevention. **Important:** The FDA has warned against the use of acitretin in women who are pregnant or who intend to become pregnant in the **3 years** following treatment.

Vitamin D₃ analogs: These agents are less effective than high-potency topical steroids but do not cause thin skin or striae.

Immunosuppressants: Both methotrexate (MTX) and cyclosporine are very effective for extensive severe psoriasis:

- MTX can cause severe liver and pulmonary toxicity, as well as bone marrow suppression. **Do not** give MTX to patients with a history of alcohol abuse, liver disease, or severe kidney impairment. (The drug is excreted renally.)
- Cyclosporine can cause renal toxicity and hypertension and is recommended only for short-term “rescue” use.

Biologic immunomodulators: These **effective** treatments for psoriasis have provided safe options for patients with moderate to severe psoriasis. The biologic immunomodulators include:

- TNF- α inhibitors: **etanercept**, **infliximab**, **adalimumab**, certolizumab
- IL-12 and IL-23 blockers—**ustekinumab** (Stelara)
- IL-17A blocker—secukinumab (Cosentyx), ixekizumab (Taltz), brodalumab
- IL-23 inhibitor—guselkumab (Tremfya), tildrakizumab (Ilumya)

Ultraviolet (UV) light can be added to the above treatments or used as monotherapy. UVB (290–320 nm) therapy is often used. Narrow-band UVB (NB-UVB; **311 nm**) is

possibly more effective than the broader-spectrum treatment and generally is the treatment of choice, but it requires more expensive equipment and a longer duration of therapy per session.

PUVA (psoralen + long-wave UVA [320–400 nm]) is also very effective and is usually given to those who fail UVB. UVA penetrates more deeply than UVB and is less likely to burn (hence, the photosensitizing psoralen), **but** it is associated with accelerated photoaging, an increased likelihood of skin cancer (squamous cell carcinoma), and possibly melanoma in fair-skinned Caucasians. Future treatment with cyclosporine increases this risk.

Any patient with psoriatic arthritis is at risk for permanent joint damage. Treat with a disease-modifying oral/injectable agent (cyclosporine, MTX, or the biologics). Classic presentation of psoriatic arthritis is symmetric DIP arthritis, but asymmetric arthritis can also be seen with a “sausage digit”; 1/3 of patients with psoriasis will get arthritis. See the [Rheumatology](#) section.

Treatment of Psoriasis

Recommended treatment for psoriasis depends on the severity of disease, percentage of body surface area (BSA) involved, and involvement of the hands, feet, or facial or genital regions. Involvement of these locations can interfere significantly with activities of daily living, irrespective of the amount of BSA involved.

Limited/mild disease (< 5% BSA): Use high-potency or ultra-high-potency topical corticosteroids. Taper to a mid-potency agent for maintenance. For scalp involvement, use topical steroid solutions, foams, or lotions.

For the face and intertriginous areas, use:

- low-potency corticosteroids,
- topical tacrolimus or pimecrolimus,
- calcitriol, or
- topical retinoids (tazarotene).

If the patient fails to respond, UV-based or short-term systemic therapy can be used.

Moderate disease (5–9% BSA): Treatment is the same as for limited disease except that UV light therapy (typically **NB-UVB**) is routinely used. PUVA can be used for those who fail UVB therapy. Depending on morbidity associated with the disease, consider treatment with systemic agents, such as MTX, acitretin, apremilast, or a biologic.

Widespread/severe disease ($\geq$ 10% BSA): NB-UVB is recommended, with consideration of PUVA for failures. Treat with MTX, cyclosporine, a biologic, or a combination of these therapies. The combination of UVB or PUVA with acitretin is especially effective for pustular psoriasis.

Guttate psoriasis: Treat with UVB +/- topical steroids. Treat any streptococcal infection.

Flexural psoriasis: Treat with low-potency topical corticosteroids or with topical tacrolimus or pimecrolimus.

LUPUS

Systemic lupus erythematosus (SLE): Malar (a.k.a. “butterfly”) rash occurs in about 1/2 of acute SLE patients and rarely occurs in patients without systemic symptoms. Classically, this rash involves both cheeks and extends across the bridge of the nose, sparing the nasolabial fold (Figure 3-17). The malar rash is erythematous and either flat or slightly edematous, and it often occurs after sunlight exposure (photosensitivity); there is no scarring.

Figure 3-17: Classic systemic lupus erythematosus rash

Rosacea can mimic a malar rash but can be distinguished by prominent telangiectasias, papules/pustules, and the lack of systemic symptoms. Likewise, seborrheic dermatitis can mimic a malar rash but can be distinguished by involvement of the nasolabial folds, which are spared with the malar rash of SLE.

SLE patients can get a red, scaly rash on the backs of the hands and fingers, often sparing the knuckles. This is in contrast to the Gottron papules of dermatomyositis, in which the rash occurs over the knuckles.

Patchy nonscarring alopecia is typical in SLE. See the Rheumatology section for more on SLE.

Subacute cutaneous lupus erythematosus (SCLE) is a distinct subset of lupus characterized by erythematous macules/papules that evolve into papulosquamous plaques on sun-exposed areas. Like the acute rash of SLE, but in contrast to discoid lupus, these lesions heal without scarring. Many patients are seropositive for SSA and/or SSB antibodies. Patients uncommonly have significant systemic manifestations.

Chronic cutaneous lupus erythematosus (discoid lupus): Discoid lesions are erythematous and raised with tightly adherent scales. They cause atrophic scarring. They typically occur on sun-exposed areas, including the face, scalp, neck, and ear canals. Only 5% of discoid lupus patients develop SLE. However, patients with SLE who develop discoid lupus lesions tend to have a very good prognosis, devoid of significant renal manifestations.

Intralesional corticosteroids are especially effective for discoid lupus. 1st line oral therapy includes antimalarials, such as hydroxychloroquine. More aggressive systemic therapy with immunosuppressants (e.g., MTX, azathioprine, mycophenolate mofetil) is used in severe cases or for treatment of SLE with significant systemic involvement.

SCLERODERMA — MORPHEA AND SYSTEMIC SCLEROSIS (SSc)

Scleroderma means “hard skin.” It is a connective tissue disorder that always involves the skin but may additionally

have systemic involvement. Skin (and subadjacent tissues) involvement is called **morphea** (a.k.a. localized scleroderma). Disease with systemic involvement is called **systemic sclerosis**.

Morphea is characterized by plaques that become sclerotic with a hypopigmented center and erythematous border. It usually occurs in children or young adults. It can be just a few lesions (localized morphea) or widespread with some confluence (generalized morphea).

SSc has systemic involvement, and patients commonly have associated fatigue, weakness, stiff joints, and pain. It has 2 major subtypes, depending on the extent of skin sclerosis:

- **Limited SSc** (previously CREST) is a grouping of symptoms that has limited systemic involvement, most commonly manifesting as skin thickening distal to the elbows and knees but sometimes affecting the face and neck. Patients classically present with several to all of the **CREST** features: calcinosis cutis (small tender nodules on the fingers), Raynaud syndrome, esophageal dysmotility, sclerodactyly of the fingers, and telangiectasias. Anticentromere antibody (ACA) is specific for limited SSc and is seen in about 50% of patients. Patients who are ACA+ tend to develop more severe digital ischemia and pulmonary hypertension.
- **Diffuse SSc** is the progressive form of SSc that leads to diffuse skin thickening and is more likely to have multiorgan involvement. Rapid skin involvement of the trunk, face (Figure 3-18), upper arms, and thighs characterizes this subset. It is frequently associated with antitopoisomerase I (anti-Scl-70) or anti-RNA polymerase III antibodies, and patients are more likely to develop interstitial lung disease and scleroderma renal crisis.

Figure 3-18: Diffuse systemic sclerosis
Source: Kimberly Salkey, MD

Raynaud phenomenon eventually develops in almost all patients with SSc. In **limited** SSc, Raynaud's usually occurs several years **before** other signs and symptoms become apparent, whereas in **diffuse** SSc, Raynaud's typically occurs simultaneously with the other manifestations.

Nail-fold capillary changes are commonly seen in both subtypes and correlate with severity of disease.

Immune modulation is the usual treatment.

SARCOIDOSIS

Sarcoidosis is a **noncaseating** granulomatous disease, of unknown etiology, that often affects the lungs, lymph nodes, eyes, and **skin**. It is most common in northern European countries (e.g., Sweden, Denmark). In the U.S., sarcoidosis affects African Americans 3–4× more often than Caucasians. Skin involvement is seen in about 25% of patients. Sarcoidosis is a great **mimicker** of other disorders, including many dermatologic diseases.

Lesions are divided into 2 categories:

- 1) Specific sarcoid skin lesions have noncaseating granulomas on biopsy and are most commonly found on the head, neck, and upper back. Specific lesions include:
 - Erythematous papules, mainly around the face (the most common presentation)
 - Scar sarcoidosis presenting as granulomatous changes in a healing skin wound or scar tissue (e.g., laceration, tattoo)
 - Plaquelike lesions
 - Micropapular lesions
- 2) Nonspecific skin lesions do not have granulomas and are considered reactive. They include:
 - Erythema nodosum is the most typical nonspecific skin lesion seen in sarcoidosis and is a marker of good prognosis. Sarcoidosis is one of the most common causes of erythema nodosum. **Do not** biopsy erythema nodosum in sarcoidosis for the diagnosis of sarcoidosis—the histopathology shows just a panniculitis (inflammation of the fat) and not granulomas. (See [Erythema Nodosum](#).)
 - Löfgren syndrome is an acute form of sarcoidosis that presents with erythema nodosum, bilateral hilar adenopathy, and arthritis and is frequently accompanied by fevers. It is usually self-limiting and requires only supportive care.

Lupus pernio is a type of sarcoidosis that has skin changes ranging from violaceous (purple) lesions on the tip of the **nose** and **earlobes** to large purple nodules/tumors on the **face** and **fingers**. It has a slow onset and almost **never** resolves! It is associated with chronic disease and extra-pulmonary involvement.

Treat cutaneous sarcoidosis with topical corticosteroids, intralesional steroid injections, antimalarials, and MTX. Lesions typically respond to treatment for pulmonary sarcoidosis.

For more information on sarcoidosis, see the [Pulmonary Medicine](#) section.

ERYTHEMA NODOSUM

Erythema nodosum ([Figure 3-19](#)) consists of red, warm, very tender nodules that are usually bilateral, symmetric, and classically located on the shins. It is more common in women than in men. **Know!** Erythema nodosum is associated with:

- Sarcoidosis (common)
- Inflammatory bowel disease
- Infection (e.g., tuberculosis, **streptococcal**, deep fungal, hepatitis B, *Coccidioides immitis*, *Histoplasma capsulatum*)
- Drugs (especially oral contraceptives, sulfas, and penicillins)
- Pregnancy
- Löfgren syndrome when arthralgia/arthritis and hilar adenopathy are also present
- Idiopathic

Figure 3-19: Erythema nodosum
Source: James Heilman, MD

Worldwide, **streptococcal infection** pharyngitis is probably the **most common cause** of erythema nodosum. Treatment consists of treatment of the underlying disorder and supportive therapy including NSAIDs.

DERMATOMYOSITIS

Buzzwords: **Gotttron papules** and **periorbital heliotropic** rash (a violaceous, sometimes scaly rash around the eyes; [Figure 3-20](#)) +/- periorbital edema.

Figure 3-20: Periorbital heliotropic rash
Source: Kimberly Salkey, MD

Patients also manifest photodistributed, erythematous, scaly plaques—similar to psoriasis. Gottron sign is macular erythema over the dorsal aspects of the interphalangeal/metacarpophalangeal (MCP) joints or over the elbows and knees.

Gottron papules, an extension of Gottron sign, are flat-topped, reddish-to-violet, sometimes scaling papules; sometimes they just look like “cigarette paper” crinkling of the skin over the **knuckles** (MCP, proximal interphalangeal (PIP), and/or DIP). Gottron papules are the most specific finding with dermatomyositis. They may be described only as a “rash” or “eruption” over the knuckles (Figure 3-21). Again, this contrasts to the finger rash in SLE, which spares the knuckles. “Mechanic’s hands” are bilateral, symmetric areas of hyperkeratotic scale most typically on the lateral fingers or on the palm. This finding is associated with antisynthetase syndrome, anti-Jo-1 antibodies, and interstitial lung disease.

Figure 3-21: Gottron papules
Source: Kimberly Salkey, MD

Patients have symmetric proximal muscle weakness but may present solely with cutaneous disease, termed amyopathic dermatomyositis.

Remember: In **older** patients, dermatomyositis may be a **paraneoplastic** phenomenon. (Genitourinary [GU]/ovarian, gastrointestinal [GI], lung, and lymphoma are most common.) Offer all patients age-appropriate cancer screening. Patients who test positive for anti-p155/p140 are at particularly high risk of cancer.

Treatment of dermatomyositis is **corticosteroids**. This is usually given for 1 year in a slowly tapering dose. A steroid-sparing drug (azathioprine, MTX, or mycophenolate mofetil) is sometimes started with initial treatment; other clinicians start it when there is failure to respond to prednisone.

Antimalarials (hydroxychloroquine is 1st line) help with the skin disease but do **nothing for the muscle disease**. IV gamma globulin may be effective in patients who do not respond to the other medications. Rituximab is an effective 2nd line treatment for systemic disease and 3rd line treatment for cutaneous disease.

More information on dermatomyositis is given in the **Rheumatology** section.

REACTIVE ARTHRITIS

Reactive arthritis is an immunologic reaction to an infection elsewhere in the body and typically occurs 1–4 weeks after a GU or GI infection. The classic triad of urethritis, conjunctivitis, and asymmetric arthritis is seen in less than 1/3 of patients. Cutaneous manifestations are common

and include keratoderma blennorrhagicum and mucocutaneous genital lesions and/or mouth ulcers.

Keratoderma blennorrhagicum (Figure 3-22) classically presents as papules/pustules with central erosion and characteristic crusting on the palms and soles. It can be indistinguishable from pustular psoriasis.

Figure 3-22: Keratoderma blennorrhagicum
Source: CDC

Circinate balanitis presents as an erythematous pustular or plaquelike lesion on the glans or shaft of the penis.

For more information on reactive arthritis, see the **Rheumatology** section.

VASCULITIS

Vasculitis presents most classically as **palpable purpura**, usually starting on the legs. Palpable purpura is the extravasation of red blood cells into the skin and is commonly caused by a small vessel vasculitis. Skin biopsy typically displays leukocytoclastic vasculitis. There are many causes of cutaneous vasculitis, including infection (e.g., viral, bacterial), collagen vascular disease, and drug reactions. Up to 50% of self-limited cutaneous cases may be idiopathic. Always look for extracutaneous manifestations, especially kidney involvement. If a young patient presents with arthralgias, abdominal pain, renal disease, and palpable purpura, think IgA vasculitis.

For more information on small vessel vasculitides, see the **Rheumatology** section.

PETECHIAE / PURPURA / ECCHYMOSIS

Defined as hemorrhage into the skin or mucosal membranes, purpura has a vast and complicated differential diagnosis. Classifying the patient’s physical findings by morphology can facilitate the evaluation of a patient with primary purpura.

Petechiae (≤ 4 mm): The etiology of petechiae can be further broken down into 3 types of pathophysiology: hemostatically relevant thrombocytopenia (e.g., immune thrombocytopenia, thrombotic thrombocytopenia, disseminated intravascular coagulation), abnormal platelet function (congenital or acquired platelet dysfunction),

and nonplatelet etiologies (e.g., trauma, scurvy, benign pigmented purpura).

Macular purpura (5–9 mm): The differential diagnosis of macular purpura includes hypergammaglobulinemic purpura of Waldenström, infection or inflammation in patients with thrombocytopenia, scurvy, and small vessel vasculitis that is minimally inflamed.

Macular ecchymosis (≥ 1 cm): Like petechiae, ecchymosis can be further broken down into 3 types of pathophysiology: procoagulant defect (especially anticoagulant use, hepatic failure, and vitamin K deficiency), poor dermal support (as with solar purpura, systemic steroid therapy, Ehlers-Danlos, and scurvy), and platelet problems (usually thrombocytopenia or von Willebrand disease).

Palpable purpura: The potential etiologies of palpable, or inflammatory, purpura are vast. It may be triggered by the deposition of immune complexes, such as those caused by infection or drugs. It may be due to small or medium vessel vasculitis, such as that seen on biopsy in mixed cryoglobulinemias, rheumatic vasculitis, and antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis. Leukocytoclastic vasculitis (LCV) is a nonspecific inflammatory neutrophilic infiltration in the setting of a small vessel vasculitis. Non-LCV causes may include erythema multiforme and benign pigmented purpura.

PYODERMA GANGRENOSUM

Pyoderma gangrenosum is an inflammatory (not infectious and not a vasculitis) ulcer typically occurring on the legs (Figure 3-23). It is most commonly associated with inflammatory bowel disease but also can be seen with rheumatoid arthritis, ankylosing spondylitis, and hematologic malignancy. However, it is idiopathic in 25–50% of patients. Although a skin biopsy is **not** diagnostic (i.e., would reveal nonspecific neutrophilic infiltrate), it serves to exclude other causes of ulceration. The classic presentation is a deep ulceration with an inflamed and violaceous border that overhangs the ulcer. Treating the colonized bacteria usually does **not** help. Patients often complain of pain out of proportion to the clinical appearance of the lesion. **Pathergy**, the appearance of ulcers or lesions at sites of cutaneous trauma, is a common phenomenon; avoid wound debridement.

In idiopathic cases, 1st line treatment is corticosteroids. Otherwise, treat the underlying disorder. Patients may still require pulse dose steroids.

Figure 3-23: Pyoderma gangrenosum
Source: Kimberly Salkey, MD

SWEET SYNDROME

Sweet syndrome is an inflammatory disorder that is also referred to as acute febrile neutrophilic dermatosis. It can be:

- Idiopathic (50%)
- Drug induced
- Postinfectious
- Pregnancy related
- Seen with inflammatory or autoimmune disorders
- Seen with underlying hematologic malignancy (e.g., acute myeloid leukemia)

Patients have **high fever** and painful red plaques, ~ 1 inch in diameter, typically on the upper extremities, trunk, neck, and face. These plaques may be bullous in nature. A skin biopsy shows a dense but benign **neutrophilic** infiltrate. The lesions respond dramatically to corticosteroids. Potassium iodide, dapsone, and colchicine are also 1st line agents.

NAIL DISORDERS

PREVIEW | REVIEW

- What nutrient deficiency is associated with spooned nails?
- What do dark red lines on a nail bed in an IV drug abuser suggest?

Koilonychia is characterized by thin, concave (spoon-shaped) nails. It resolves spontaneously in children but often is secondary to occupational demands or severe iron deficiency in adults.

Psoriatic changes of the nails are covered in [Nail Changes in Psoriasis](#) on page 3-10.

Clubbing of the nails is common. See the [Pulmonary Medicine](#) section for more information.

Onychomycosis has varied clinical findings depending on its cause. The most commonly observed pattern is the distal or lateral subungual type with invasion of the hyponychium. This is characterized by nail thickening, subungual debris, and yellow or brown discoloration.

The superficial white type is caused by direct invasion into the nail plate and may have white patches or white linear striations. This pattern may be associated with immunosuppression such as that seen in AIDS.

The proximal subungual type may also be associated with immunosuppression and caused by invasion of the proximal nail fold.

Diagnosis of onychomycosis can be confirmed with KOH scraping, periodic acid-Schiff (PAS), and/or culture of a nail clipping and should be done before treating as 50% of suspected cases do not have a fungal infection and treatment with oral antifungals, although most efficacious,

can be toxic. Psoriasis and nail dystrophy can mimic fungal infection. Terbinafine is given for 12 weeks for toenail infections and 6 weeks for fingernail infections. Terbinafine is associated with hepatic failure, Stevens-Johnson syndrome (SJS)/TEN, and pancytopenia.

Onycholysis frequently involves the fingernails, and affected nails are detached from the nail bed. Idiopathic onycholysis may be due to exposure to irritants or water exposure. White or green discoloration may accompany changes. Onycholysis also can be secondary to trauma, psoriasis, tetracyclines, hypothyroidism, or fungal infections. As mentioned previously, onycholysis with pitting is a strong predictor of psoriatic arthritis. See [Nail Changes in Psoriasis on page 3-10](#).

Paronychia can be acute or chronic. Acute paronychia is characterized by swelling, redness, and pus of the proximal nail fold. It is most commonly caused by bacterial infection following trauma. If it is recurrent, consider HSV and perform culture or polymerase chain reaction (PCR). Treatment includes drainage of the abscess and appropriate antimicrobial treatment (antibiotics for bacterial etiology and antivirals for those cases due to HSV). Clinical features of chronic paronychia include erythema and edema of the proximal nail fold and absence of the cuticle ([Figure 3-24](#)). It is thought to be secondary to exposure to irritants or allergens and has a prolonged course. Treatment is avoidance of exacerbating factors, topical steroids, and antiseptics. Do not confuse a paronychia with a felon (which causes a painful infection involving the finger pad and nail bed) or a herpetic whitlow with an associated herpetic vesicular lesion (contagious).

Figure 3-24: Paronychia

Splinter hemorrhages are dark red, thin lines usually located to the distal portion of the nail ([Figure 3-25](#)). They are most commonly due to trauma, psoriasis, or onychomycosis. They may also indicate underlying systemic disease such as endocarditis, vasculitis, and antiphospholipid syndrome. Splinter hemorrhages can be seen in IV drug abusers, who are also at risk of endocarditis.

Figure 3-25: Splinter hemorrhage

Nail-fold telangiectasias are common in patients with connective tissue disorders. Patients with dermatomyositis and scleroderma may have reduced capillary density with avascular areas that alternate with dilated capillary loops. Patients with lupus may have normal capillary density with dilated capillary loops.

CUTANEOUS MANIFESTATIONS OF NUTRITIONAL DISORDERS

PREVIEW | REVIEW

- What vitamin deficiency causes a photosensitivity dermatitis?
- What are the dermatologic manifestations of zinc deficiency?
- What vitamin deficiency causes follicular hyperkeratosis?

Deficiency of B₁₂, folate, or niacin may cause diffuse hyperpigmentation, as well as hair and nail changes.

Niacin deficiency results in pellagra (remember the **3 Ds**: dermatitis [photosensitive areas], diarrhea, and dementia). **Isoniazid** and **carcinoid syndrome** (which is characterized by flushing of the skin) can also induce pellagra. Isoniazid is a competitive inhibitor of nicotinamide adenine dinucleotide (niacin precursor) and impairs pyridoxine functioning, which is essential for niacin synthesis from tryptophan.

Tryptophan can be metabolized to niacin or serotonin by 2 separate pathways. In carcinoid syndrome, most of the L-tryptophan is diverted to the production of serotonin, leaving the patient at risk for niacin deficiency.

Zinc deficiency causes an irritant eczematoid red rash that has a predilection for periorificial (e.g., perioral, periocular, anogenital) and acral (i.e., hands and feet) areas.

Iron deficiency is usually associated with hair loss, fragile longitudinal nail ridges, and koilonychia (spoon-shaped nails).

Vitamin C deficiency can result in follicular hyperkeratosis, especially on the posterolateral aspect of the arms, resembling keratosis pilaris. The hairs within these plugged follicles become curled, resulting in “corkscrew” hairs. Perifollicular purpura and petechiae develop as the disease advances.

ENVIRONMENTAL INJURY TO THE SKIN

Thermal burns are categorized by depth:

- **Superficial** (previously 1st degree): limited to epidermis; red, blanches with pressure, **dry**, minor swelling, and minor **pain**. Commonly resolves in 5–7 days.
- **Partial-thickness** (previously 2nd degree) is divided into superficial and deep:
 - Superficial partial-thickness: papillary dermis; blistering, pink, **moist**, much more painful. Typically heals in 2–3 weeks without scarring.
 - Deep partial-thickness: reticular dermis; blistering, red and/or white with poor blanching and capillary refill, moist or dry, typically **painful** with variable sensation to light touch. Can take 3–9 weeks to heal, often with scarring.
- **Full-thickness** (previously 3rd degree): entire epidermis and dermis; dry, leathery, waxy, and **painless**. Requires skin grafting unless small. When fully circumferential, a full-thickness burn can form a strangulating eschar that causes ischemia distally.
- **4th degree** involves skin, subcutaneous tissue, and underlying structures (i.e., fascia, muscle, bone).

General treatment of superficial or superficial partial-thickness burns includes cool compresses for pain relief and infection prevention with application of topical antimicrobial agents such as silver sulfadiazine. Deep partial-thickness, full-thickness, and 4th degree burns often require surgical debridement and skin flaps.

Frostbite (FB) occurs when skin temperature falls below 28.0°F (–2.0°C). It can be divided into 4 categories of severity:

- 1st degree FB is characterized by edema, erythema, and transient pain. Patients have full recovery.
- 2nd degree FB is characterized by severe erythema, edema, and blistering. Patients may have lasting neuropathy.
- 3rd degree FB is characterized by full-thickness loss of the dermis with hemorrhagic bullae and waxy, dull skin.

- 4th degree FB can result in loss of skin, as well as loss of underlying structures such as muscle and bone. Damage of this degree may require amputation.

Treatment includes rapid rewarming and reestablishment of circulation.

SKIN INFECTIONS

PREVIEW | REVIEW

- What is the significance of finding a lesion of ecthyma gangrenosum on physical exam?
- What 2 organisms can cause impetigo?
- Characterize the lesions of disseminated gonorrhea.

- Characterize the rash of erythema migrans.
- What antibiotic is used to treat a cat bite?
- What tinea infections require oral therapy?
- Molluscum contagiosum, if seen in an adult, should raise your suspicion for what immunodeficiency?
- How does the dose of acyclovir differ when the drug is used to treat varicella and herpes simplex infections in the immunocompromised?
- What are the treatments for head lice? What topical treatment is not pesticide based? What drug is the most potent for head lice?
- What type of lice is sexually transmitted?
- How do the effects of the venoms of the brown recluse and black widow spiders differ?
- What spider bite has a longer recovery time?

BACTERIAL SKIN AND SOFT TISSUE INFECTIONS

Many of the following infections and treatments are covered more fully in the [Infectious Disease](#) section.

Cellulitis and Abscesses

Erythrasma is a well-defined, red lesion with some slight scaling. It is usually found in the axilla, groin, and toe webs. In the **obese**, it is seen **under the breasts**. Gram-positive *Corynebacterium minutissimum* is frequently isolated from the lesion (especially after it has become scaly or macerated). **Differential diagnosis**: tinea cruris, *Candida*, and intertrigo (an irritant dermatitis typically found in the skin folds of obese patients; see [Intertrigo on page 3-2](#)). Diagnosis: Erythrasma fluoresces **bright red** (attributed to coproporphyrin III) with a Wood lamp (UV light). Treat with benzoyl peroxide or topical erythromycin +/- an “-azole” antifungal cream. In severe cases, oral erythromycin or tetracycline may be used.

Folliculitis

Folliculitis inflammation of hair follicles usually caused by *S. aureus*. **Furuncles** (deep folliculitis or “boils”) are a folliculitis that extends deep into the dermis. **Carbuncles** are collections of furuncles that have coalesced under the skin, forming a networked, single mass. Treatment includes oral or parenteral antibiotics and moist heat; consider surgical drainage of fluctuant lesions.

Be aware that folliculitis associated with **hot tubs** is often caused by *Pseudomonas*, **not** *Staphylococcus*, and is acquired in hot tubs with inadequate chlorination. The resulting pustules usually occur around the buttocks and thighs or in occluded skin areas (e.g., in skinfolds; under a swimsuit). Pseudomonal folliculitis resolves **without** treatment in ~ 1 week. 5% acetic acid (i.e., vinegar) compresses can be used for symptomatic relief.

A much more serious infection is *Pseudomonas* septicemia with the initial dermatologic finding of small, dark-centered (necrotic) papules. In a very ill, **neutropenic** patient, this papule progresses and becomes the pathognomonic **ecthyma gangrenosum**, a necrotic ulcer with an erythematous rim (Figure 3-26).

Figure 3-26: Ecthyma gangrenosum
Source: Kimberly Salkey, MD

Impetigo

Staphylococcus aureus is by far the most common cause of impetigo, although it also may be caused by group A *Streptococcus*. It starts as an erythematous, vesicular lesion that quickly becomes pustular and crusty (a honey-colored crust). Impetigo is highly contagious, and patients generally do not appear systemically ill. The face and exposed areas are most commonly affected. Methicillin-resistant *S. aureus* (MRSA) causes many **community outbreaks**. When impetigo, an infection of the epidermis, extends into the dermis, it is called **ecthyma**.

Limited skin lesions can be treated with topical mupirocin for 5 days. Extensive lesions and ecthyma require oral treatment with antibiotics that cover both *S. aureus* and streptococci. These include dicloxacillin or cephalexin with erythromycin as an alternative for allergic patients. If MRSA is suspected by history or culture, use clindamycin, trimethoprim/sulfamethoxazole (TMP/SMX), or doxycycline. The usual course of treatment with oral agents is 7 days.

Note: Bullous impetigo usually occurs in young children < 2 years of age and presents with the acute onset of large, loose bullae (Figure 3-27). An exotoxin/exfoliatin toxin causes cleavage of the epidermis.

Figure 3-27: Bullous impetigo
Source: CDC

Erysipelas

Erysipelas is an explosive superficial infection (often caused by group A *Streptococcus*) that is confined to the dermis and spreads quickly through skin **lymphatics** (Figure 3-28). The area of infection is **clearly demarcated**, red, and palpable. It usually starts from a superficial abrasion, typically around the central face, with erythema and swelling. Lymphangitic spread with red **streaking** is seen. Initial treatment is IV antibiotics followed by oral therapy.

Figure 3-28: Erysipelas
Source: CDC

Necrotizing Fasciitis

Necrotizing fasciitis (NF) is a deep soft tissue infection involving planes of subcutaneous fat and fascia. This area contains the nerve bundles, which, when damaged, cause extreme pain followed by anesthesia. Blood supply can also be damaged, so antibiotic

response is poor and necrosis of the overlying tissue occurs. Unlike erysipelas, NF does not have a distinct border and can be difficult to diagnose early. NF can be hard to distinguish from cellulitis in the early stages, but in NF, the pain is usually out of context to the physical signs and there are septic symptoms. Enquire about any history of skin trauma. Cellulitis is characterized by erythema, swelling, and lymphangitis. Lymphadenopathy is absent in NF, and skin changes rapidly progress with violaceous discoloration and sometimes blisters (necrosis) and crepitus. Diagnosis of NF should lead to antibiotic therapy and urgent surgical exploration.

There are 2 types: **Type I**, the most common type, is a **polymicrobial infection** (including anaerobes) seen in **immunocompromised** patients, such as diabetics. **Type II** is generally caused by group A *Streptococcus* or MRSA and most commonly affects **healthy individuals**. If suspected, obtain cultures, start antibiotic therapy, and consult surgery immediately as this is a **surgical emergency** and there is a **high mortality rate** even with appropriate medical and surgical intervention. Avoid wasting time with computed tomography scans if diagnosis is suspected.

Gonococcus and Meningococcus

Disseminated gonococcal infection causes a few (commonly < 12) hemorrhagic pustules on the extremities, often around the joints. Culture of the skin lesions is typically negative. Swab for cultures from the initial site of infection (oral mucosa, cervix, urethra, or rectum) because there is a much higher yield.

Meningococcemic skin signs start as macular or petechial lesions and evolve to large purpura. Purpura fulminans consists of purpura, ecchymoses, and confluent maplike, gray-to-black, necrotic skin lesions. It is associated with severe infection and diffuse intravascular coagulation.

Staphylococcal Scalded Skin Syndrome (SSSS)

SSSS primarily affects newborns and children < 5 years of age, but, rarely, it affects immunocompromised adults. Patients with SSSS present with **tender, red, peeling skin**—due to circulating toxins from localized *Staphylococcus* infection or colonization that generally is initiated at a **nonskin site** (e.g., sinuses, umbilicus in infants). Skin changes are similar to those seen in toxic epidermal necrolysis (TEN), which is noninfectious (i.e., a side effect of drugs), so consider it during the workup. The skin in SSSS separates **much more superficially** than in TEN. The peeling skin is caused by a similar exotoxin or exfoliatin toxin, as seen in bullous impetigo (a localized form of SSSS); however, it **circulates systemically in SSSS**. Treatment includes debridement of necrotic superficial epidermis, topical antibiotics for bullous impetigo lesions, and systemic antibiotics for more severe and/or widespread disease.

Toxic Shock Syndrome (TSS)

TSS is caused by *Staphylococcus aureus* and *Streptococcus pyogenes*. First described in 1978 in association with the use of highly absorbent tampons in menstruating women, today > 50% of cases are not associated with menstruation.

Staphylococcal TSS presents with abrupt development of fever, shock, and **multiorgan** system failure. In the acute phase, patients develop a diffuse, painless, macular erythrodermic rash (“sunburn”) followed by desquamation of the palms and soles during the convalescent phase. Patients are commonly < 30 years of age, and mucosal involvement is typical. Treatment includes supportive care and systemic antibiotics.

Streptococcal TSS causes symptoms similar to those of staphylococcal TSS. Treatment is with IV penicillin (PCN) + clindamycin +/- intravenous immunoglobulin (IVIG). In contrast to staphylococcal TSS, blood cultures are **usually positive** in streptococcal TSS.

See the **Infectious Disease** section for more information on TSS.

Scarlet Fever

Scarlet fever primarily presents in children with streptococcal pharyngitis and a rash known as “**scarlatina**”—a fine, red, sandpaper-like rash that is more prominent in skin folds (Pastia lines) and involves the trunk and extremities but spares the palms and soles. “**Strawberry tongue**” also commonly presents in the acute phase. During the convalescent stage, desquamation of the palms and soles occurs.

Strep Throat

PCN is by far the best treatment for group A *Streptococcus* throat infection. Give oral PCN (× 10 days) or intramuscular (IM) benzathine PCN. Give **erythromycin** for PCN-allergic patients. **Clindamycin** is often added to PCN when there is serious infection (to decrease toxin production), such as necrotizing fasciitis or toxic shock.

Rocky Mountain Spotted Fever (RMSF)

RMSF is usually heralded by several days of fever. Then, small lesions develop that progress from peripheral to central (centripetal) distribution and from macular to petechial to purpuric type. As you can see from **Figure 3-29**, the skin findings can be deceptively nondescript. Treat with **doxycycline** or chloramphenicol.

Figure 3-29: Rocky Mountain spotted fever

Spirochetal Skin Infections

Lyme disease: The first stage of Lyme disease is often associated with erythema migrans (Figure 3-30). Typically, this is a slowly enlarging (over about 1 week), annular, erythematous rash with a clear center (looks like a bull's-eye). Occasionally, the center is not clear. Treat early Lyme disease with oral antibiotics—including doxycycline, amoxicillin, or cefuroxime axetil—to reduce the signs and symptoms and decrease the risk of late Lyme disease development.

Figure 3-30: Erythema migrans
Source: CDC

Syphilis: A chancre (painless ulcer at site of inoculation) indicates primary syphilis. This is commonly on the penis or vagina but can present on the pharynx or anus depending on sexual practices. A few weeks after the chancre appears, a diffuse scaling nonitchy macular papular rash is seen on the palms and soles. This rash is a hallmark of secondary syphilis but it also can be found on the trunk, head and neck, genitals, and mucosal surfaces. White, thickened plaques (condylomata) are additional secondary syphilis signs. There is lymphadenopathy. Gummas occur in tertiary syphilis; these are painless, indurated, nodular, or ulcerative lesions.

Animal Bites

Both *S. aureus* and *Pasteurella multocida* infections are caused by dog and cat bites, but cat bites more commonly cause *P. multocida* infection. Human bite infections are caused by multiple bacteria (e.g., *Eikenella*) and can be severe.

Clean and lavage well and give amoxicillin/clavulanate as prophylaxis and treatment. Doxycycline can be given alone if allergic to penicillin. Trimethoprim/sulfamethoxazole or cefuroxime or ciprofloxacin does have coverage against *Pasteurella*, but they need to be combined with clindamycin or metronidazole to provide adequate full anaerobic coverage.

Macrolides (erythromycin), clindamycin, and antistaphylococcal penicillins (dicloxacillin) lack activity against *P. multocida*.

Use antibiotic prophylaxis in the following situations:

- Immunocompromised host
- Facial bites
- Significant tissue destruction
- Presenting edema
- Clear crush injury

- Near a bone or joint
- On the hand

Bites on the hand are prone to deep infection due to the relative paucity of soft tissue above bones and joints.

Assess the tetanus immunization status with all bites. Give a tetanus vaccine:

- If patient has received fewer than 3 doses of vaccine in lifetime
- If the wound is clean and it has been longer than 10 years since the last dose of tetanus
- If the wound is dirty and it has been longer than 5 years since the last dose of tetanus

In addition, if the wound is contaminated, tetanus immune globulin may be recommended if the person has had fewer than three tetanus vaccines in lifetime or does not know status.

The animal should be observed for 10 days if possible; rabies postexposure immunization is necessary only if the animal shows signs of illness or if the animal cannot be quarantined.

FUNGAL INFECTIONS OF THE SKIN

Superficial Fungal Infections

Dermatophytes (*Microsporum*, *Epidermophyton*, and *Trichophyton*) cause superficial fungal infections (outer layer of skin) and are named according to the site involved:

- Tinea capitis (scalp ringworm)
- Tinea corporis (common ringworm on torso or extremities; Figure 3-31)
- Tinea cruris (jock itch)
- Tinea unguium/onychomycosis (nails; Figure 3-32)
- Tinea pedis (athlete's foot; Figure 3-33)

Figure 3-31: Tinea corporis

Figure 3-32: Tinea unguium
Source: CDC

Figure 3-33: Tinea pedis
Source: Kimberly Salkey, MD

The diagnosis is often made **clinically** but can be confirmed with potassium hydroxide (KOH) test on skin scrapings, which reveals **branching filamentous hyphae**.

Topical antifungal creams, such as ketoconazole, miconazole, clotrimazole, and terbinafine (Lamisil), control most fungal skin infections. Systemic therapy (the same as is used for tinea capitis; see below) is required for those who fail topical therapy or who have extensive skin involvement. Due to the potential for liver toxicity with terbinafine, liver function tests should be done at baseline and periodically throughout therapy.

Tinea unguium (onychomycosis) can be treated with either **topical** or **oral** antifungal agents.

Use topical treatments when < 1/2 of the distal nail plate is affected. Topical options include ciclopirox (e.g., Penlac, Loprox) 8% and efinaconazole (Jublia) 1% nail solutions, as well as tavaborole (Kerydin) 5% solution. Duration of topical treatment is 48 weeks.

Oral therapy may be needed for topical therapy failures and generally is more efficacious. Oral treatment for tinea unguium is terbinafine, itraconazole, or fluconazole.

Obtain a nail clipping sample and send it to the lab. Up to 50% of patients with suspected onychomycosis do not have a fungal nail infection. Common conditions, such as psoriasis or a nail dystrophy, can mimic onychomycosis. Given the potentially severe toxicity of terbinafine, confirmation of a fungal infection is recommended prior to initiation of therapy. Terbinafine is rarely associated with hepatic failure, Stevens-Johnson syndrome (SJS)/TEN, and pancytopenia. The diagnosis can be confirmed with a nail clipping with KOH scraping, periodic acid-Schiff (PAS), and/or culture.

Oral terbinafine is prescribed for 12 weeks when toenails are involved; it is prescribed for 6 weeks for fingernails. Check transaminases at baseline and consider repeating at 6 weeks.

Tinea capitis must **always** be treated with **oral** antifungals: griseofulvin, terbinafine, fluconazole, or itraconazole for 8 weeks. Tinea capitis is a superficial fungal infection caused by dermatophytes: *Microsporum*, *Epidermophyton*, and *Trichophyton*. This is an infection of the scalp and causes

erythema, scale, pruritus, and localized alopecia. KOH scraping shows branching (filamentous hyphae).

Tinea corporis is spread primarily by direct skin-to-skin contact or secondarily from other sites of fungal infection. Classic presentation is an annular, scaly rash with raised, advancing erythematous margin and scale that is clear toward the center with a history of pet contact. A differential diagnosis includes the herald patch of pityriasis rosea and granuloma annulare (GA). Itch is a differentiating factor (present in tinea), and GA lacks scales. Nummular eczema is similar. Microscopically, these demonstrate long, narrow hyphae; spores are not seen. Tinea corporis can be treated with topical antifungals or oral antifungals. Oral treatment is the same as for tinea capitis.

Tinea versicolor (pityriasis versicolor) is caused by *Malassezia globosa* or *M. furfur*. Skin infection results in hypopigmented or hyperpigmented (depending on the patient's skin tone/color) spreading macules, usually on the upper torso and upper arms, but the infection can spread over the body. Microscopic KOH skin scraping reveals **"spaghetti and meatballs"** (Figure 3-34). Treatment is topical: imidazole creams, selenium sulfide, or ketoconazole shampoo and/or oral: itraconazole or fluconazole. Always consider secondary syphilis when evaluating disseminated rashes on the body, although the hallmark sign for syphilis is on the palms and soles.

Figure 3-34: Tinea versicolor (KOH prep)
Source: Kimberly Salkey, MD

Deeper Fungal Infections

Candidiasis intertrigo is a **deeper** skin fungal infection that causes red patches in intertriginous areas. These sites are often chronically moist with lack of circulation. A variant occurs in the interdigital spaces of the hands, especially for persons in occupations where hands are frequently in water such as dishwashers or nurses. Candidiasis of the mouth (thrush) causes white semiadherent plaques on the tongue and mucosa. Unlike hairy leukoplakia, these **can be scraped off**. Vaginal candidiasis has similar plaques with cheesy discharge. Other presentations are perleche and diaper dermatitis. Treatment can be with topical formulations or systemic agents, depending on the area affected and patient's comorbidities. Visualization demonstrates pseudohyphae and yeast cells. Treatment is topical imidazoles (e.g., clotrimazole).

Cutaneous mucormycosis is a rare infection caused by extremely common fungus of the class *Mucorales*. Infection can occur after inoculation of the fungal spores, usually by trauma, into the dermis of an

immunocompromised person, most commonly a poorly controlled diabetic. It first appears as a single tender and painful indurated area that quickly spreads, causing tissue necrosis. Cutaneous mucormycosis usually remains cutaneous and does **not** spread to the deeper dermis tissues or become systemic.

VIRAL SKIN INFECTIONS

Human Papillomavirus (HPV)

Warts are caused by any 1 of > 100 types of HPV. They often **resolve spontaneously**, but this can take up to **2 years**. However, because of their appearance, patients may request treatment, which typically involves some form of tissue destruction:

- Verruca vulgaris is the common wart. Treatments include liquid nitrogen, topical acids, and CO₂ laser.
- Verruca plana is the flat wart. Treatment is the same as that for verruca vulgaris, but note that these lesions **do** exhibit koebnerization (i.e., spread) with trauma to the skin.
- Verruca plantaris is the plantar wart (Figure 3-35). Initial treatment may consist of a strong acid (trichloroacetic acid), concentrated (40%) salicylic acid plaster, liquid nitrogen, or laser.
- Condylomata acuminata are anogenital warts. 90% are caused by HPV-6 or -11. They are sometimes coinfecting by HPV-16, -18, or -31—the **oncogenic HPV** types (associated with cancer of the cervix and anus). If unsure of diagnosis, do a shave biopsy. Treat with topical podophyllin, trichloroacetic acid, imiquimod (e.g., Aldara, Zyclara), liquid nitrogen, or CO₂ laser. Podophyllin is teratogenic, so do **not** give it to **pregnant** patients.

Figure 3-35: Plantar wart
Source: Kimberly Salkey, MD

Molluscum Contagiosum

Know: Molluscum contagiosum is caused by a poxvirus. It consists of smooth, umbilicated, pearly papules (Figure 3-36). It usually occurs in children (anywhere on the body except the palms and soles), but you may also see it in the pelvic area of sexually active young adults—and it is **common in AIDS patients** (can be sexually transmitted). Although molluscum contagiosum often resolves spontaneously, except in immunosuppressed patients (e.g., AIDS), treatment options include cryotherapy with liquid nitrogen, surgical curettage, and cantharidin application. Antiretroviral treatment imiquimod is used to treat molluscum associated with HIV infection.

Figure 3-36: Molluscum contagiosum

Measles and Rubella

Know: Measles (rubeola) has several stages. The prodromal stage lasts 3–4 days with fever, malaise, sinus discharge, and a hacking cough. Koplik spots (Figure 3-10 on page 3-7; pathognomonic) often appear on the palate from 1 to several days before the onset of rash. As the Koplik spots begin to disappear, a red maculopapular rash starts on the face and behind the ears and quickly spreads downward and outward, with the densest concentration of lesions from the face to the shoulders. The palms and soles are affected last. Lesions gradually fade in order of appearance and may have some desquamation.

Rubella (a.k.a. German measles and 3-day measles) is benign **except** when it occurs in pregnant women. The rash is similar to measles but lasts only 3 days. Rubella has been eradicated in the Americas, but there are still ~ 120,000 cases/year worldwide. Congenital rubella results in a variety of serious birth defects:

- Heart malformations
- Ocular defects
- Microcephaly
- Intellectual disability
- Deafness
- Thrombotic thrombocytopenic purpura (TTP)
- Bone problems

Varicella-Zoster Virus (VZV)

VZV causes 2 diseases: chickenpox and herpes zoster (shingles). **Both** diseases present with vesicles on an erythematous base. Herpes zoster is reactivation of VZV in a person who has had chickenpox.

Chickenpox (Figure 3-37) has decreased in incidence with routine childhood vaccination. Rash is initially maculopapular and rapidly progresses to vesicles and then to scabbed lesions. These tend to come in “crops” over 2–4 days.

Figure 3-37: Chickenpox

Herpes zoster (shingles; [Figure 3-38](#)) manifests as grouped vesicles along a dermatome with focal pain and is unilateral. Affected dermatomes can include the regions of the eye (herpes zoster ophthalmicus; [Figure 3-39](#)) and ear (herpes zoster oticus). Older age and immunosuppression (e.g., HIV) are risk factors. Zoster occurring along the 1st branch of the trigeminal nerve (V1) affecting the **nasal tip** is known as Hutchinson sign. Zoster in this pattern runs the risk of zoster ophthalmicus, a **sight-threatening** condition, and requires an ophthalmology evaluation. Treatment of herpes zoster is 800 mg oral acyclovir 5×/day for 7–10 days, but if the patient has an immunocompromised status, such as an HIV-infected patient, then intravenous acyclovir is needed at 10 mg/kg 5×/day for 7 days (adjust dose for chronic kidney disease).

Figure 3-38: Herpes zoster (shingles)

If started within 72 hours of onset, antiviral therapy with acyclovir, famciclovir, or valacyclovir decreases disease duration. Systemic steroids can help reduce acute pain, but its use is controversial, whereas gabapentin can reduce the likelihood of progression to postherpetic neuralgia.

More information on the VZV and herpes zoster vaccine is in the [Infectious Disease](#) section.

Herpes Simplex Virus

See herpes simplex infections under [Oral Blisters and Ulcers](#) on page 3-7.

Figure 3-39: Herpes zoster ophthalmicus

Source: Jason Reichenberg, MD

INFESTATIONS AND BITES

Note: Parasitic skin infection outbreaks typically occur in schools, nursing home communities, and camps.

Lice

Head lice (*Pediculus humanus capitis*) have a 1-month life span, during which the females lay ~ 10 eggs per day and firmly attach them to the base of hair strands. Transmission is through direct contact with the head of an infected person. Diagnosis is made by direct visualization of lice and/or nits (eggs) in the hair. A Wood lamp examination can be performed in difficult cases: Live nits are fluorescent white when illuminated with a Wood lamp, but empty nits are fluorescent gray.

Treatment is pesticide based or uses asphyxiation, followed by nit removal. Chemical treatments:

- Topical ivermectin is the strongest drug. It requires a single application and has an effectiveness of ~ 95%. Oral ivermectin can also be effective but is not FDA approved.
- Malathion is a pesticide-based treatment that kills both lice and eggs. Effectiveness of malathion is ≥ 90%, but it is expensive and flammable (!) and must be left on for 8 hours.
- Spinosad is derived from a soil bacterium, *Saccharopolyspora spinosa*. It overexcites the central nervous system (CNS) of the lice, interacting with their acetylcholine (ACh) receptors. Second application is done only if live lice are seen 7 days later. It has an effectiveness of ~ 85%.

- Benzyl alcohol lotion 5% (Ulesfia) contains **no** neurotoxic pesticides. It kills by suffocating the lice. It is safe in children older than 6 months. Retreatment after 7 days is required. It has an effectiveness of ~ 75%.
- Over-the-counter treatments include permethrin cream 1% and a lotion with permethrin + piperonyl butoxide. Unfortunately, in the U.S., resistance is growing against permethrin preparations and malathion. Effectiveness of permethrin treatments is not very high (< 50% overall and even worse in areas of high resistance).
- 1% lindane shampoo is a 2nd line treatment because of neurotoxicity.

Removal of nits with a fine-toothed comb is done following application of all medications and is a necessary step for eradication of the lice. There are professional services that for a fee will remove lice in their clinics or in the patient's home. Treat infested close contacts and bed mates at the same time and disinfect brushes, combs, and hats.

Body lice (*Pediculus humanus corporis*; **Figure 3-40**)

live in clothes and are on the body only when feeding. Treatment is bathing and discarding or carefully **laundering** clothes and bed linens, using hot water. Clothes can also be ironed with focus on the seams. If the patient has a few nits on body hair, additionally treat with permethrin 5% cream.

Figure 3-40: Body louse
Source: CDC

Pubic lice (*Phthirus pubis*): The crab louse is sexually transmitted and can also infect the eyelashes. Fomites **rarely** transmit crab lice. Itching in the groin area is the most common manifestation of infection. The bluish macules (maculae ceruleae) are not always present, but examination may reveal them in the groin area, usually in patients who have been infested for a prolonged period. Treatment is similar to that of head lice. Use topical permethrin or pyrethrin + piperonyl butoxide. Wash bedding and clothing in hot water and use a hot dryer.

Scabies

Scabies is caused by a the tiny (0.2–0.4 mm) (*Sarcoptes scabiei*) mite that **tunnels** into the skin to lay eggs (**Figure 3-41**). It is spread by **skin-to-skin contact**—the mites do not live > 48 hours without a host! Consider it in anyone with unexplained, intense itching in areas of erythematous papules that is worse at night and after a hot shower, particularly in hospitalized or institutionalized patients. Classically, scabies is associated with itching of the flexor aspects of wrists, axilla, and interdigital spaces. Diagnosis is made by microscopic visualization of the mite, feces, or eggs from skin scrapings that are prepped with mineral oil.

Figure 3-41: Scabies burrow

Treat with 5% permethrin applied to **all** areas of the body from the head down and washed off after 8–14 hours. A 2nd dose in 7 days is recommended. Treat all household contacts simultaneously. Alternatives: crotamiton lotion 10% and crotamiton cream 10% (crotamiton is for scabies in adults only and is not very effective), sulfur (5–10%) ointment, or lindane lotion 1% (not 1st line). Use oral ivermectin for severe or recalcitrant cases, with a repeat dose in 1 week, although it is not FDA approved for this use. In nursing homes and for cases of crusted scabies (Norwegian scabies), a combination therapy of topical permethrin and oral ivermectin, 2 doses given 7 days apart, may be used. Oral therapy alone is also used in institutions, when a patient is mentally impaired, or when permethrin is inappropriate. Lindane has CNS toxicity, so do not use during pregnancy, in infants, or in young children. Permethrin can be used in pregnancy. Precipitated sulfur is also considered safe to use during pregnancy but may be less effective. Wash all linens and clothing in hot water.

Bedbugs

Bedbugs (*Cimex lectularius*;

Figure 3-42) are blood-sucking ectoparasites that hide in cracks and crevices during the day and feed at night. They cause edematous pink papules that may have a central punctum. Bites are often found in groups of 3 in a linear array (breakfast, lunch, and dinner) but can be scattered (**Figure 3-43**). Reactions to bites can take days to develop. Symptoms can be treated with topical corticosteroids, but insects need to be eradicated from the home, which can be difficult and can require professional extermination.

Figure 3-42: Bedbug

Figure 3-43: Bedbug bites

Spiders

In the U.S., the spider whose bite can cause a necrotic reaction is the **recluse** spider (genus *Loxosceles*). The brown recluse (*Loxosceles reclusa*) is found in the south-central U.S.; other recluse species are found along the southwestern border of the U.S. See Figure 3-44 for their distribution in the U.S.

Figure 3-44: Geographic distribution of *Loxosceles* species spiders in 2018

Brown recluse spiders (Figure 3-45) tend to hide in wood-piles, attics, closets, and seldom-worn clothing. Adults have a leg span of ~ 25 mm, 6 eyes, and a dark **violin** pattern on the dorsal front portion of the body (cephalothorax); thus, they are also called “fiddleback” or “violin” spiders. Their venom contains sphingomyelinase and other substances that lyse cell walls, activate complement, and cause local necrosis.

Figure 3-45: Brown recluse spider. Note the violin pattern on the dorsal cephalothorax.

The reaction to the bite of all the recluse spiders is similar. Initially, the bite is painless; pain develops at the site 2–8 hours later. Over the next 1–2 days, a hemorrhagic blister develops that eventually progresses to a necrotic ulceration. Patients rarely have systemic symptoms, such as fever, chills, nausea, or vomiting. Cutaneous

loxoscelism is the term given for the ulcerative effect of the recluse bite (genus *Loxosceles*). It is the only spider that affects humans this way.

Treatment is supportive with local wound care, because these bites are seldom infected but can take a week to heal. (If there is obvious infection, think **MRSA** instead.) The lesions may continue to expand for as long as 10 days, but most eventually heal spontaneously without surgical or other intervention. Other treatments (e.g., dapsone, steroids) are controversial because data on effectiveness is lacking. Dapsone is commonly used to prevent the wound from necrosing. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a contraindication.

Black widow spiders (Figure 3-46) are found throughout the U.S. (except Alaska); the southern black widow and western black widow spiders are most commonly responsible for serious symptoms. Widow spiders hide in dimly lit, warm, dry outhouses and sheds. They are large, with leg spans of up to 40 mm. Patients usually have a recent history of outdoor activity, such as cleaning out a garage. Female spiders are twice the size of males and cause the most severe bites; a mature black widow female has a **red or orange hourglass** marking on the **ventral** surface of the abdomen.

Figure 3-46: Black widow spider. Note the red/orange hourglass on the ventral abdomen.

Black widow spider venom is a neurotoxin that causes very little local reaction, although cutaneous reactions can include erythema, edema, and piloerection. Initial signs and symptoms include pain at the site, diaphoresis, muscle cramping, chest tightness, vomiting, malaise, sweating, abdominal pain (can mimic appendicitis), agitation, and hypertension.

Treatment includes local wound care, analgesia, and tetanus prophylaxis. Usually, all symptoms resolve within 24–48 hours. More severe cases can be treated with widow antivenin. Be aware that widow antivenin, like snakebite antivenin, can cause anaphylaxis.

Wounds from the painless bite of the brown recluse can take a week or longer to heal as a result of the enzymatic tissue breakdown, whereas the wound from the painful bite of a black widow releasing a neurotoxin heals more rapidly and with no tissue destruction.

CUTANEOUS ULCERS

PREVIEW | REVIEW

- Where is the preferred biopsy site of a cutaneous lesion?
- Venous ulcers are usually related to what underlying disorders?

Ulcers, defined by loss of both epidermis and dermis, can be quite challenging to diagnose and treat. They are most commonly found on the lower legs and have a vast range of causes. Biopsy and culture of ulcers can aid in ruling out neoplastic or infectious etiologies, respectively. The biopsy should be performed at the edge or margin of the ulcer rather than the center to allow for better healing and control of bleeding and to avoid a biopsy of nondiagnostic necrotic debris. The 3 most common causes are venous, arterial, and neuropathic etiologies.

Venous ulcers are commonly located on the medial malleolus and are related to venous hypertension or venous insufficiency. They typically have irregular, shallow borders and a yellow fibrinous base and may be accompanied by clinical findings of stasis dermatitis, lymphedema, varicosities, and edema. Hemosiderin deposition and/or petechiae may also be observed.

Arterial ulcers are often located on distal sites and bony prominences. The base of these ulcers may be yellow and fibrinous or dry and necrotic. Lesions are described as punched out. Surrounding skin can be shiny and devoid of hair. Peripheral pulses may be weakened or absent.

Neuropathic ulcers, like arterial ulcers, are located at pressure sites and may be described as punched out; however, they may also be surrounded by thick callus. Accompanying clinical findings include peripheral neuropathy and foot deformities.

Pyoderma gangrenosum (PG) (Figure 3-23 on page 3-15) is a neutrophilic, ulcerating disorder. Lesions start as tender nodules, papules, or pustules that progress to necrotic ulcerations with violaceous, rolled borders and a rim of erythema. PG is a diagnosis of exclusion, and other causes must be worked up and ruled out. Patients can have a history of underlying disease, or it can be idiopathic. It occurs often in inflammatory bowel disease, ulcerative colitis, rheumatoid arthritis, and multiple myeloma. Other associations with PG include Sweet's, Behçet's, and Sjögren's. It may be idiopathic in up to 50% of cases. Treatment includes topical steroids, systemic corticosteroids, dapsone, immunosuppressive medications, and TNF- α inhibitors. PG is worsened by trauma (pathergy), so debridement or other procedures should be avoided.

There is a wide range of less common causes of cutaneous ulcers, including infection, vasculitis, physical trauma (e.g., prolonged pressure, burns, factitial), hematologic disease (e.g., sickle cell disease, α - and β -thalassemias, hereditary spherocytosis), hypercoagulable states, and vaso-occlusive disease.

HAIR DISORDERS

PREVIEW | REVIEW

- What form of alopecia is from an autoimmune state?
- What is the origin of excessive hair growth that is located centrally?
- What causes excessive facial hair in women?

NONSCARRING HAIR LOSS (ALOPECIA)

Androgenic alopecia results from the genetic sensitivity of hair follicles to androgens. This leads to miniaturization of the follicles and subsequent hair thinning and loss. Thinning occurs in the frontotemporal regions and vertex in men and on the central crown in women. Treatment includes topical minoxidil and oral antiandrogens, such as finasteride.

Alopecia areata is an autoimmune disease specific to hair and presents with discrete round patches of hair loss without scarring. It can progress to alopecia totalis (loss of scalp hair) and alopecia universalis (loss of scalp and body hair). Nails in patients with alopecia areata may have pitting in a regular or geometric pattern.

Treatment for limited disease includes topical and intralesional steroids. For more extensive disease, treatment with systemic steroids has been successful but temporary, and while topical irritant therapy (e.g., with squaric acid) may be helpful, results are not consistent. Immunosuppressives may also be helpful, but, again, results are not consistent. There is no FDA-approved Janus kinase treatment for alopecia, although research is promising.

Trichotillomania is a self-inflicted hair disorder and often associated with psychological stress or a personality disorder. Clinical features include irregular patches of hair loss with hair of varying lengths. Patients may also pluck hairs from other areas, such as the eyebrows, eyelashes, and body.

Traction alopecia is most commonly seen in African American female patients in their 30s to 40s. It typically involves the frontotemporal regions. It results from consistent traction of the hair over years. In early stages, it may be reversible, but over time, it becomes permanent as the hair follicles become scarred.

Telogen effluvium occurs when large numbers of hairs simultaneously enter the telogen phase and shed. This can be triggered by a pathological or physiological change in the patient's health status, such as pregnancy, extreme dieting, thyroid disorder, surgery, medications, and severe stress. Hair loss occurs 4–6 months after the precipitating event and is diffuse. Eventual complete hair regrowth is possible, particularly if the underlying cause is eliminated.

EXCESSIVE HAIR

Hirsutism is defined as excessive body hair in areas where it is usually absent or scarce. It may be caused by increased androgens or an increased sensitivity to androgens. It may be associated with seborrhea, acne, or androgenic alopecia. It is useful to determine the source of the affecting androgens, such as an ovarian source or adrenal source. The patient's pattern of hair growth can be useful. If it is centrally located, then it is likely adrenal in origin. If the hair is mostly located on the areolae and lateral neck and face, then it is likely ovarian in origin. Polycystic ovarian syndrome is the most common cause of hirsutism in women. Other etiologies include Cushing syndrome, anabolic steroids, and androgen-secreting tumors. For more information on hirsutism, see the [Endocrinology](#) section.

SKIN CANCER AND PRECANCEROUS LESIONS

PREVIEW | REVIEW

- What is the metastatic potential for basal cell carcinoma?
- Squamous cell carcinoma has the highest rates of metastasis on what body areas?
- What measurement is most important when determining melanoma prognosis?
- What are the main forms of cutaneous T-cell lymphoma? Which has the worse prognosis?

DYSPLASTIC NEVI

Dysplastic nevi are “odd-looking” moles and may even look like melanomas (Figure 3-47). However, **most** melanomas **arise de novo**—**not** in a preexisting nevus. Therefore, removing all moles does **not** prevent melanoma development. Closely monitor patients with these lesions, using photographic documentation. If a patient with a dysplastic nevus has 2 relatives with malignant melanoma, the patient has a 300× chance of getting malignant melanoma!

Figure 3-47: Dysplastic nevus

PREMALIGNANT SKIN CONDITIONS

Actinic keratoses are **precancerous** lesions that can develop into squamous cell carcinoma (SCC). Like SCC, these lesions are found on sun-exposed areas, more often in those with fair skin. These types of lesions can be treated with cryotherapy, photodynamic therapy, topical 5-fluorouracil, and topical imiquimod.

MALIGNANT CONDITIONS

Basal cell carcinoma (BCC) arises from epidermal basal cells and is the most common form of skin cancer, especially in **Caucasians** (Figure 3-48). The usual type of BCC is characterized by translucent pearly papules, often with arborizing vessels. It often has raised borders. It spreads by **local extension** and, when large enough, gets a “rodent-eaten” appearance.

Figure 3-48: Basal cell carcinoma

Source: Charles Crutchfield, III, MD

BCC is caused by UV radiation from sun exposure. It is typically found on **sun-exposed areas**, such as the head and neck, but it may appear elsewhere. Diagnose on clinical presentation with skin biopsy to confirm pathology.

Know that the **metastatic** potential of BCC is **< 0.1%**. BCCs are usually surgically removed. Treatment is most often excision, Mohs surgery, cryo- or radiation therapy, and/or topical immunomodulation (e.g., 5-fluorouracil, imiquimod). Intralesional 5-fluorouracil and interferon, photodynamic therapy, and laser therapy have also been used.

Squamous cell carcinoma (SCC): SCC develops from keratinizing epidermal cells, occurring especially in **fair-skinned** persons and on sun-exposed areas, such as the forearms, ears, lower lip, and dorsal surfaces of hands (Figure 3-49). In contrast to the low metastatic potential of BCC, SCC has a 0.3–5.0% metastatic potential—and even higher when it appears on the head and neck: **ear** (11%) and **lower lip** (13%)! The metastatic rate of **recurring tumors** is 30%, and the rate in SCC originating from **scars** approaches 40%.

Figure 3-49: Squamous cell carcinoma

Other risk factors associated with a higher metastatic rate include size > 2 cm, depth > 4 mm, poorly differentiated lesions, and immunocompromised hosts (e.g., transplant patient). Histopathology obtained from a shave biopsy confirms the diagnosis.

SCCs are generally removed with wide local excision or Mohs surgery, depending on location and size.

SCC in situ (a.k.a. Bowen disease) is a noninvasive form of SCC that presents as small, red, scaly patches that grow slowly. These tumors are associated with sun exposure, especially on the face, scalp, hands, and lower legs, or with HPV infection in the genital area. They are also caused by arsenic exposure. These lesions tend to grow slowly, with gradual asymptomatic enlargement over many years. SCC in situ can be treated with topical 5-fluorouracil, topical imiquimod, and surgical excision. In addition, the FDA has approved photodynamic therapy.

Melanoma: This also tends to occur more commonly in fair-skinned, light-haired, and freckled people with sunlight exposure, especially those who had severe sunburns in childhood (Figure 3-50). There has been a 300% increase in incidence of melanoma in the past 40 years. Other risk factors are numerous dysplastic nevi, a family history of melanoma, a high number of ordinary nevi, a congenital nevus, previous personal history, and immunosuppression.

Figure 3-50: Malignant melanoma

Melanoma is more common in women < 50 years of age and in men > 50. It commonly presents on the lower legs of women and the backs of men.

There are 4 types of melanoma: superficial spreading, lentigo maligna, acral lentiginous (palms, soles, nails, and mucosa), and nodular. Nodular is the only 1 of the 4 types that does not exhibit radial growth; instead, it grows deeply vertical, with an increased incidence of early metastasis.

Think **ABCDE** when assessing a lesion that might be malignant melanoma:

- Asymmetry
- Borders are irregular.
- Color variation
- Diameter > 6 mm is suspicious.
- Evolving lesions are more suspicious.

General prognostic factors include **age** and sex of the patient (better prognosis for patients who are < 50 years of age and female), **location** of the lesion (improved outcomes: extremities > trunk > head and neck), and, most importantly, the **depth** of the lesion (deeper lesions have a poorer outcome). Specific prognosis factors are depth of the lesion, mitotic index, ulceration, number of regional lymph nodes, and systemic metastases. Early diagnosis of this lesion **does** affect prognosis. Excisional biopsy should be done promptly, because early diagnosis and excision reduce mortality.

Refer for an **excisional biopsy** of any suspicious lesion with a 1- to 3-mm rim of normal skin and contiguous subdermal fat on the bottom; a saucerization of the lesion can also be done, with a 1- to 3-mm rim of normal skin. Punch biopsy is not recommended.

A partial biopsy may result in an inaccurate diagnosis as size, symmetry, and circumscription are important histologic criteria when evaluating melanocytic lesions.

Staging is based on the American Joint Committee on Cancer's *AJCC Cancer Staging Manual, Eighth Edition* and refers to the TNM (tumor size, lymph node involvement, and metastases), which corresponds to different stages. Previously, the Breslow thickness (i.e., the depth of the lesion found on biopsy) alone was used.

If melanoma is found and the lesion depth is < 1 mm, the lesion is excised with a 1-cm, tumor-free margin. If the lesion is 1–2 mm, then excision is with a 1- to 2-cm margin. If the lesion is > 2 mm, then excision is with a 2-cm margin. If the lesion is < 0.8 mm but with ulceration, in a young person, has lymphovascular invasion, or has a high mitotic rate, sentinel lymph node biopsy (SLNB) should be discussed. In addition, if the lesion is between 0.8 and 1 mm, discuss the option of a sentinel lymph node procedure with the patient and the surgeon, according to 2017 National Comprehensive Cancer Network guidelines.

Always recommend an **SLNB** for patients with lesions > 1 mm in depth.

Survival rates for melanoma Stages 0, I, and II are 99%; that for Stage III is 65%; and that for Stage IV is 25%.

Treatments depend on stage at diagnosis:

- Stage 0: excision
- Stages I and II: excision +/- SLNB
- Stage 3 resectable: excision, SLNB, adjuvant therapy, and immunotherapy
- Stage 3 unresectable, Stage 4, and recurrent: intralesional immunotherapy and signal transduction inhibitors, chemotherapy and palliative care
- Adjuvant therapy is based on whether **BRAF** positive (combination therapy) or **BRAF** negative (programmed cell death-1 inhibitor).

Know: Dark-skinned individuals also get melanoma. The lesions tend to be in acral areas (palms, soles, and nail beds). **Hutchinson** nail sign is an important clinical clue to subungual melanoma, which is typified by extension of brown or black pigment from the nail bed, matrix, and nail plate to the adjoining cuticle and proximal or lateral nail folds.

Mycosis fungoides and **Sézary syndrome** are the main forms of cutaneous T-cell lymphoma. Mycosis fungoides (Figure 3-51) can be mistaken for psoriasis or eczema. Sézary syndrome has peripheral blood involvement in addition to the skin manifestations and is associated with a poorer prognosis. Patients with Sézary syndrome are often erythrodermic (erythema affecting ≤ 90% BSA).

Figure 3-51: Mycosis fungoides
Source: Jason Reichenberg, MD

Paget disease of the nipple is a **rare** form of breast cancer and is something to consider anytime there is a **persistent** unilateral oozing from the nipple and/or from eczematous plaques on the **areola**. It is usually due to underlying intraductal breast cancer and is due to retrograde extension of the tumor. By far, the **most common** causes of an acute eczema-type rash on an areola are **contact dermatitis** or **skin irritation**; consider Paget disease if there is **no** response to treatment.

Nevoid basal cell carcinoma syndrome (NBCCS; a.k.a. Gorlin syndrome) is an **autosomal dominant** disorder caused by mutations in the *PTCH1* tumor suppressor gene. Bifid ribs, calcification of the falx cerebri, and hyper-telorism are found in addition to numerous BCCs, palmar and plantar pits, and bone cysts, especially of the mandible (Figure 3-52). There is a small chance for children with

NBCCS to develop medulloblastoma. Management consists of regular surveillance by a dermatologist, treatment of BCCs, and surgical excision of bone cysts. Prognosis is generally good.

Peutz-Jeghers syndrome is an autosomal dominant syndrome consisting of multiple hamartomatous polyps in the GI tract and melanotic pigmentation (lentigines) on the lips and buccal mucosa. These patients are at **higher risk** for **GI malignancy**. Note that healthy, darkly pigmented individuals and those with Addison disease may have similar intraoral dark spots.

Metastases to the skin: The 5 cancers with the most **cutaneous metastases** are lung cancer, GI cancer, melanoma, renal cancer, and breast cancer.

BLISTERING LESIONS

PREVIEW | REVIEW

- Characterize the skin findings associated with porphyria cutanea tarda (PCT).
- What type of hepatitis is associated with PCT?
- Dermatitis herpetiformis is associated with what gastrointestinal disorder?

Porphyria cutanea tarda (PCT; Figure 3-53 on page 3-30 and Figure 3-54 on page 3-30) is the most common type of porphyria. PCT causes **hyperpigmentation, tense blisters, scaly macules, vesicles, or hemorrhagic bullae** in **sun-exposed** areas; milia; skin fragility; and increased **facial hair**. PCT is caused by a congenital or acquired **decreased** activity of uroporphyrinogen decarboxylase (UROD), which allows a buildup of phototoxic porphyrins in the skin. Symptoms can be induced by **estrogens, alcohol, hepatitis C virus infection, HIV infection, and smoking**. Check for hepatitis C virus, HIV, and hereditary hemochromatosis. Whenever a patient with HCV presents with a photosensitive rash isolated to the hands, think of PCT. Lab results usually show increased serum iron, ALT, and AST. To screen, check for increased urinary **coproporphyrins** and **uroporphyrins**. Patients may have **dark or pink urine**.

Figure 3-52: Signs of nevoid basal cell carcinoma syndrome: (A) bifid ribs; (B) intracranial calcification (falx cerebri); (C) nevoid basal cell carcinoma; (D) palmar pits (plantar pits may occur); (E) keratocystic odontogenic tumor (mandible)

Figure 3-53: Porphyria cutanea tarda
Source: Kimberly Salkey, MD

Figure 3-54: Porphyria cutanea tarda with blisters

Treatment is the same as for hemochromatosis: regular phlebotomy. Iron can inhibit the activity of UROD. By decreasing iron stores with phlebotomy, the activity of UROD increases, resulting in porphyrins being metabolized quickly, thus preventing them from building up in the skin. Antimalarials (e.g., hydroxychloroquine, chloroquine) are also effective, helping to mobilize porphyrins. They are typically used when phlebotomy is contraindicated. PCT due to hepatitis C virus infection resolves with treatment of hepatitis. Protecting skin from the sun and discontinuing aggravating agents, including alcohol and estrogen, are also indicated.

Porphyria variegata (variegate porphyria) is also known as South African porphyria. It is called variegate because patients can present in a variety of ways. They can have acute episodes (e.g., acute intermittent porphyria [AIP]), chronic skin manifestations (e.g., PCT), or both. Patients may get blisters on sun-exposed areas and have mechanical fragility of the skin. These patients may also have abdominal pain, polyneuropathies, and mental disturbances. The symptoms are due to a deficiency of protoporphyrinogen oxidase, which leads to the build-up of excess porphyrins.

Treatment of acute attacks is the same as for AIP: glucose and heme. Glucose and heme theoretically work by inhibiting aminolevulinic acid (ALA) synthase and preventing the accumulation of toxic precursors. Differential diagnosis: Note that AIP presents similarly to variegata

porphyria, except without the skin changes. PCT presents with the skin changes but without the neurologic/mental changes!

Epidermolysis bullosa: Congenital structural defects of the skin cause blistering after minor skin trauma such that the skin splits at the junction of the epidermis and the dermis. There are many different classifications, all of which are genetically transmitted, and each is due to a specific gene mutation. The major classifications include epidermolysis bullosa simplex (EBA), which affects the keratin genes *KRT5* and *KRT14*; junctional epidermolysis bullosa (JEB), which affects the laminin and collagen genes; and dystrophic epidermolysis bullosa (DEB), which affects the collagen 7 gene.

Nikolsky sign: Slight lateral pressure on the skin causes sloughing of the epidermis. It is positive in pemphigus vulgaris, pemphigus foliaceus, TEN, and staphylococcal scalded skin syndrome (SSSS). It is negative in bullous pemphigoid.

Bullous pemphigoid causes recurrent crops of tense, deep, intact blisters with negative Nikolsky sign (do not spread laterally with pressure). It usually starts on the legs and can remain there for years before spreading (Figure 3-55). Elderly individuals are usually affected. The disease process is classified as a Type 2 hypersensitivity reaction and can appear similar to urticaria when it starts. It is intensely pruritic and does not involve the mucosa. It has an autoimmune

Figure 3-55: Bullous pemphigoid
Source: Kimberly Salkey, MD

etiology with formation of antiepithelial basement membrane antibodies. Precipitating events include exposure to UV light, radiation therapy, and certain drugs, including furosemide, ibuprofen, captopril, and penicillamine. Therapy includes topical (mild disease) and systemic corticosteroids and immunosuppressants.

Pemphigus vulgaris (Figure 3-56) is an autoimmune disease with intraepidermal antibodies against the desmosome desmoglein 3. This causes acantholysis (i.e., the separation of epidermal cells from each other due to decreased cohesion), which results in the formation of large, superficial, loose bullae that peel off and leave denuded skin. Nikolsky sign, which is the production of blistering through mechanical pressure at the edge of a blister, is often present. Oral mucosal involvement is common, and any cutaneous area can be affected. Lesions tend to be quite painful. Treatment of pemphigus vulgaris is similar to that of bullous pemphigoid but rituximab was FDA approved in 2018 for pemphigus vulgaris. Rituximab is used as 1st line treatment both to control disease severity and induce remission.

Figure 3-56: Pemphigus vulgaris

Source: Kimberly Salkey, MD

Table 3-1 summarizes key differences between pemphigus vulgaris and bullous pemphigoid.

Table 3-1: Comparison of Pemphigus Vulgaris and Bullous Pemphigoid

	Pemphigus Vulgaris	Bullous Pemphigoid
Age	30–60 years	Elderly
Rash	Flaccid bullae with mostly erosions (+ Nikolsky sign)	Tense blisters
Autoantibodies	Intraepidermal junctions	Basement membrane

Pemphigus foliaceus is caused by antibodies against the desmosome desmoglein 1 and is characterized by superficial erosions that favor the face, upper trunk, and scalp. Due to their superficial nature, vesicles are not often visualized, and clinical presentation is more consistent with crusts and scale that may be confused with impetigo. In contrast to pemphigus vulgaris, mucosal involvement is rare. Treatment is similar to that of pemphigus vulgaris, although systemic treatments are not usually necessary and the condition may be controlled with potent topical steroids only.

SJS is a severe mucocutaneous reaction considered to be on the milder end of the spectrum of TEN. SJS is usually caused by medications including a variety of antibiotics, allopurinol, antiseizure medications (especially phenytoin and carbamazepine), and NSAIDs. Less commonly, SJS is associated with infections. In SJS, sloughing affects < 10% of the BSA. Treatment requires removal of the offending drug and supportive care. Corticosteroids are controversial; use for only a very short time and prior to skin sloughing, if at all. Diagnosis is clinical + biopsy (shave or punch). For treatment, discontinue offending drug and provide supportive care in a burn unit. For more information on SJS, see the [Allergy & Immunology](#) section.

TEN is considered a variant or more severe form of SJS. It is caused by a hypersensitivity reaction to a drug (especially allopurinol, antiseizure medications, NSAIDs, sulfas, and antibiotics). Early symptoms include fever and skin pain and tenderness out of

proportion to physical findings. Like SSSS, it results in a peeling or exfoliation of large areas of skin, but it occurs at a deeper level than SSSS. By definition, sloughing affects > 30% of the BSA. Treatment requires removal of the implicated drug, aggressive skin care, and supportive care in an intensive care burn unit. Prognosis is poor with a mortality rate of up to 40%. See more on TEN in the [Allergy & Immunology](#) section.

Dermatitis herpetiformis (DH) is a skin disease where pruritic vesicular lesions appear on the extensor surfaces and the mid-to-lower back (Figure 3-57). Lesions are caused by IgA deposition in the dermal papillary tips. Given the extreme pruritus, intact vesicles are often not apparent. DH is associated with celiac disease (gluten-sensitive enteropathy). DH and celiac disease can both be treated with a gluten-free diet. Alternatively, oral dapsone can be used to treat DH but is not effective for celiac disease.

Figure 3-57: Dermatitis herpetiformis

ROUND LESIONS

PREVIEW | REVIEW

- In what age group does nummular eczema occur? How is it treated?
- What skin disorder is characterized by a “Christmas tree” pattern and a herald patch?
- What is the pathognomonic lesion for erythema multiforme? What virus is often the cause?

Granuloma annulare is an idiopathic, annular, ringworm-like lesion without scaling, commonly appearing on the distal portion of the extremities (Figure 3-58). It often occurs in children and young women. It usually is self-limited, disappearing in months to a few years. Other treatment options include topical or intralesional corticosteroids.

Figure 3-58: Granuloma annulare

Source: CDC

Nummular eczema consists of small, circular (nummular = coin-shaped), pruritic lesions that are more typical on the extremities and often are associated with dry skin and atopy. The lesions are very common in the **elderly** and have **no** pathologic significance. Rule out fungal infection. Treat with mid- to high-potency topical steroids.

Pityriasis rosea (PR) is a pruritic rash that is common in children and young adults. Its etiology is unknown, but it may be infectious in origin (possibly human herpesvirus 6 or 7). The disease is **self-limited** and asymptomatic (occasionally mildly pruritic), usually lasting 4–8 weeks. Prodromal symptoms of sore throat or runny nose may be present before the rash appears.

A **herald patch** presents as a single, pink, oval patch, often on the trunk, and precedes subsequent pityriasis rosea lesions by 1–2 weeks (**Figure 3-59**). This patch is sometimes confused with tinea corporis (**Figure 3-31 on page 3-20**), but the 2 are **not** related. Subsequently, small, scaly, pruritic, papulosquamous, oval lesions with the long axis parallel to skin folds and rib lines develop in a “**Christmas tree**” pattern, usually on the trunk

Figure 3-59: Herald patch
Source: CDC

(**Figure 3-60**). The scale is at the periphery of the lesion and appears as a collarette (or trailing scale), unlike psoriasis, which has confluent scale over the entire plaque. Treatment is reassurance. However, topical corticosteroids, phototherapy, and/or sunlight may help. Acyclovir reduces symptoms and reduces length of disease. Pityriasis in pregnancy can cause spontaneous abortion.

Urticaria (hives) are raised pruritic papules and plaques on the skin that result from a Type 1 hypersensitivity reaction. The mast cell is the main effector cell. Mast cells have high affinity to IgE and therefore may trigger IgE-dependent allergic responses. Individual lesions of urticaria, by definition, do not last longer than 24 hours and can have **smooth or irregular borders or may be annular**. They are accompanied by pruritus, which often is severe. Common causes of acute urticarial (episodes occurring ≤ 6 weeks) include upper respiratory infections, drugs, and foods. 50% of patients have idiopathic acute urticaria. Chronic urticaria (episodes occurring more often than twice a week for > 6 weeks) may be associated with autoimmune disease or infection or can be idiopathic. Dermatographism is a type of urticaria due to mechanical stimuli and is characterized by whealing of the skin in response to moderate stroking. Simple dermatographism occurs in $\sim 5\%$ of the general population and is considered an exaggerated physiological response. Symptomatic dermatographism is characterized by pruritus and whealing at sites of friction and scratching. Treatment of urticaria

Figure 3-60: Pityriasis rosea with “Christmas tree” distribution

includes avoiding triggers and aggravating factors, such as NSAIDs, aspirin, codeine, and morphine. Cooling and antiitch creams, such as those containing pramoxine, may be helpful. Antihistamines are 1st line therapy, followed by 2nd line therapies, such as systemic corticosteroids. Chronic urticaria may require immunotherapy.

Dermatofibromas are dome-shaped papules resulting from benign dermal proliferation. They are quite common and are most often idiopathic, but they can also be caused by trauma or bites. A “dimple sign” with central depression is often displayed secondary to lateral pressure and is specific to diagnosis. Treatment is observation only, although biopsy can be indicated if the diagnosis is in question. Multiple dermatofibromas may suggest underlying systemic disease such as immune disorders, autoimmune disease, or HIV infection, and previous and current medications should be reviewed.

Erythema multiforme consists of well-defined asymptomatic lesions varying from annular to targetoid (**Figure 3-61**). Palms and soles are frequently involved, and mucous membranes may be affected. These immune-mediated “target” lesions (those with 3 defined zones) are pathognomonic for erythema multiforme. Erythema multiforme is associated with HSV, *Mycoplasma*, and, much less frequently, drugs (e.g., NSAIDs, PCNs). Treatment involves antimicrobial therapy (if a causative organism, such as *Mycoplasma*, is found) or removal of an offending medication. Patients with a history of cold sores and recurrent erythema multiforme may benefit from suppressive antiviral therapy (i.e., valacyclovir, acyclovir, or famciclovir taken daily for ~ 6 months).

Figure 3-61: Erythema multiforme

Source: Kimberly Salkey, MD

PIGMENT CHANGES

PREVIEW | REVIEW

- Hyperpigmented areas of the axilla are associated with what underlying disease states?
- What diseases are on the short list of causes of black lesions?
- What skin discoloration occurs rarely with a polyglandular autoimmune deficiency syndrome?

HYPERPIGMENTATION

Diffuse hyperpigmentation may occur in primary biliary cholangitis (previously known as primary biliary cirrhosis), scleroderma, Addison disease, and hemochromatosis (patients have a grayish/bronze coloration) and with use of the cancer drug busulfan. Other causes include PCT, malabsorption and/or Whipple disease, pellagra (niacin deficiency), B₁₂ deficiency, and folate deficiency. Check for metastatic melanoma in “slate-blue” patients!

Hyperpigmentation in sun-exposed areas can be caused by amiodarone, PCT, and phenothiazines. Hyperpigmentation is diffuse but darker in sun-exposed areas in pellagra, biliary cholangitis, and scleroderma. MTX can cause reactivation of sunburn.

Melasma is an acquired hyperpigmentation often seen in pregnancy or with oral contraceptive use. Diagnose based on history and clinical appearance. Hyperpigmentation occurs in sun-exposed areas of the face and is treated with varying degrees of success using skin protection from the sun and skin-lightening modalities.

Pigmented growths, such as acquired melanocytic nevi, seborrheic keratoses, and solar lentigines, are usually benign and common in the general population:

- **Nevi**—Commonly encountered nevi include:
 - **Common acquired** nevi are round to ovoid lesions typically measuring 2–6 mm. They are generally orderly and symmetrical.

- **Junctional** nevi are macular and often darker in color, compared to compound nevi, which vary in elevation and are slightly lighter in color.
- **Dermal** nevi are even more raised, often dome shaped, and lighter or more evenly pigmented. Over time, the number of nevi seen in a given patient increases and peaks by the 3rd decade of life. Indications for removing a nevus include a lesion that is changing, cosmetic concerns, irritation, and an atypical clinical appearance.

- **Seborrheic keratoses** are light brown, yellow, or dark brown macules, papules, or plaques that are waxy and “stuck-on” in appearance. They are commonly found on the face, head, neck, and back but can be located on any hair-bearing area of the body. They exhibit a familial predisposition, but sun exposure has also been implicated in their development and they are common with increasing age. Conditions associated with abrupt onset of multiple lesions followed by regression include pregnancy, erythroderma, and HIV infection. Rarely, this abrupt onset of seborrheic keratoses is associated with internal malignancy and is called the Leser-Trélat sign. Such onset should lead to investigation for a neoplasm.

- **Solar lentigines** are most commonly found in sun-exposed areas of older individuals but may also be found in younger patients after sun exposure. They are well-circumscribed, round or irregularly shaped brown macules that range from light to dark brown or black. These should be distinguished from pigmented actinic keratoses, which tend to have a rough surface, and lentigo maligna, which tends to be larger and have more pigment variation and irregularity of borders than a solar lentigo.

Peutz-Jeghers syndrome (multiple intestinal hamartomatous polyps) should be ruled out in patients with melanotic pigmentation (**lentigines**) on the lips and buccal mucosa.

Café au lait spots

(Figure 3-62) are brown macules that occur in association with neurofibromatosis Type 1 (a.k.a. von Recklinghausen disease) and McCune-Albright disease. Café au lait spots occur in people with no disease (1 or 2 spots are normal and typical). In neurofibromatosis, 78% of patients have > 6 spots—and 95% have at least 1 spot > 1.5 cm. In McCune-Albright disease, the spots have a more irregular outline and can be rather large.

Figure 3-62: Café au lait spots
Source: Jennifer Vickers, MD

Acanthosis nigricans is hyperpigmented skin with a thickened, velvety appearance, noticed mostly in the skin folds. Involvement of the axilla is commonly shown as an example (Figure 3-63). It is rarely familial. Acanthosis nigricans is associated with:

- Obesity
- Gastrointestinal malignancies
- Endocrinopathies such as diabetes mellitus, Cushing disease, hyper-/hypothyroidism, acromegaly
- Autoimmune problems

Malignant acanthosis nigricans is severe and progressive and is usually associated with gastric adenocarcinoma. It is more commonly seen on the lips, oral mucosa, and palms.

Black lesions—The etiology for black lesions is somewhat extensive, but especially consider the following:

- Rhinocerebral mucormycosis
- Anthrax
- Ecthyma gangrenosum
- Emboli to distal extremities
- Melanoma/Lentigo/Pigmented BCC
- Warfarin skin necrosis
- Necrotic spider bite
- Kaposi sarcoma

WHITE AND HYPOPIGMENTED LESIONS

Pityriasis alba is frequently seen in children and teens with atopic dermatitis. Ill-defined white macules and patches with overlying fine scale are located on the face and, occasionally, the arms. Postinflammatory hypopigmented skin changes can appear similarly after resolution of atopic dermatitis. Pityriasis alba generally improves with age, and its appearance can be minimized with use of sunscreen and sun protection.

Tinea (pityriasis) versicolor is characterized by well-defined, hypopigmented spreading macules, usually on the upper torso and upper arms. The associated fine scale may not be observed unless the skin is stretched. It can be confirmed with use of KOH prep (Figure 3-34 on page 3-21). The associated hypomelanosis may persist for several months after eradication of the organism, but the lesions do not have scale.

Vitiligo is an autoimmune disease that causes destruction of melanocytes, resulting in depigmentation (Figure 3-64). It usually occurs in otherwise healthy persons but can

Figure 3-63: Acanthosis nigricans

Source: Kimberly Salkey, MD

rarely occur as part of a polyglandular autoimmune (PGA) syndrome. Any of the following may be seen with a PGA: diabetes mellitus, autoimmune thyroid disease (hyper- or hypo-), Addison disease/adrenal insufficiency, hypoparathyroidism, and pernicious anemia. Any time you see a patient with vitiligo, think of these possibilities and screen appropriately!

Figure 3-64: Vitiligo

Tuberous sclerosis is uncommon and autosomal dominant. It is associated with seizures, intellectual disabilities, periungual fibromas, and hypopigmented (ash-leaf) macules (Figure 3-65). You see these macules best with a Wood lamp. **Adenoma sebaceum** manifests in these patients as numerous midfacial papules, which are actually angiofibromas (Figure 3-66).

Figure 3-65: Hypopigmented (ash-leaf) macules

Figure 3-66: Angiofibromas

PRURITUS

Pruritus is severe itching as an effect of various conditions. It may be localized or generalized. The most common

cause of pruritus in elderly patients is **dry skin**. Other causes seen across the age spectrum include:

- Hyper- or hypothyroidism
- Malignancy (Think lymphoma—especially Hodgkin's, but also breast cancer.)
- Iron deficiency (even if patient is not anemic)
- Polycythemia vera
- Aquagenic pruritus
- Chronic kidney disease (but not acute kidney injury)
- Cholestatic liver disease
- Diabetes mellitus
- HIV/AIDS

Treat pruritus first by attempting to reverse the cause. With severe systemic disorders, this often is not possible.

Treatment of the itching itself starts with general measures:

- Skin moisturization
- Covering the itchy areas to decrease trauma from scratching
- Making the environment cool and humid
- Education and psychological support to decrease stress and give the patient more control of the situation

Try topical agents if more relief is needed:

- Corticosteroid creams
- Capsaicin cream (yes, the stuff in chili peppers!). Initial burning, which occurs in the first 2–3 weeks of use, is followed by decreased pruritus. Treatment is especially effective in neuropathic disorders and with chronic kidney disease.
- Anesthetic creams
- Antihistamine creams
- Phosphodiesterase 4 inhibitors

Phototherapy is often effective for localized and systemic pruritus.

Systemic therapy is reserved for generalized pruritus not controlled by topical solutions:

- Oral antihistamines are usually the first therapy tried, but they decrease the pruritus only when it is due to histamine release, such as with urticaria or mastocytosis. Antihistamines also cause drowsiness, which can help by decreasing the perceived intensity of itching.
- Opioid receptor antagonists (naltrexone, naloxone, and nalmefene) may help in certain cases.
- Gabapentin and pregabalin are GABA (γ-aminobutyric acid) analog antiseizure medications. They appear to help with neuropathic pruritus caused by nerve entrapment.
- Thalidomide is effective, but it has a lot of side effects and is very teratogenic.
- Aprepitant is a newer, expensive drug that is being used in refractory cases.

HIV- AND AIDS-RELATED SKIN LESIONS

PREVIEW | REVIEW

- What gram-negative infection in AIDS can resemble Kaposi sarcoma?
- What cutaneous neuroendocrine tumor is more common in HIV?

Many common and uncommon skin conditions become more prevalent in HIV/AIDS:

- Infection
 - Bacterial
 - Bacillary angiomatosis (*Bartonella henselae*, the same organism that causes cat scratch disease) lesions appear as vascular purple lesions that bleed easily and can be confused with Kaposi sarcoma. Treatment is with antibiotics for several months.
 - Folliculitis usually occurs in uncontrolled HIV infection and may be caused by *S. aureus*; it improves with antiviral therapy and antibiotics. Of note, people who are HIV positive may also have eosinophilic folliculitis, which is **not** associated with an infectious organism.
 - Viral
 - Herpes simplex
 - Herpes zoster (shingles) is often refractory to treatment in patients with HIV/AIDS. Treat with acyclovir or famciclovir. Valacyclovir is not recommended due to its association with thrombotic thrombocytopenic purpura (TTP) in the immunocompromised. For more on herpes zoster, see [Varicella-Zoster Virus \(VZV\) on page 3-22](#).
 - Condyloma acuminatum (HPV)
 - Molluscum contagiosum (poxvirus)
 - Oral hairy leukoplakia (Epstein-Barr virus; [Figure 3-12 on page 3-7](#)) is corrugated (“hairy”) white lesions along the lateral surface of the tongue that cannot be scraped off. It improves with antiviral therapy.
 - Kaposi sarcoma in HIV is frequently associated with HHV-8.
 - Merkel cell skin cancer (associated with Merkel cell polyoma virus)
 - Fungal/Yeast
 - Oral candidiasis can be scraped off the tongue and mucosal surfaces.
 - Folliculitis usually occurs in uncontrolled HIV infection and may be caused by *Pityrosporum orbiculare*; it improves with antiviral therapy and antibiotics.

- Disseminated *Cryptococcus* infection (Figure 3-67) is an AIDS-defining condition and may imitate molluscum contagiosum. *Cryptococcus neoformans* is a life-threatening fungal infection seen in immunocompromised patients. Cutaneous lesions may present as umbilicated papules similar to molluscum in patients with HIV infection. Other lesions may be papules, pustules, nodules, ulcers, or draining sinuses. Yeast can be seen with India ink stain of the capsule or with tissue slides with mucicarmine stain. Treatment is systemic antifungals.

Figure 3-67: Disseminated *Cryptococcus* infection
Source: CDC

- Neoplastic
 - Kaposi sarcoma, a vascular soft tissue malignancy, usually presents as < 0.5-cm, purple/red/violet/black, maculopapular lesions, which are generally concentrated on the head, neck, and lower extremities (Figure 3-68) but can also occur in the GI tract and the lung. It is common in patients with advanced HIV and improves with antiviral therapy. The CDC considers it an AIDS-defining condition.
 - Basal cell carcinoma risk is 2–3× greater than in the HIV-negative population and occurs in regions of the body not exposed to sunlight.
 - Merkel cell carcinoma, a neuroendocrine tumor, has a 10-fold increased incidence in HIV patients. It is associated with Merkel cell polyoma virus and is a fast-growing, painless, vascular-appearing, intracutaneous, firm nodule on sun-exposed areas. Treatment involves wide surgical excision.
- Other
 - Xerosis (dry skin)
 - Atopic dermatitis
 - Eosinophilic folliculitis
 - Seborrheic dermatitis (occurs in virtually all patients!) improves with antiviral therapy. For more information on this topic, see [Seborrheic Dermatitis on page 3-2](#).
 - Telangiectasias

Figure 3-68: Kaposi sarcoma

SKIN SIGNS OF SYSTEMIC DISEASES

PREVIEW | REVIEW

- What is the significance of eruptive xanthomas?
- What is the significance of dark atrophic macules in a diabetic?

DIABETES MELLITUS

Necrobiosis lipoidica diabetorum (Figure 3-69) can be associated with diabetes in approximately 10–20% of cases. This thin, atrophic, hyperpigmented plaque, appearing on the **shins**, is subject to trauma and ulceration and is thought to be due to microangiopathy.

Figure 3-69: Necrobiosis lipoidica diabetorum
Source: Kimberly Salkey, MD

Eruptive xanthomas are caused by severe hypertriglyceridemia. They are often seen in diabetic ketoacidosis, appearing abruptly as yellowish-red papules over the extensor surfaces and buttocks (Figure 3-70). These lesions resolve when the hyperglycemia is controlled.

Figure 3-70: Eruptive xanthomas in a patient with diabetes

Diabetic dermopathy (“shin spots”) are dark atrophic macules; they are common and often appear on the shins. They have no clinical significance.

Acanthosis nigricans is characterized by velvety hyperpigmented patches commonly seen in intertriginous areas such as the neck, axillae, and groin. It is associated with diabetes and insulin resistance. If seen on the lips, oral mucosa, and palms, it may be malignancy related. For more on acanthosis nigricans, see [Hyperpigmentation on page 3-33](#).

KIDNEY DISEASE

Calciophylaxis occurs in patients with end-stage renal disease, particularly diabetic, Caucasian, obese women on long-term hemodialysis. Ischemic necrosis results from the calcification of dermal arterioles. Early lesions can manifest as painful erythematous nodules or livedo reticularis. Older lesions appear as indurated subcutaneous nodules with overlying retiform purpura and necrosis. They are exquisitely painful and carry a poor prognosis, especially when located proximally, such as on the trunk, thighs, and buttocks. Treatment includes sodium thiosulfate, control of pain, and wound care, including debridement.

ENDOCRINE DISORDERS

Cushing syndrome: Patients with Cushing syndrome may exhibit a rounded face (moon facies), a buffalo hump, and global atrophy that may manifest as purpura, striae, cutaneous fragility, and poor wound healing.

Hereditary hemochromatosis: Patients with hereditary hemochromatosis can have diffuse bronzing of the skin (sparing the mucous membranes) that is secondary to increased melanin.

Addison disease: Patients with Addison disease can experience diffuse hyperpigmentation, particularly in sun-exposed areas, hair and nails, palmar creases, mucous membranes, and the axillae, perineum, and nipples. They may also note loss of pubic and axillary hair (in postpubertal women) and fibrosis of the cartilage of the ear.

RHEUMATOLOGIC DISORDERS

Gout: Patients with tophaceous gout may have deposits of monosodium urate that manifest as skin-colored to yellow-hued dermal or subcutaneous nodules or papules. They may be smooth or lobulated. The most common location for these lesions is the helix of the ear or overlying joints. They may be ulcerated or drain a chalky material.

Lupus erythematosus can have varied cutaneous findings. Acute cutaneous lupus erythematosus (ACLE) is characterized by pink, scaly, and/or edematous lesions in sun-exposed areas. A malar rash on the cheeks and nasal bridge that spares the nasolabial folds exemplifies these lesions ([Figure 3-17 on page 3-12](#)). They heal

without scarring. Erythematous scaling plaques occur on the dorsal hands and spare the knuckles.

Subacute cutaneous lupus erythematosus (SCLE) is characterized by annular lesions with raised red borders and central clearing in sun-exposed areas. These lesions also do not typically scar and can be seen in association with Sjögren syndrome. They are often caused by sunlight exposure and drugs, such as antihypertensive medications. The face is spared.

Lesions of discoid lupus erythematosus (DLE) are commonly found on the head and neck. They are initially erythematous and indurated plaques. Chronic lesions may exhibit hypopigmentation centrally with peripheral hyperpigmentation and often leave disfiguring scarring.

Rheumatoid arthritis (RA): Patients with RA may have numerous cutaneous manifestations of their disease. More common findings include rheumatoid nodules, vasculitic lesions, pyoderma gangrenosum, and Sweet syndrome.

Sweet syndrome (acute febrile neutrophilic dermatosis) can resemble RA and presents with leukocytosis, fever, and tender, erythematous papules and plaques, with painful joints and nodules on the skin (see [Sweet Syndrome on page 3-15](#)).

Rheumatoid nodules are found in 20% of patients with RA and are firm, somewhat mobile papules and nodules that occur over extensor surfaces and areas of pressure or trauma. They can be asymptomatic or tender.

THE MEDSTUDY HUB: YOUR GUIDELINES AND REVIEW ARTICLES RESOURCE

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub at

medstudy.com/hub

The Hub contains the **only** online consolidated list of **all** current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source. MedStudy maintains the Hub as a service to the medical community and makes it available to anyone and everyone at no cost to users.

URINARY TRACT INFECTIONS (UTIs)

PREVIEW | REVIEW

- In which 3 settings would you treat asymptomatic bacteriuria?
- What are the standard treatments for uncomplicated cystitis, complicated cystitis, uncomplicated pyelonephritis, and complicated pyelonephritis?
- What 2 types of prostatitis require antibiotic therapy, and which drugs should be given?

CYSTITIS AND PYELONEPHRITIS

Microbiology

A wide variety of organisms cause UTIs, but *Escherichia coli* and other gram-negative aerobic enterics are the most common causes. Among gram-positive organisms, *Enterococcus* is the most common genus. In the absence of a urinary catheter, *Staphylococcus aureus* is an uncommon cause of a UTI, and its presence in the urine should raise the concern that it seeded the kidney via a bacteremia from another source. Coagulase-negative staphylococci are rarely true pathogens and suggest contamination of the urine from skin flora. The one exception is *Staphylococcus saprophyticus*, which is a definite cause of cystitis but rarely a cause of pyelonephritis.

Epidemiology

Risk factors for UTIs in women include sexual activity, diaphragm use, vaginal atrophy, and diabetes mellitus. UTIs are less common in men, and sexual activity is not a risk factor **except** in men who have sex with men. In heterosexual men, UTIs are usually the result of a structural abnormality in the urinary tract, such as vesicoureteral reflux or obstruction from prostatic hyperplasia. UTIs are the most common nosocomial infections. In either sex, UTIs are increased in the presence of diabetes mellitus, sickle cell disease, or renal stones. *Proteus* infections are specifically associated with urinary stones, so if *Proteus* is identified in the urine, order imaging tests to look for stones. Group B *Streptococcus agalactiae* infections are more commonly seen in pregnancy (see the [Women's and Men's Health](#) section).

Presentation

The classic symptoms of UTIs include dysuria, frequency, and urgency. Flank pain and fever are seen in ~ 50% of patients with pyelonephritis but are not common with uncomplicated cystitis.

Diagnosis

Confirm the diagnosis by culture growth of $\geq 10^5$ gram-negative organisms/mL of urine. Yeast or gram-positive organisms can cause infection with lower colony counts. A positive urine culture in the absence of symptoms is **not** considered a UTI; it is called asymptomatic bacteriuria. In a nonneutropenic patient, the absence of pyuria has good negative predictive value and essentially rules out a UTI. The presence of pyuria alone, however, is not sufficient to diagnose a UTI.

Treatment

The 1st step in determining treatment for a positive urine culture is to determine if the patient has signs or symptoms of infection. If signs or symptoms are present, it is a UTI; if not, it is asymptomatic bacteriuria. **Treat asymptomatic bacteriuria under only 3 circumstances:**

- 1) Treat pregnant women to prevent progression to pyelonephritis and to decrease maternal and fetal morbidity and mortality. Safe regimens in pregnancy include a 3-day course of trimethoprim/sulfamethoxazole (TMP/SMX; during weeks 12–36 only), nitrofurantoin (not at term), or cephalexin.
- 2) Treat patients about to undergo an invasive urologic procedure.
- 3) Treat renal transplant recipients within the first month after transplantation to decrease the risk of a symptomatic UTI, which increases the risk of rejection.

With **symptomatic** UTIs, the 2nd step is to determine whether the infection is in the lower tract (cystitis) or upper tract (pyelonephritis). Cystitis usually has no systemic signs of infection or flank tenderness, and fever is usually low grade if present. Pyelonephritis typically has high-grade fever (often $> 102.0^\circ\text{F}$ [38.9°C]) and flank pain. Sepsis may be present, and blood cultures are positive in ~ 10% of patients.

The 3rd step is to determine whether the UTI is complicated or not. **Complicated** UTIs occur with structural anomalies, foreign bodies, or prior resistant organisms and in patients who are immunocompromised, have diabetes, or are male.

Uncomplicated cystitis can be treated based on symptoms alone and does not require a urine culture. Do a urine culture for all other UTIs. In cystitis, do not perform imaging of the urinary tract (ultrasound [U/S] or computed tomography [CT]). In **uncomplicated pyelonephritis**, perform imaging of the urinary tract only if symptoms persist after 72 hours of culture-guided therapy.

Antibiotic therapy:

- **Uncomplicated cystitis:** The treatment of choice is either nitrofurantoin monohydrate/macrocrystals or a 3-day course of TMP/SMX depending on local resistance patterns (do **not** use TMP/SMX if there is $\geq 20\%$ resistance in the community), the patient's allergy history, and whether prior antibiotics have been used. A single dose of fosfomycin is a 2nd line treatment due to slightly lower cure rates. Avoid the use of fluoroquinolones for uncomplicated cystitis because of resistance and toxicity issues (discussed in [Fluoroquinolones on page 4-82](#)).
- **Complicated cystitis or uncomplicated pyelonephritis:** Treat with a fluoroquinolone, TMP/SMX, or a β -lactam depending on the culture and sensitivity (C&S) data.
- **Complicated pyelonephritis and/or hospitalized patients:** Treat with a fluoroquinolone, ceftriaxone, a β -lactam + a β -lactamase inhibitor, or ampicillin + aminoglycoside for 7–10 days. Adjust the antibiotic regimen based on the C&S results.

Change a urinary catheter only if the UTI is symptomatic.

Differentiate **recurrent** UTIs into 2 types: **relapses** (the same strain within 2 weeks of the end of prior therapy) or **reinfection** (a different strain than the initial infection). Relapses are commonly due to a persistent nidus of infection (e.g., stones, abscess, urethral/ureteral/bladder diverticula, obstruction) in the urinary tract. So, to evaluate relapses, perform a renal U/S and/or CT of the abdomen and pelvis with contrast. Reinfection is sometimes related to diaphragm use, spermicides, and sexual activity. If this is the case, consider alternative contraception, but if the reinfection is correlated with sexual intercourse, give low-dose prophylaxis (e.g., TMP/SMX 1/2 single-strength tablet, nitrofurantoin 50 mg) before or after sexual activity. If there is no sexual activity and the patient has < 3 episodes a year, treat the UTIs as they occur. If the patient has ≥ 3 episodes a year, consider chronic low-dose suppression for 6 months.

Complications

A perinephric abscess can occur as a complication of pyelonephritis, usually from infection with gram-negative organisms, by the direct spread of the renal infection. The diagnosis can be difficult since the symptoms are nonspecific and insidious. These include fever, chills, abdominal pain, fatigue, and weight loss. Dysuria and increased frequency are uncommon because the infection is often completely **outside** of the urinary tract and organisms are not entering the bladder. The patient typically has unilateral costovertebral flank pain on physical examination. Occasionally, a flank mass is palpated if the abscess is large enough.

Lab work reveals leukocytosis and elevated inflammatory markers (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]). Pyuria may be present if the

abscess communicates with the collecting system. Obtain blood and urine cultures. U/S may be the initial imaging, but a CT scan has a higher sensitivity and may show renal enlargement and inflammation with extrarenal fluid and gas collections. Perform CT- or U/S-guided percutaneous drainage for C&S testing and to therapeutically drain the abscess.

The treatment consists of empiric antibiotics directed toward Enterobacteriaceae, such as the regimens recommended for pyelonephritis (refer to [Treatment on page 4-1](#)), until the culture results are known, at which time the therapy is tailored to the culture results. If the abscess occurs in the setting of staphylococcal bacteremia, modify the selection of antibiotics and complete the entire course with intravenous (IV) antibiotics. The inflammatory markers help monitor the clinical status.

PROSTATITIS

Prostatitis has 4 subtypes based on symptoms, the presence or absence of bacteria, and the presence or absence of inflammation.

Type I prostatitis is **acute** bacterial prostatitis. The causative organisms are the same as for cystitis. Acute bacterial prostatitis typically has a very dramatic presentation, with frequency, dysuria, hesitancy, perineal pain, and referred penile tip pain and associated high-grade fevers and chills. Bacteremia is common. All antibiotics penetrate well into prostatic tissue during acute infection. Severely ill patients with **Type I** prostatitis require hospital admission and IV antibiotics (e.g., ceftriaxone). Once stable, treat patients with 6 weeks of antibiotics based on the susceptibility of the organism cultured.

Type II prostatitis is **chronic** bacterial prostatitis. Patients with this type of prostatitis present with recurrent UTIs with the same organism (relapsing UTIs). The symptoms are less dramatic than for Type I disease; Type II presents as cystitis or persistent/recurrent bacteriuria. Penetration of antibiotics into the chronically, more mildly inflamed gland varies among antibiotic classes. Prostatic secretions are acidic, so drugs with alkaline pharmacokinetics (i.e., fluoroquinolones, TMP/SMX) penetrate best. Give a fluoroquinolone as the 1st line treatment for Type II prostatitis and TMP/SMX as an alternative. Antibiotics are given for at least 6 weeks, but recurrences are common. If there is a recurrence, retreat the infection with 6 more weeks of a fluoroquinolone. Consider atypical organisms such as *Ureaplasma* or *Chlamydia* in sexually active men, and treat empirically with a tetracycline if prior antibiotic failure has occurred.

Type III chronic prostatitis/chronic pelvic pain has 2 forms, Type IIIA and Type IIIB, neither of which is an infectious disease. Both forms present like Type II. Type IIIA has evidence of prostatic inflammation (white blood cells [WBCs] in expressed prostatic secretions or

post-prostatic massage urine specimens) but **no bacterial** infection on culture. Type IIIB has neither signs of prostatic inflammation nor bacterial infection. Use α -blockers as the initial treatment, and if symptoms persist, refer to a urologist.

Type IV prostatitis is asymptomatic inflammatory prostatitis. Prostate inflammation is found incidentally when tissue is removed for another reason, such as prostate biopsy or resection. Patients do not require antibiotics.

CATHETER-ASSOCIATED UTIs (CAUTIs)

Indwelling urinary catheters are a common cause of UTIs, especially in hospitalized patients. Studies show that 23% of patients in U.S. hospitals, up to 70% of patients in critical care units, and up to 10% of patients in long-term care facilities have an indwelling urinary catheter. Consider indwelling catheters that are in place for ≤ 30 days as short term and those that are in place for > 30 days as long term. It is important (and often difficult) to distinguish between catheter-associated asymptomatic bacteriuria (CA-ASB) and a CAUTI, because the former does not warrant antibiotic treatment.

Catheter-Associated Asymptomatic Bacteriuria (CA-ASB)

CA-ASB develops quickly in patients with an indwelling urinary catheter. The daily risk of acquiring CA-ASB is 3–10%, and CA-ASB is present in almost all patients after 2 weeks. In addition to catheterization, other risk factors for CA-ASB are older age, female sex, diabetes mellitus, and errors in catheter care. Up to 80% of hospitalized patients with urinary catheters get antibiotics for a variety of infections, and this may lead to acquisition of organisms with antibiotic resistance.

Symptomatic UTIs

Anywhere from 10% to 25% of patients with CA-ASB will develop symptoms and thus have a CAUTI. CAUTIs account for 20% of all health care-associated bacteremias, and patients with CAUTIs have a mortality rate of $\sim 10\%$.

Pathogens

E. coli infection is the most common infection. Other pathogens include *Klebsiella*, *Enterococcus*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, and *Candida*.

P. mirabilis infection becomes more prevalent in patients with long-term indwelling catheters. *P. mirabilis* produces urease, which alkalinizes the urine. This increases the risk of urolithiasis from struvite stones.

Diagnosis

Establish the diagnosis of CA-ASB in a patient with $> 100,000$ CFU/mL of an organism with no symptoms of a CAUTI. Catheters in place for > 2 weeks have an established biofilm, so samples collected from the catheter may reflect organisms in the biofilm but not in the bladder. The suggestion is to replace the catheter and send a sample from the new catheter to be sure the organism is present in the bladder and not just in the biofilm.

The diagnosis of a CAUTI can be made if there is no other explanation for fever, malaise, altered mental status, hematuria, or costovertebral angle tenderness. Suprapubic tenderness may also be present. If a catheter is no longer present, the patient may have dysuria, frequency, or urgency.

Finding the same organism in urine and blood cultures is useful to diagnose a CAUTI.

Pyuria in itself does not establish the diagnosis of a CAUTI because it may reflect inflammation from either the indwelling catheter or other diseases such as interstitial nephritis. By itself, pyuria is not a reason for treatment.

Treatment of CAUTIs

For CAUTIs:

- Consider empiric therapy that accounts for local common isolates and antibiotic resistance patterns.
- Data exists that suggests empiric antibiotics do not lead to a better outcome.
- Consider changing the catheter prior to administering antibiotics.
- Since CAUTIs are considered to be a complicated UTI, treatment is generally longer than for uncomplicated UTIs. There is no consensus as to the duration of treatment, but it is generally 5–21 days.

Prevention of CAUTIs

Avoiding the use of urinary catheters is clearly the most effective way to prevent CAUTIs. Along those lines, when a catheter is in use, providers should remove the catheter as soon as possible. Automatic stop orders (orders for catheter removal) can reduce the occurrence of CAUTIs. Smaller catheters may be safer because they cause less trauma. There is no proven benefit with the use of antimicrobial-coated catheters or the administration of prophylactic antibiotics after catheter insertion. Avoid treatment of CA-ASB.

Some accepted indications for urinary catheters are:

- Tracking urine output in critically ill patients or during surgery
- Urinary obstruction or retention
- Perioperative use for certain surgeries

- Urologic surgery or surgery in the adjacent areas
- When giving large amounts of fluids or diuretics during surgery
- To facilitate skin healing with pressure sores or grafts in a patient who is not continent of urine (consider condom catheters instead for men)
- Patient comfort, such as hospice care

UPPER RESPIRATORY TRACT INFECTIONS

PREVIEW | REVIEW

- Otitis externa is usually due to which organism?
- How many days of symptoms are required to diagnose a patient with bacterial sinusitis and prescribe antibiotics?
- What are the usual causative organisms of bacterial sinusitis?
- What are some symptoms of rhinocerebral mucormycosis, and what is the best treatment?
- How can you differentiate allergic rhinitis from bacterial rhinosinusitis?
- What antibiotics should be given for sinusitis?
- What clinical findings eliminate the need to test for group A β -hemolytic streptococcal pharyngitis?

ACUTE OTITIS MEDIA (AOM)

AOM is very uncommon in adults, and its presence suggests structural anomalies or immunocompromise. It presents with ear pain and hearing loss +/- fever. Diagnose AOM by visualizing both inflammation of the tympanic membrane (erythema or purulent drainage) and fluid in the middle ear. *Streptococcus pneumoniae* is the most common infecting bacterium. Nontypeable *Haemophilus influenzae* and *Moraxella catarrhalis* are also causative agents.

Treat with amoxicillin alone if the patient has not taken antibiotics recently. Treat with amoxicillin/clavulanate, cefuroxime, ceftriaxone, or quinolones if the patient has recently taken other antibiotics or if initial treatment failed. If patients do not respond, perform tympanocentesis to obtain culture data.

OTITIS EXTERNA (SWIMMER'S EAR)

Otitis externa is also predominantly a pediatric infection. Only 5% of cases are in adults > 20 years of age. It is predisposed by trauma, foreign bodies, dermatitis, and moisture, especially from swimming (hence the term "swimmer's ear"). Otitis externa presents with pain and itching in the external auditory canal. The causative organism is usually *Pseudomonas aeruginosa*. Note that

Staphylococcus epidermidis and *Staphylococcus aureus*, even when combined, are still a distant 2nd. Treat otitis externa with a topical fluoroquinolone.

Malignant (necrotizing) otitis externa is potentially fatal. Over 90% of patients are diabetic, and immunosuppression is another risk factor. Malignant otitis externa presents the same as otitis externa but progresses to an invasive and destructive infection of the soft tissue and bone. *P. aeruginosa* is the cause in > 95% of cases. Treat the infection with IV antibiotics directed against *P. aeruginosa* (e.g., a fluoroquinolone, an antipseudomonal β -lactam), and adjust the treatment based on the culture results. Therapy is usually required for 6–8 weeks.

SINUSITIS

Sinusitis is inflammation of the paranasal sinuses.

The classification is based on the duration:

- Acute sinusitis: persists $\leq$ 4 weeks
- Subacute sinusitis: persists 4–12 weeks
- Chronic sinusitis: persists > 12 weeks
- Recurrent sinusitis: > 3 episodes of acute sinusitis per year

Most sinusitis stems from viral infections. Use clinical criteria (see below) to decide whether there is a likelihood of bacterial infection and thus a benefit to giving antibacterials. The pathogenesis of bacterial sinusitis is obstruction of the sinus ostia that allows bacteria that are usually transient colonizers to persist in the sinus cavity.

There are 2 clinical findings predictive of bacterial sinusitis:

- 1) Duration of symptoms $\geq$ 10 days or
- 2) Worsening of symptoms after an initial improvement (double sickness) that occurs after $\geq$ 3 days

Unless these criteria are met, most infectious sinusitis is viral, and should be treated symptomatically with nasal saline. There is no role for decongestants and antihistamines.

Fever > 102.0°F (38.9°C) with purulent drainage or facial pain for $\geq$ 3 days at the beginning of the illness supports the diagnosis of acute bacterial sinusitis.

The most common causative bacterial organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* (the same 3 as for AOM). **Chronic sinusitis** can also be caused by *Staphylococcus aureus*, group A *Streptococcus*, enteric gram-negative bacilli (GNBs), *Pseudomonas aeruginosa* (especially with cystic fibrosis), and anaerobes, such as *Fusobacterium* and *Bacteroides*. Cultures are difficult to interpret in this setting, because patients often have received multiple courses of antibiotics, and the cultures usually represent colonization.

Fungal sinusitis (specifically mucormycosis) is seen in patients with diabetes, cancer, iron overload, and hematologic malignancies and in those receiving corticosteroid therapy. A patient with rhinocerebral mucormycosis

may present with symptoms of only a sinus infection or with unilateral nasal congestion. Tissue necrosis occurs as infection spreads outside of the sinuses, with the resulting distinctive **black eschar** sometimes visible on the palate and/or nasal mucosa. (See the discussion on **Mucormycosis** on page 4-57.) This is not the same as for asymptomatic patients who have had multiple courses of antibiotics and are colonized with fungi.

Symptoms can assist in localizing which sinus is involved. Frontal sinusitis can include headache that is worse when leaning forward (known as bowler's headache). Maxillary sinusitis sometimes presents with maxillary tooth pain, which is a very specific finding. Sphenoid sinusitis can include headache at the vertex of the skull.

Patients with chronic sinusitis commonly have > 1 symptom, including nasal congestion, alteration in smell, facial pressure or headache, and purulent rhinorrhea.

It is important to differentiate bacterial rhinosinusitis from allergic rhinitis, especially if seasonal. Both allergic rhinitis and nonallergic rhinitis with eosinophilia syndrome show a high number of eosinophils on a nasal smear. Bacterial rhinosinusitis, however, shows large numbers of neutrophils and bacteria.

Bacterial sinusitis is treated empirically, but failure to respond or frequent relapses warrant sinus cultures, which can be obtained endoscopically. Consider cystic fibrosis if *Pseudomonas* grows from a sinus culture (especially in a young adult with a history of recurrent respiratory issues).

Radiography: Sinusitis is generally a clinical diagnosis; imaging is not typically required and does not help differentiate a viral from a bacterial infection. Only perform imaging (CT or magnetic resonance imaging [MRI]) for patients who fail to respond to empiric therapy or who have frequent relapses to look for a structural abnormality.

Treatment of sinusitis: If you suspect acute bacterial sinusitis based on the above criteria, start amoxicillin/clavulanate. 2nd line drugs are the fluoroquinolones and doxycycline. The recommended duration of therapy is 5–7 days for amoxicillin/clavulanate and 7–10 days for the 2nd line agents. Intranasal corticosteroids and saline irrigation can be used as adjunctive treatment. Intranasal decongestants and antihistamines are not useful.

Chronic sinusitis rarely responds to antibacterial therapy. An ear, nose, and throat (ENT) consultation is helpful to obtain cultures, provide surgical drainage, and correct any anatomical causes.

Treatment of rhinocerebral mucormycosis requires emergent measures, including the correction of any underlying diseases (e.g., diabetic ketoacidosis), radical surgical debridement, and lipid amphotericin B to decrease the high mortality rate. (The lipid formulation is used so that you can give higher amphotericin B doses with less toxicity.) Posaconazole or isavuconazole is used after patients begin to improve on amphotericin B or in patients who cannot tolerate amphotericin B.

DEEP INFECTIONS OF HEAD AND NECK

Deep infections of the head and neck are named by their location and include submandibular space infections (which include infections of the sublingual and submylohyoid spaces), lateral pharyngeal space infections, and retropharyngeal space infections. An infection can spread from one space to another.

All of these infections are caused by a mixed oral flora that includes oral anaerobic bacteria. They develop from an extension of the normal oral flora into deeper locations from more superficial infections (e.g., tonsillitis leading to a peritonsillar abscess) and/or from the invasion of a high inoculum of bacteria due to poor dental hygiene. The presentation depends on which space is infected, and more than one infection can occur at the same time. Treatment is with antibiotics directed at normal flora and surgical drainage if abscess forms.

Submandibular space infection (a.k.a. Ludwig angina):

- Cellulitis of the floor of the mouth and submandibular neck
- If it extends posteriorly, it can obstruct the airway.

Lateral pharyngeal space infection:

- Anterior to the sternocleidomastoid muscle
- Contains carotid artery, jugular vein, cranial nerves 9 through 12
- Carotid infection can lead to infected cerebral emboli.
- Jugular infection can lead to infected pulmonary emboli.
- Can be caused by *Fusobacterium necrophorum*, an anaerobic GNB. This is known as **Lemierre syndrome**.

Retropharyngeal space infection:

- Contiguous spread from pharyngitis, tonsillitis, or other neck space
- Descends to C7–T1
- Presents with dysphagia and neck pain increased with hyperextension and possibly stridor
- Posterior to this is the **danger space**, so called because it tracks to the mediastinum.
- Posterior to this is the **prevertebral space**, which is a space that travels down to the pelvis.

In an otherwise healthy patient without comorbidities, ampicillin-sulbactam or a similar antibiotic is appropriate. In a patient with extensive surgery, neoplasm, or prior antibiotic therapy, use broad-spectrum antibiotics pending the surgical culture data.

PHARYNGITIS

The majority of pathogens that cause a sore throat are viruses and are self-limited. The most common of these are rhinoviruses, coronaviruses, and enteroviruses. *Streptococcus pyogenes* (group A β -hemolytic *Streptococcus* [GABHS]) is the bacterial pathogen that causes adult pharyngitis with enough frequency to consider routine testing.

The only other bacteria that cause pharyngitis amenable to treatment are *Neisseria gonorrhoeae* (pharyngeal gonorrhea) and *Corynebacterium diphtheriae* (diphtheria).

The 2012 Infectious Diseases Society of America (IDSA) guidelines for the management of group A streptococcal pharyngitis delineate which adults to test for GABHS, which diagnostic tests to perform, and who to treat based on this testing.

Use associated symptoms to assess the likelihood of GABHS vs. a viral infection. GABHS rarely infects below the pharynx, so having an associated cough and hoarseness are not typical. It does not inflame the nasopharynx; therefore, coryza is not seen, and it does not cause ulcerative lesions. It rarely causes conjunctivitis. Respiratory viruses can cause all of these symptoms, so the presence of these symptoms makes it unnecessary to test for or treat GABHS. Conversely, do test an adult with pharyngitis who has none of these symptoms and has a fever or swollen lymph nodes.

Initially test for GABHS via a rapid antigen-detection test (RADT). This test has a sensitivity of ~ 80% but a specificity of > 95%. Because of its high specificity, a positive test is sufficient evidence for GABHS infection to begin treatment.

Adults generally are not at high risk for streptococcal pharyngitis; therefore, a negative RADT result has a sufficient negative predictive value, and no further testing or treatment is required; however, do obtain cultures for all adults with high exposure to children and adolescents (e.g., school teachers, day care center workers) even with a negative RADT result. Regardless of which test is performed, treat only patients with a positive test result.

Treatment of GABHS infection decreases the risk of local complications (e.g., peritonsillar abscess) and rheumatic fever as long as it is given within the first 72 hours. If the RADT result is negative and clinical suspicion is low, it is appropriate to wait for a positive culture prior to treatment to avoid overtreatment of viral pharyngitis. It is also not clear whether treatment decreases the occurrence of poststreptococcal glomerulonephritis. Treat for 10 days with oral penicillin (PCN) or amoxicillin. Treat PCN-allergic patients with clindamycin for 10 days or azithromycin for 5 days.

Only a few infectious diseases cause pharyngitis with a rash. These are limited to scarlet fever caused by GABHS (which presents with diffuse erythema with fine, sandpaper-like papules), acute human immunodeficiency virus (HIV, which presents with a maculopapular rash), *Arcanobacterium haemolyticum* (which presents with diffuse erythema), *Mycoplasma pneumoniae* (which presents with erythema multiforme), Epstein-Barr virus (which presents with a maculopapular rash in 30% of patients and up to 90% of patients given ampicillin), and coxsackieviruses (which present with a vesicular rash).

EPIGLOTTITIS

Infection of the epiglottitis is a potentially life-threatening disease due to the possibility of airway compromise. It presents as sore throat and odynophagia but can be differentiated from pharyngitis if patients also have drooling or stridor. The base of the tongue inserts next to the epiglottis, so 50% of patients have pain with movement of the tongue and speak as if they have hot food in their mouth (referred to as the “hot potato” voice). They also may be more comfortable with neck flexion rather than extension. The most common infecting organism is *Haemophilus influenzae*, but there are myriad other bacterial pathogens (including *Streptococcus pneumoniae* and *Staphylococcus aureus*) and viral pathogens, and in most cases the blood and throat cultures are negative.

Diagnose epiglottitis by demonstrating inflammation of the epiglottis with the gold standard, direct laryngoscopy (the oropharyngeal examination is often normal), or with imaging showing a swollen epiglottis on a lateral neck film (indicated by a thumb sign) or neck CT scan.

Paramount treatment consists of protecting the airway immediately if there are any signs or symptoms suggestive of airway compromise and administering empiric antibiotics. Throat cultures are only obtained after airway safety is secure. Empiric antibiotics to use are ceftriaxone or cefotaxime plus an agent with methicillin-resistant *S. aureus* (MRSA) coverage (e.g., vancomycin).

SKIN / SOFT TISSUE, JOINTS, BONES

PREVIEW | REVIEW

- What factors determine the approach to therapy of common skin and soft tissue infections?
- What is the clinical presentation of *Mycobacterium marinum*?
- How is a prosthetic joint infection diagnosed?
- Which organism besides *Staphylococcus aureus* causes osteomyelitis in a patient with sickle cell disease?

COMMON SKIN AND SOFT TISSUE INFECTIONS

As of 2014, the IDSA recommends that skin and soft tissue infections (cellulitis affecting the deeper dermis and subcutaneous tissues) be separated into purulent and nonpurulent categories that are predictive of their microbiologic cause and best empiric treatment. Purulent cellulitis is most commonly caused by *Staphylococcus aureus*, and nonpurulent cellulitis is most commonly caused by *Streptococcus pyogenes*. The approach to management is based on the presence or absence of purulence and the severity of illness.

Patients with mild cellulitis have no associated systemic signs or symptoms. Patients with moderate cellulitis have systemic signs (e.g., fever, chills, myalgias). Patients with severe cellulitis have associated sepsis, have skin bullae or sloughing, or are immunocompromised.

Purulent Cellulitis

Incise and drain purulent cellulitis.

A **mild purulent** soft tissue infection does not require culture. Studies from 2016 show a benefit in giving a 7-day course of TMP/SMX with respect to cure, the need for repeat incision and drainage, and the spread of infection to household contacts. Doxycycline is an alternative in the sulfa-allergic patient.

Culture **moderate purulent** soft tissue infections and then give empiric therapy that targets MRSA, which is the pathogen in ~ 50% of these cases. Treat moderate infections with oral TMP/SMX or doxycycline. These inexpensive antibiotics remain active against ~ 90% of *S. aureus* strains regardless of methicillin sensitivity. Alter the treatment if needed based on the C&S report.

Culture **severe purulent** cellulitis and begin IV agents active against MRSA (e.g., vancomycin, daptomycin, linezolid) empirically.

Nonpurulent Cellulitis

The absence of pus makes obtaining cultures difficult. Treat **mild nonpurulent** cellulitis with oral agents that target *Streptococcus pyogenes*, such as penicillin, a 1st generation cephalosporin, cephalexin, or clindamycin. Because of the rapidly progressive nature of *S. pyogenes* infections, give IV therapy with the same agents or ceftriaxone to patients with **moderate** disease and obtain blood cultures.

Severe disease, especially if there is bullae formation or slough, requires immediate surgical debridement to rule out necrotizing fasciitis (see [Necrotizing Fasciitis](#)) and to obtain tissue cultures along with blood cultures. Because organisms other than *S. pyogenes* can cause necrotizing fasciitis, treat empirically with vancomycin and piperacillin/tazobactam while awaiting these culture results.

Rapidly Progressive Cellulitis

A few soft tissue infections are rapidly progressive and can spread up to 1 cm/hour through infected tissue.

Necrotizing Fasciitis

Necrotizing fasciitis is a life- and limb-threatening infection that only a handful of organisms can cause. These infections can progress as rapidly as 1 cm/hour. Solitary organisms capable of doing this include group A or B *Streptococcus*, *Vibrio vulnificus*, *Staphylococcus aureus*, and *Clostridium* species. A mixed infection with

gram-negative aerobic and anaerobic organisms can also cause necrotizing fasciitis. This can occur if stool flora contaminate a pressure ulcer near the anus or as a post-delivery obstetrical complication. Patients with microvascular disease from diabetes are at increased risk. When these organisms gain entrance to the fascial plane, there is little physical resistance to their spread. In addition, neurovascular bundles run along the fascia, and destruction of these bundles leads to the classic symptoms that occur.

The destruction of the arterial supply of the skin causes necrosis with resultant bleb formation (often black) and sloughing. The inflammation of cutaneous nerves leads to initial extreme pain, often disproportionate to the skin appearance, that paradoxically improves as the disease progresses due to nerve destruction. If gas-forming organisms (e.g., *Clostridia* GNBs, enteric GNBs) are the cause, there can be crepitus on examination. Imaging may show fascial inflammation and/or gas, but the definitive diagnosis is made by surgical exploration, which should be done emergently to debride dead tissue and obtain cultures. Empiric broad-spectrum antibiotics are important but are only adjunctive to surgery because they do not reach the infected devascularized tissue. Repeated surgical intervention is often needed.

Erysipelas

Erysipelas is the name given to streptococcal lymphangitis characterized by well-demarcated, raised borders affecting the superficial dermis and lymphatics. Lymphatic involvement with streaks in infected limbs is common and is predisposed by lymphedema or trauma to the lymphatic system (e.g., postmastectomy in the arms, post-saphenous vein harvesting in the legs, liposuction).

Pasteurella multocida

Pasteurella multocida is a GNB that causes infection in many animals and colonizes their mouths. Transmission to humans is typically via a dog or cat bite. Initially there may be little inflammation, but a rapidly progressive, nonnecrotizing cellulitis can ensue. The overall management of bite wounds is discussed in more detail under [Animal Bites on page 4-9](#). *P. multocida* is susceptible to most antibiotics. Amoxicillin/clavulanic acid is the treatment of choice. Alternative drugs include 3rd generation cephalosporins, doxycycline, and the fluoroquinolones.

UNIQUE SOFT TISSUE INFECTIONS

Vibrio vulnificus is a GNB that causes a necrotizing soft tissue infection after ingestion or inoculation of salt water into nonintact skin (e.g., skin penetrated by a fishing hook, fish spines, or oyster shucking knife). It is common in coastal, warm, salt, or brackish water. Particularly susceptible to sepsis are those who are immunocompromised or have chronic liver disease

or hemochromatosis. It can also cause fever, shaking chills, and bullous lesions. Diagnose *V. vulnificus* infection by culture, and treat with ceftriaxone and doxycycline.

Mycobacterium marinum is an acid-fast organism often called the fish tank bacillus. It causes nonhealing ulceronodular skin lesions when inoculated into the skin in people exposed to freshwater or saltwater via swimming or fish tanks. Infection can present as a single granuloma, but the organism often invades the lymphatics and can cause a series of nodular lesions along the lymphatic drainage similar to the lesions seen in sporotrichosis. It can also penetrate to joints or bones. The lesions tend to localize in the distal extremities because the organism does not grow well at core body temperature. Diagnose *M. marinum* infection by biopsy and acid-fast bacilli (AFB) stain and culture. (It needs to be incubated in lower temperatures for growth.) Mild disease can be treated with a single agent (clarithromycin, doxycycline, or TMP/SMX), but treat severe or progressive disease with a combination of clarithromycin and ethambutol or rifampin. The duration of treatment is at least 1–2 months after the lesions have resolved.

Erysipelothrix rhusiopathiae is a gram-positive rod that infects a large number of domestic and marine animals and causes a zoonotic skin infection in fish and meat handlers. The lesions are usually localized nodules, with lymphangitis occurring in ~ 25% of affected patients. Systemic disease with bacteremia is uncommon and more likely in those with alcohol use disorder. The major complication is endocarditis. Treat this infection with PCN. If the patient is allergic to PCN, use a quinolone or 3rd generation cephalosporin—oral for localized lesions and parenteral for bacteremia.

SEPTIC ARTHRITIS

Joints become infected by 2 routes: direct inoculation (e.g., adjacent cellulitis, trauma, surgery) or hematogenously from another focus. Risk factors for joint infection are injection drug abuse, diabetes mellitus, and prior joint disease or injury (e.g., rheumatoid arthritis, trauma, surgery). By far the most common infecting organism in native joints is *Staphylococcus aureus*. It presents with the acute onset of monoarticular joint pain, swelling, and redness.

Perform joint aspiration urgently (and prior to antibiotics to increase the yield) and send for a WBC count, Gram stain, and culture. Crystal disease (e.g., gout, pseudogout) can mimic and/or accompany septic arthritis, so send joint fluid for crystal analysis. Gonococcal arthritis is discussed separately under [Disseminated Gonorrhea on page 4-20](#). Nongonococcal septic arthritis shows organisms ~ 50% of the time on Gram stain and > 95% of the time on culture if no prior antibiotics have been given. Synovial fluid usually has a WBC count > 40,000/μL ($40 \times 10^9/L$).

Initial therapy can be based on the Gram stain: vancomycin for gram-positive cocci (GPC) or a 3rd generation cephalosporin for GNBs. The definitive therapy is based on the culture results. Treat septic arthritis typically for 3 weeks with IV antibiotics or 2 weeks with IV antibiotics followed by oral therapy. To decrease joint damage from the organisms and the inflammatory reaction to them, perform repeat joint aspirations if fluid reaccumulates while the patient is on treatment. Endemic fungi and Lyme disease from *Borrelia burgdorferi* cause a chronic monoarticular septic arthritis (see [Endemic Fungi on page 4-55](#) and [Lyme Disease on page 4-51](#)).

Prosthetic joint infection: Having a joint prosthesis is a major risk factor for septic arthritis. Joint infection occurs in 1–5% of prosthetic joint recipients. Manifestations are wound drainage, cutaneous erythema and warmth, prosthetic joint pain, and/or abnormal motion of the joint. Plain x-rays are helpful if they show a widening of the bone-cement interface, changes in the position of the prosthesis, cement fractures, a periosteal reaction, or motion of the components on stress views. Other imaging, such as bone scans, CT, MRI, and positron emission tomography (PET), are not useful in most cases. The diagnosis is definitively made by a joint aspiration; *S. aureus* and coagulase-negative staphylococci are the most commonly recovered bacteria.

There are 3 approaches to combined surgical and antibiotic therapy that attempt to preserve the joint. Incision and drainage with retention of hardware can be considered if the infection occurs within 30 days of surgery, the prosthesis is well fixed, and there is no sinus tract. In this setting, give 2–6 weeks of pathogen-specific IV antibiotics with oral rifampin if you have identified *Staphylococcus*. This can be followed by up to 6 months of oral therapy. A 1-stage procedure (incision and drainage with the exchange of prosthetic components) can be considered, especially in patients who may not tolerate 2 surgical interventions due to comorbidities. This decision is usually left to the discretion of the orthopedist at surgery. For most cases, consider a 2-stage procedure (prosthesis removal, 4–6 weeks of pathogen-specific IV antibiotics, and prosthesis reinsertion). Patients with comorbidities that place them at high risk of not tolerating surgical procedures can be tried on lifetime suppressive therapy if the organism is susceptible to oral antibiotics with high bioavailability.

OSTEOMYELITIS

Osteomyelitis is either acute or chronic, the distinction being that the latter has **necrotic bone**. Acute osteomyelitis is most commonly caused by *Staphylococcus aureus*. Some organisms have certain epidemiologic niches. In IV drug abusers, *Pseudomonas aeruginosa* and *Serratia* may be causative and have a predilection for the sternoclavicular joint, symphysis pubis, and vertebrae. In the U.S., the most common etiologic agent causing osteomyelitis in patients with sickle cell disease is *Salmonella*.

Diagnosis of diabetic foot osteomyelitis has high accuracy if a solid probe is able to reach the bone on examination. Otherwise, image in order to demonstrate osteomyelitis prior to recommending bone biopsies for culture. Initial plain x-rays can be done with the understanding that radiolucency requires > 50% demineralization of the bone, and this takes weeks to occur. MRI is the most sensitive and the study of choice. Do not use bone scans because they are very nonspecific and have a very high false-positive rate.

If probing to bone or MRI is suggestive of osteomyelitis, perform cultures of the bone to confirm the diagnosis and guide antibiotic therapy. Superficial cultures are not reliable predictors of infecting organisms. Evidence of osteomyelitis on imaging and a positive blood culture are presumptive evidence of microbiologic causation.

Except for small bone disease and early prosthetic joint infection (< 30 days from insertion of the prosthesis), all necrotic bone and prosthetic material must be removed before chronic osteomyelitis can be cured with antibiotics. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) assays can be used to help follow the course of the disease.

ANIMAL BITES

Animal bites create 3 specific problems:

- 1) Bacterial infections
- 2) Tetanus
- 3) Rabies

Bacterial infection: The risk of infection is highest from human bites, followed by cat bites and then dog bites. Causative agents can be from the animal's mouth (e.g., *Pasteurella*, streptococci, anaerobes) or inoculated from colonized skin at the bite site (e.g., *Staphylococcus aureus*). Wash and debride wounds immediately and take images if there is suspicion of joint or bone injury. Empiric antibiotic treatment is recommended for all human bites. Other bites can be observed without antibiotics unless the patient is immunocompromised, the bite is to the face or hand or is near a joint or bone, there is obvious crush injury, or there is edema (suggesting deep involvement or crush injury). Amoxicillin/clavulanate covers most of the causative organisms and is the empiric drug of choice.

Tetanus: All bites are considered tetanus-prone injuries; decide when to give prophylaxis with tetanus toxoid +/- tetanus immunoglobulin based on the patient's prior immunization history. See [Approach to Tetanus Prevention on page 4-88](#).

Rabies: The risk of rabies from a bite and the need for the rabies vaccine +/- rabies immunoglobulin is based on the type of animal involved. This is discussed further under [Rabies on page 4-24](#).

FEVER AND RASH

OVERVIEW

The febrile patient with skin lesions can run the gamut from a benign infection to a medical emergency. Not all patients have an infectious disease as the etiology of this combination, but the approach to patients with infectious causes of fever and rash is outlined in the following topics.

LIFE-THREATENING ETIOLOGIES

A few etiologies of fever and rash constitute potentially life-threatening infectious diseases. These require urgent diagnosis and treatment and are recognized by the specific dermatologic manifestations they cause. Neutropenic patients with fever require immediate empiric antibiotics even without rash (see [Febrile Neutropenia on page 4-38](#)). Neutropenic patients with *Pseudomonas aeruginosa* bacteremia can have characteristic skin lesions known as **ecthyma gangrenosum**, which are black, necrotic, ulcerative lesions ([Figure 4-1](#)). Neutropenic patients with candidemia may have a symmetric maculopapular rash as a tip-off.

Figure 4-1: Ecthyma gangrenosum

Petechial rash with fever can be seen from disseminated intravascular coagulation (DIC) from any cause. It also occurs without DIC from the viral hemorrhagic fevers, meningococcemia, and Rocky Mountain spotted fever.

Disseminated varicella-zoster virus or herpes simplex virus (HSV) infection causes fever and **vesicular lesions**.

Toxic shock syndrome associated with *Staphylococcus aureus* manifests as fever, hypotension, and a diffuse, erythematous, **sunburn-like rash**.

NON-LIFE-THREATENING ETIOLOGIES

Nodular or ulcerated nodular lesions with fever can be seen with disseminated infection from any of the endemic fungi, *Mycobacterium marinum*, other nontuberculous mycobacteria, sporotrichosis, *Erysipelothrix*, or *Leishmania*.

Vesicular lesions can result from infection with the enterovirus family of viruses (e.g., enterovirus, coxsackievirus, echovirus).

Pustules are seen in disseminated gonococcemia.

Secondary syphilis can produce any form of rash, with the exception of vesicles and bullae.

GASTROINTESTINAL (GI) INFECTIONS

PREVIEW | REVIEW

- What is the incubation period for the toxin-induced syndromes causing nausea and vomiting?
- Which findings on stool evaluation suggest invasive diarrhea?
- Know the recommendations for the prophylaxis and treatment of traveler's diarrhea.
- *Salmonella* infection is spread by which animals?
- What is a possible adverse consequence of treating infectious diarrhea due to *E. coli* O157:H7 with antibiotics?
- What is the treatment for *Shigella* infection?
- *Vibrio vulnificus* can cause severe disease in which groups of patients?
- What is the treatment of choice for patients with severe *Clostridioides* (formerly *Clostridium*) *difficile* diarrhea?
- What is the treatment recommendation for the 1st recurrence of *C. difficile* infection?
- Which infection control precautions must be used on patients with *C. difficile* diarrhea?

FOOD POISONING

Food poisoning is the common term for GI diseases resulting from bacterial toxins, although it is sometimes extended to include all foodborne illnesses. The 3 organisms that produce illness from ingestion of toxins are *Staphylococcus aureus*, *Bacillus cereus*, and *Clostridium perfringens*.

S. aureus produces disease due to ingestion of preformed enterotoxin. Food handlers can contaminate food through improper handling and inadequate temperature controls, allowing for an increased quantity of emetogenic toxins to be ingested. The incubation period is 1–6 hours, so the causative meal is usually evident. Mayonnaise and cream pies are frequent culprits, although meat, eggs, and produce can be contaminated as well. The predominant symptom is vomiting that lasts < 24 hours. Vomiting with concomitant cramps and diarrhea is characteristic. Disease is self-limited and treatment is supportive.

B. cereus grows best in starchy foods such as rice, and its spores are very heat resistant. It, too, causes vomiting

within 1–6 hours but can also cause a diarrheal illness within 8–16 hours depending on which toxin it has produced. Disease is self-limited and treatment is supportive.

C. perfringens is a bowel colonizer of almost all animals that humans ingest and has an incubation period of 8–16 hours prior to causing a watery diarrhea of 1–2 days' duration. Disease is self-limited and treatment is supportive.

VIRAL GASTROENTERITIS

There are many viral causes of diarrhea. **Rotavirus** is the most common cause of severe diarrhea in infants; it infrequently infects older children but can infect adults. It is easily found in the stool via an enzyme-linked immunosorbent assay (ELISA) or polymerase chain reaction (PCR) assay. **Noroviruses** (formerly known as Norwalk-like viruses) are the most common viral cause of gastroenteritis in adults. They are highly contagious (with low inoculum needed) and spread via person-to-person transmission, fomites, and food (e.g., salads, shellfish, fruit). Often called the “winter vomiting disease,” noroviruses can cause outbreaks on **cruise ships**, in schools, and on athletic teams. Noroviruses can be detected via reverse transcriptase polymerase chain reaction (RT-PCR) in stool samples. The treatment is supportive. There are no antivirals active against these viruses.

BACTERIAL DIARRHEA

Bacteria cause diarrhea after ingestion only if they are ingested in sufficient quantities to survive the hostile environment of the stomach and competition for nutrients with our normal microbiome, allowing them to invade the small bowel and/or colon or to produce inflammatory toxins. Detection of WBCs in the stool is a quick but variably sensitive indicator of an **invasive** bacterial diarrhea, with a sensitivity of 50–70% and a specificity of 50–80%. Detection of the WBC protein lactoferrin has a higher sensitivity and specificity: > 90% and > 80%, respectively.

In the U.S., *Salmonella* is the most common cause of non-toxin-related bacterial diarrhea, with *Campylobacter* being a close second, each causing ~ 1 million cases a year. Shiga toxin-producing *Escherichia coli* (enterohemorrhagic *E. coli* [EHEC]) causes ~ 200,000 cases a year, and *Shigella* causes ~ 150,000 cases a year. Since many patients are empirically treated and do not get cultures, these incidences represent significant underreporting.

Traveler's Diarrhea

This is the most common infection to occur in travelers and affects 50 million U.S. travelers to all destinations except northern Europe, Canada, Australia, and New Zealand. For those traveling to less developed regions, the risk can approach 60%. Almost 50% of those infected are forced to change their itinerary, 20% spend 1 day in bed, and 1% are hospitalized.

The majority of infections are due to strains of *E. coli*, followed by *Salmonella*, *Campylobacter*, and *Shigella*.

Educate patients on how to prevent traveler's diarrhea by suggesting the following:

- Avoid consumption of local, untreated water or ice, including in mixed alcoholic drinks.
- Boil or filter any water before ingesting.
- Avoid fresh fruits that cannot be peeled.
- Even at luxury resorts, avoid uncooked vegetables, meat salads (e.g., tuna), and condiments (e.g., salsas).

Carbonated drinks without ice are okay. A good general rule: Boil it, peel it, cook it, or forget it.

Prophylactic antibiotics are **not** routinely indicated, but they are justified for those with immunodeficiencies or a history of cardiac, kidney, or inflammatory bowel disease. They are also appropriate for persons conducting important business who cannot afford to be ill. Prophylactic regimens include:

- Ciprofloxacin 500 mg daily
- Rifaximin 200 mg daily or twice a day (bid)

Often a fluoroquinolone (e.g., ciprofloxacin), rifaximin, or azithromycin is given as a pretrip prescription to be taken should diarrhea occur.

For self-treatment, the patient should determine the severity of diarrhea and treat it accordingly. Mild diarrhea should be treated with aggressive oral hydration. Bismuth subsalicylate can be of benefit. Antibiotics are only required for severe disease (i.e., > 4 stools/day, high fever, or blood/pus/mucus in stools). For severe disease, prescribe one of the following:

- Ciprofloxacin 500 mg bid $\times$ 1–2 days
- Azithromycin 1,000 mg $\times$ 1 dose
- Rifaximin 200 mg 3 times a day (tid) $\times$ 3 days

Antidiarrheals (e.g., loperamide) can be used cautiously along with the antibiotics, but an antidiarrheal should **not** be the only treatment in severe disease because of the risk of causing toxic megacolon.

Salmonella

S. enterica is found in the stool of many different host animals and is the only *Salmonella* species that infects humans. *Salmonella* can be spread by frozen foods (especially chicken), milk, and eggs. Baby chicks, iguanas, turtles, and other exotic pets also can be sources of infection.

An inoculum of $> 10^5$ organisms is typically required to produce disease, but fewer organisms are needed in patients on acid-suppressive drugs. After an incubation period of 1–3 days, a usually nonbloody diarrhea with fever occurs. Untreated, the fever resolves by day 3 and the diarrhea by day 7.

Do not give antibiotic treatment routinely because it prolongs the shedding of the organism in the stool, increases antibacterial resistance, and does not shorten the course of disease. Because a small percentage of patients can

have severe disease, however, treat patients > 50 years of age, with significant comorbid illnesses, or who are immunosuppressed. Also, severe exacerbations of pre-existent inflammatory bowel disease can occur, so treat these patients as well. Treatment, if required, is with a quinolone, TMP/SMX, or amoxicillin if susceptibilities are known. If intravenous therapy is required, use ceftriaxone.

***S. enterica* serotype Typhi** (a.k.a. ***Salmonella* Typhi**; formerly *S. typhi*) causes typhoid fever after ingestion of contaminated food, milk, or water. This organism is found in humans only. Infection commonly begins with fever, chills, initial constipation followed by diarrhea, leukopenia, and the appearance of classic **rose spots** on the trunk (Figure 4-2), which appear ~ 1 week after the fever starts. These look like little, 2–3 mm angiomias. There may be relative bradycardia as a clue. Blood cultures are usually positive during the 1st week, followed by stool cultures and then urine cultures

Figure 4-2: Typhoid fever with classic 2–3 mm “rose spots”
Source: CDC

Treat typhoid fever with quinolones, 3rd generation cephalosporins, ampicillin, trimethoprim/sulfamethoxazole (TMP/SMX), or chloramphenicol depending on the sensitivities. Carriers (those excreting the organism for > 12 months) without gallbladder disease or stones can typically be cleared with 4 weeks of fluoroquinolone administration. Chronic carriers with gallstones are at increased risk of biliary cancer.

There are moderately effective live attenuated and polysaccharide vaccines that can be given to travelers (> 2 years of age) who go outside of the usual tourist areas of Latin America, Asia, and Africa.

Campylobacter

C. jejuni and *C. coli* cause human disease usually from ingestion of undercooked meat—most notably poultry, as these bacteria often inhabit the lining of their intestinal tracts. Diarrhea, with cramping and often a high fever, occurs after 1–7 days. The disease is self-limited, and antibiotic therapy only decreases the duration of illness by an average of 1 day. Treat those with severe disease or who are immunocompromised. Although resistance has been reported, most strains are susceptible to fluoroquinolones and macrolides.

Escherichia coli

E. coli is the most common cause of bacterial diarrhea worldwide. Depending on which strain is responsible, *E. coli* produces diarrhea via one of the following mechanisms:

- Production of a secretory toxin (enterotoxigenic *E. coli* [ETEC]), which causes a noninflammatory watery diarrhea
- Production of a Shiga toxin (enterohemorrhagic *E. coli* [EHEC]), which causes mucosal injury and bloody diarrhea
- Invasion (enteroinvasive *E. coli* [EIEC]), which causes a watery or bloody stool. EIEC's mechanism of infection is similar to that of *Shigella* and causes a similar presentation.

ETEC is the most common cause of traveler's diarrhea. Refer to [Traveler's Diarrhea on page 4-10](#) for information on prophylaxis and treatment.

EHEC, which is usually from serotype O157:H7, causes localized outbreaks of hemorrhagic colitis, thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS), typically after eating undercooked beef or unpasteurized milk. Fever is conspicuously absent, but nausea and vomiting are common. Do **not** treat diarrhea caused by *E. coli* O157:H7 with antibiotics because killing large numbers of organisms can release large amounts of Shiga-like toxin, resulting in an increased risk of HUS development.

Shigella

Shigella species (*S. sonnei* and *S. flexneri* being the most common) produce Shiga toxin, causing fevers, bloody diarrhea, cramping, and tenesmus. It is the most contagious bacterial diarrhea, with an inoculum of 10 organisms being sufficient to cause disease in 50% of individuals; thus, it is easily spread from person to person (men who have sex with men are at especially high risk), via contaminated food, or even via flies that have had contact with infected feces. Because of increasing resistance to quinolones, as of 2017, the CDC no longer recommends treating all patients with *Shigella*. Only treat patients if they are immunocompromised or have severe disease. Treatment may also be directed by local health departments to quell outbreaks. Fluoroquinolones can be used if the minimum inhibitory concentrations (MICs) show sensitivity; otherwise, use other agents based on lab-reported susceptibilities.

Yersinia

Y. enterocolitica causes diarrhea (sometimes bloody), fever, right lower quadrant (RLQ) abdominal pain (mimicking appendicitis), and often **sore throat**. Pigs are the major reservoir, and disease can occur after ingesting undercooked pork. This pathogen is siderophilic; therefore, conditions with iron overload, such as hemochromatosis

and those requiring frequent transfusions (such as some patients with sickle cell disease), increase its pathogenicity. The use of deferoxamine also increases risk. Treatment is typically supportive, but antibiotic therapy is warranted for invasive disease. Options include 3rd generation cephalosporins, TMP/SMX, and tetracyclines.

Vibrio

Vibrio species grow in salt water and are transmitted via raw or undercooked seafood and shellfish, which, as filter feeders, concentrate the organism. *V. cholerae* O1 (which causes cholera) is occasionally seen in Gulf Coast crabs but is more common in the endemic regions of Africa and Asia from contaminated water sources. The diagnosis is made clinically with the presentation of profuse watery diarrhea and significant, life-threatening volume loss. **Rice-water stool** is the classic descriptor; it looks like the soaking water from rice. The treatment is aggressive rehydration; without it, mortality approaches 70%. The addition of antibiotics (e.g., a fluoroquinolone, a macrolide, doxycycline) can decrease shedding in the stool and should be selected based on known regional susceptibilities or culture results.

The non-O1 *V. cholerae*, *V. parahaemolyticus*, and other *Vibrio* species are even more frequent causes of shellfish-associated diarrhea. They cause abdominal pain and diarrhea that is often bloody. Treatment is supportive and antibiotics (doxycycline, macrolides or fluoroquinolones) are given when the disease is severe. *V. vulnificus* causes skin infections and sepsis, especially in immunocompromised patients and those with chronic liver disease. See [Unique Soft Tissue Infections on page 4-7](#) for additional information.

Vibrio parahaemolyticus is acquired from ingestion of saltwater fish or crustaceans and presents with abdominal pain and bloody diarrhea.

Summary of Bacterial Diarrhea

The initial presentation of infectious diarrhea is often not sufficient to determine a specific etiologic organism. Send a stool sample for a WBC count or for lactoferrin testing to determine if it is likely to be an infectious bacterial diarrhea. If bacteria are detected, send the sample for bacterial cultures. For patients with mild disease, give hydration but no empiric antibiotics. Avoid antimotility drugs. Treat severe disease or patients at risk for severe disease (e.g., immunocompromised patients) with a fluoroquinolone unless EHEC is suspected or cultured.

DIARRHEA DUE TO CLOSTRIDIODES DIFFICILE

Background and Presentation

Clostridia has been a catch-all basket for bacteria that have similar findings—strictly anaerobic, spore-forming,

gram-positive rods. Recent findings place *C. difficile* with bacteria that are far removed phylogenetically from other clostridia. Its name has been changed from *Clostridium difficile* to *Clostridioides* (clostridia-like) *difficile* to minimize potential confusion from a more radical name change.

Diarrhea due to *C. difficile* infection (CDI) is discussed apart from the other bacterial diarrheas due to several unique characteristics. Diarrhea during or after the administration of antibiotics is usually caused by an alteration of fecal flora (resulting in the decreased breakdown of small molecules and an osmotic diarrhea) or the promotility action of some antibiotics (e.g., macrolides); however, if the fecal flora is altered and acquisition of *C. difficile* occurs, CDI ensues. Clindamycin, cephalosporins and quinolones are the most common precipitants of CDI. Most cases occur in health care settings, but an increasing number of cases are occurring in the outpatient setting. The use of proton pump inhibitors increases the risk.

Symptoms can develop up to **10 weeks** after the antibiotics are stopped. The diarrhea is typically a watery diarrhea but may be bloody in 15% of patients. An ileus without diarrhea is common. Fever and very high peripheral WBCs can be seen.

Diagnosis

A PCR assay using a stool sample (or perirectal swab in cases of ileus) to detect the cytotoxin-producing genes of *C. difficile* is superior to enzyme immunoassay (EIA) used to detect the toxins themselves. Although the organism can also be cultured from the stool, this has no utility because it takes several days to grow the bacteria and many strains do not produce toxins or disease.

Treatment

The Infectious Diseases Society of America (IDSA) clinical practice guideline for the treatment of CDI, updated in 2017, recommends stopping the offending antibiotics if possible and treating disease based on its severity.

Treat **nonsevere** disease (a WBC count < 15,000/ μ L [15×10^9 /L] **and** a serum creatinine < 1.5 mg/dL [132.6 μ mol/L]) with vancomycin or fidaxomicin (FDX) given by mouth (PO). Use metronidazole **only** if these drugs are not available or are too expensive.

Treat **severe** disease (a WBC count > 15,000/ μ L [15×10^9 /L] **or** a serum creatinine > 1.5 mg/dL [132.6 μ mol/L]) with PO vancomycin or PO FDX. Metronidazole is **not** a recommended option.

Fulminant disease is present when patients have ileus, megacolon, or hypotension. Give these patients high-dose PO vancomycin and IV metronidazole. Give vancomycin by enema if the PO route is not an option or if there is severe ileus. Consider colectomy in patients with rising lactate levels, peritoneal signs, or sepsis.

Relapse

Relapses occur in ~ 25% of patients. **Treatment for the 1st relapse depends on the initial therapy:**

- If a standard vancomycin regimen was used initially, use FDX or a pulsed, tapered vancomycin regimen.
- If a standard FDX regimen was used initially, use a pulsed, tapered vancomycin regimen.
- If metronidazole was used initially, use a standard vancomycin regimen.

There are several options for **treating > 1 relapse:**

- A standard or pulsed, tapered vancomycin regimen
- FDX
- Fecal microbiota transplantation (FMT)

FDX has a 50% lower relapse rate than vancomycin and thus can be given to patients with multiple relapses or in whom a relapse would be devastating due to comorbid disease (e.g., an ICU patient). FMT is a highly successful procedure for treating severe, recurrent CDIs.

Prevention

Sanitizing hand gels do **not** prevent transmission because they do not kill the spores of *C. difficile*. Only handwashing with soap and water prevents spread. Isolate patients with *C. difficile* diarrhea in a private room and place them on contact precautions. Because the organism is found on various surfaces throughout the infected patient's room, even those who do not examine the patient should use precautions.

PROTOZOAL DIARRHEAS

Protozoal diarrheas include amebiasis, giardiasis, and several acid-fast organism infections that are discussed under [Protozoa on page 4-57](#).

LIVER AND BILIARY INFECTIONS

PREVIEW | REVIEW

- What is the treatment for bacterial liver abscesses?
- To which 3 groups of patients should you give antibiotic prophylaxis for primary peritonitis?
- How is secondary peritonitis treated?

LIVER ABSCESS

Liver abscesses are most commonly bacterial or amebic. Amebic abscesses are discussed under [Entamoeba on page 4-58](#). Patients with prolonged neutropenia can develop hepatosplenic candidiasis, in which there are numerous fungal (candidal) abscesses throughout the liver and spleen.

Bacterial liver abscesses are either due to direct bacterial spread from infection in the biliary tree (e.g., cholecystitis, cholangitis) or from transmission of gut flora to the liver from the venous drainage of the mesenteric veins through the portal vein. Many liver abscesses have no clear cause and are called cryptogenic. The microbiology is mixed fecal flora (e.g., GNBs, enterococci, anaerobes).

The presentation may initially be overshadowed by the primary infectious process. Symptoms are fever and right upper quadrant (RUQ) pain. The liver can be enlarged and tender on examination, and there may be a positive Murphy sign (pain with inspiration while patient in supine position and examiner palpating the right subcostal area).

Confirm the diagnosis by imaging, and perform aspiration to discern the microbiologic cause and guide antibiotic therapy.

The treatment includes drainage and culture-guided antibiotics. Drain abscesses < 5 cm by aspiration. For larger abscesses, place and maintain a catheter until the drainage becomes minimal. Surgical intervention is required if complete drainage cannot be obtained by other means.

CHOLANGITIS

Cholangitis is a bacterial infection of the biliary tree. Entry of bacteria into bile occurs on a regular basis because the sphincter of Oddi is not a one-way valve and the duodenum is not sterile. Despite this, cholangitis does not typically ensue because biliary pressures flush organisms back into the duodenum and bile salts are bacteriostatic. Thus, a prerequisite in the vast majority of cases of cholangitis is biliary obstruction, typically from stones, benign strictures, or cancer.

The bacteriology usually shows enteric GNBs (or enterococci for acute cases), but if there is a chronic process such as tumor obstruction or stents, then anaerobes can be part of the polymicrobial flora.

Many patients have the **Charcot triad** of fever, RUQ pain, and jaundice. Confirm the diagnosis by imaging, which shows biliary dilation and/or obstruction.

No antibiotics reliably enter an obstructed biliary tree, so treatment includes urgent biliary drainage by endoscopic retrograde cholangiopancreatography (ERCP), performed either percutaneously or surgically. Antibiotics are guided by the culture results of the drainage.

PERITONITIS

Infection of the peritoneal cavity can be primary or secondary. Primary peritonitis has no evident intraabdominal, surgically treatable source. Other cases are secondary, meaning they are caused by a surgically treatable source (e.g., bowel perforation).

It is critical to differentiate primary from secondary bacterial peritonitis because:

- the mortality rate is ~ 80% for patients with primary peritonitis who undergo an exploratory laparotomy and
- the mortality rate is ~ 100% for patients with secondary bacterial peritonitis who do not go to surgery.

Primary peritonitis occurs in the presence of ascites and hypoalbuminemia. The low albumin, in addition to creating the ascites, causes bowel edema, which allows the aerobic bowel flora to transmigrate (i.e., swim across) from the mucosal to the serosal surface of the bowel and enter the peritoneum. When the ascites is due to cirrhosis or nephrotic syndrome, patients have a markedly decreased ability to opsonize these organisms due to decreased complement production (cirrhosis) or loss of complement and antibodies in the urine (nephrotic syndrome). The most common causative organisms of primary peritonitis are GNBs, with *Escherichia coli* and *Klebsiella* causing the majority of cases. *Streptococcus pneumoniae* is seen as well. Anaerobes are not found.

Because of the decreased amount of opsonins, inflammation is blunted and many patients are asymptomatic. If symptoms occur, they include fever, abdominal pain, abdominal tenderness, and altered mental status, but not necessarily simultaneously. Suspect primary peritonitis in a cirrhotic patient with worsening portosystemic encephalopathy, even in the absence of symptoms. The diagnosis of primary peritonitis is made if the paracentesis fluid shows > 250 polymorphonuclear leukocytes (PMNs), the Gram stain is positive, or the culture is positive and no other cause of peritonitis is evident. This is usually a monomicrobial infection. Treat primary peritonitis empirically with a 3rd generation cephalosporin. Give antibiotic prophylaxis for primary peritonitis to 3 groups of patients who are at high risk for this disease:

- Patients with cirrhosis and ascites if the ascitic fluid protein is < 1,000 mg/dL
- Patients with cirrhosis and a GI bleed
- Patients with a prior episode of primary peritonitis

Use ciprofloxacin or TMP/SMX.

Secondary bacterial peritonitis is an infection of the peritoneal cavity due to the direct entry of bacterial flora from disruption of the integrity of the bowel. Unlike with primary peritonitis, patients with secondary peritonitis almost always have abdominal pain, fever, and peritoneal signs. The ascitic fluid has a markedly elevated WBC count (often > 5,000/ μ L [5×10^9 /L]) and can be grossly purulent. Cultures are usually polymicrobial. Imaging typically reveals the source, necessitating emergency surgical intervention while administering antibiotics to cover gram-negative aerobes and anaerobes. Acceptable regimens include piperacillin/tazobactam or a carbapenem.

Peritonitis from peritoneal dialysis can also occur; this is discussed in the [Nephrology](#) section.

INTRAABDOMINAL ABSCESS

Intraabdominal abscesses are walled-off pockets of infection that occur after peritonitis. Anaerobic flora are major participants in the process, and abscesses commonly do not occur after primary peritonitis. Instead, they usually occur after bowel perforation or appendicitis (secondary peritonitis). Abscess formation takes several days to occur and often presents itself after initial surgical and antibiotic treatment of the underlying process. Signs and symptoms include the new onset and/or recurrence of fever, abdominal pain, abdominal tenderness, and leukocytosis. The bacteriology is similar to that of secondary peritonitis, which is often a precursor, and includes gram-negative aerobic rods and anaerobes. If an abscess is recurrent or occurs after a course of antibiotics, *Candida* and coagulase-negative staphylococci are common. Diagnose an intraabdominal abscess by imaging, and treat it with percutaneous or surgical drainage with antimicrobial therapy. Antibiotic therapy is similar to that for secondary peritonitis (i.e., piperacillin/tazobactam or a carbapenem) but is directed at cultured organisms from the abdomen. Empiric treatment for enterococci and *Candida* species is not recommended unless these are present on prior or subsequent cultures from drainage. Multiple abscesses or abscesses due to gross fecal soiling often require repeated surgical drainage.

SEXUALLY TRANSMITTED INFECTIONS (STIs)

PREVIEW | REVIEW

- Who and how do you test for gonorrhea? For chlamydia? For syphilis?
- What are the stages of syphilis, and how are they treated?
- What drugs are used to treat syphilis in pregnancy? What if the woman has an anaphylactic penicillin allergy?
- How do primary syphilis and chancroid differ?
- Discuss the clinical manifestations of lymphogranuloma venereum and granuloma inguinale.
- What are the outpatient and inpatient regimens for the treatment of pelvic inflammatory disease?
- What is the empiric treatment for cervicitis?
- What are the clinical presentations of disseminated gonorrhea?

- Which 3 tests are useful to determine the etiology of vaginitis? In what way are the tests useful?
- Women with recurrent or recalcitrant vulvovaginal candidiasis should be tested for which 2 associated illnesses?

OVERVIEW

Most STIs are categorized into those that cause urethritis, cervicitis, and pelvic inflammatory disease (PID; i.e., gonorrhea and chlamydia) and those that cause genital ulcers (i.e., syphilis, chancroid, herpes simplex virus [HSV], lymphogranuloma venereum [LGV], and granuloma inguinale). The following discussions reflect the diagnostic and treatment guidelines recommended by the CDC in its 2015 Sexually Transmitted Diseases Treatment Guidelines.

SCREENING

General

Populations that are at increased risk for STIs include the following:

- Persons 15–24 years of age
- African Americans
- Individuals with a new partner in the past 2 months
- Individuals with multiple partners
- Persons with a history of previous STIs
- Drug users
- Persons with recent exposure to a jail or detention facility
- Individuals who find sex partners from the internet
- Persons who have contact with sex workers
- Men who have sex with men

Gonorrhea Screening

Since most men with gonorrhea are symptomatic, there is no recommended screening for them. Screen sexually active women annually if they are < 25 years of age or if they are older and in one of the general risk groups. Screen for gonorrhea in women using nucleic acid amplification testing (NAAT) of a vaginal swab.

Chlamydia Screening

The CDC's 2015 recommendations for chlamydia are similar to those for gonorrhea, with no recommended screening in men and screening of women in the same risk groups. NAAT of a vaginal swab is the test of choice.

Syphilis Screening

Screen for syphilis in all the general risk groups and in women during each pregnancy. See [Syphilis on page 4-16](#) and the [Women's and Men's Health](#) section for additional information.

Hepatitis Screening

Screen for hepatitis B virus (HBV) and hepatitis C virus (HCV) in patients with risk factors (e.g., sexual contacts, injection drug users) and for each pregnancy (see the [Women's and Men's Health](#) section). Screen for HBV by sending serum for hepatitis B virus surface antigen (HBsAg) and hepatitis B core antibody (anti-HBc) detection. Screen for HCV by sending serum for anti-HCV antibody detection.

Human Immunodeficiency Virus (HIV) Screening

Screen for HIV in women during each pregnancy (see the [Women's and Men's Health](#) section). The CDC also recommends HIV screening in all persons 13–64 years of age at least once. Test those outside of this age range who are in a high-risk group. High-risk individuals are considered those who use IV drugs, men who have sex with men, and those presenting for STI testing or who have a history of STIs or a new diagnosis of tuberculosis (TB). Test **high-risk groups annually**. Otherwise, repeat screening based on clinical circumstances.

Herpes Simplex Virus (HSV) Screening

No general screening is recommended for HSV infections.

INFECTIOUS GENITAL ULCERS

Genital ulcer diseases include syphilis, HSV, chancroid, LGV, and granuloma inguinale. See [Table 4-1](#).

Syphilis

Treponema pallidum, a motile spirochete, causes syphilis, which is a reportable disease in the U.S. Syphilis has 3 stages. The 3rd stage has 3 forms, and one of the 3 forms, neurosyphilis, has 3 manifestations. (Thus, it is $3 \times 3 \times 3$.)

Primary syphilis presents with a **painless** chancre at the site of inoculation—usually genital, anal, or oral—within 3–40 days depending on the number of inoculated organisms. This may be followed by painless regional lymphadenopathy. In women, if the infection is cervical, it is often unnoticed. Even without treatment, it lasts 2–6 weeks and then resolves.

Secondary syphilis occurs ~ 2 months later as spirochetes disseminate throughout the body. Symptoms include generalized lymphadenopathy, fever, malaise, and mucosal and/or cutaneous lesions that can mimic many other lesions (“the great imitator”). The skin lesions are macular or papular but **never** vesicular. They can occur on the palms and soles and are described as “nickel and dime” lesions ([Figure 4-3](#)). Condylomata lata are cauliflower-like wet lesions in the genital areas or mouth that teem with treponemes. Meningovascular disease can also occur in secondary syphilis and presents as strokes or blindness in a young person. Nonneurologic signs and symptoms resolve in 3–12 weeks, after which the disease goes into a latency period. Untreated, 1/3 of secondary syphilis cases eventually proceed to tertiary syphilis.

Figure 4-3: Secondary syphilis “nickel and dime” lesions
Source: CDC

Table 4-1: STIs with Genital Ulcers

Disease	Organism/ Virus	Characteristic Ulcer	Treatment
Syphilis	<i>T. pallidum</i>	Painless 1- to 2-cm ulcer; “punched out,” clean-appearing ulcer with nonexudative base; sharp, firm, slightly elevated indurated borders	Penicillin G
Herpes genitalis	Herpes simplex	Painful grouped vesicles that rupture to form shallow, painful ulcers	Acyclovir or famciclovir or valacyclovir
Chancroid	<i>H. ducreyi</i>	Painful , shallow, soft, friable ulcer with ragged margins and a foul-smelling necrotic purulent exudate	Preferred: azithromycin or ceftriaxone Alternative: ciprofloxacin or erythromycin
Lymphogranuloma venereum	<i>C. trachomatis</i> L1, L2, or L3	Painless general ulcer	Preferred: doxycycline Alternative: erythromycin or azithromycin
Granuloma inguinale	<i>K. granulomatis</i>	Painless, friable, progressive, beefy-red ulcerative lesion with raised, rolled margin	Azithromycin or doxycycline or ciprofloxacin

Tertiary syphilis occurs in 15–30% of untreated patients and manifests 1–15 years or more after initial infection. There are 3 forms:

- 1) **Gummatous** syphilis presents with ≥ 1 gumma, which is a noncaseating granulomatous lesion that is locally destructive.
- 2) **Cardiovascular** syphilis is obliterative endarteritis of the aortic vasa vasorum, which results in ascending aortic aneurysms and aortic insufficiency.
- 3) **Neurosyphilis** has several manifestations:
 - **Chronic meningovascular syphilis** can present with brain and/or spinal cord strokes similar to meningovascular disease in secondary syphilis.
 - **Tabes dorsalis** is due to destruction of the posterior spinal cord columns, leading to the loss of position sense, an abnormal foot-slapping gait, and a positive Romberg sign.
 - **General paresis** is the name given to diffuse cortical disease seen in neurosyphilis. Its numerous manifestations can be remembered with the following mnemonic:
 - **P** = defects in personality
 - **A** = reduced affect
 - **R** = abnormal reflexes
 - **E** = eye problems (Argyll Robertson pupil, which is miotic and irregular; it accommodates but does not react to light)
 - **S** = defects in sensorium
 - **I** = defects in intellect
 - **S** = defects in speech
 - **Ocular syphilis** can involve any structure of the eye including keratitis, uveitis, retinitis, and optic neuritis.
 - **Otosyphilis** presents with hearing loss from involvement of the cochlea and/or the auditory nerve.

Latent syphilis is defined as a serology diagnostic of syphilis with **no** active manifestations of infection. It can occur in the 4–10 weeks between primary and secondary syphilis but is most commonly diagnosed in the much longer asymptomatic period after secondary syphilis. Latent syphilis is divided into early latent and late latent depending on whether the last manifestations of syphilis or seroconversion to syphilis occurred within 1 year or after 1 year, respectively. This distinction arose from observational studies that showed that 90% of patients become symptomatic within the 1st year of infection.

The diagnosis of syphilis was historically based on direct visualization of the organism via dark-field microscopy of chancre exudate or cutaneous lesions of secondary syphilis; however, this is unavailable in most laboratories. Serology is otherwise required to confirm the diagnosis of syphilis. There are 2 types of serologic tests:

- 1) **Nontreponemal tests** (Venereal Disease Research Laboratory [VDRL] and rapid plasma reagin [RPR] tests)

detect antibodies directed against the cardiolipin-cholesterol-lecithin antigen (a.k.a. reagin). These are predominantly immunoglobulin M (IgM) antibodies and are absent in $\sim 1/3$ of patients with primary syphilis because the disease has not been present long enough to have produced an IgM response. These antibodies are present in essentially all patients with secondary syphilis. A third of patients with tertiary syphilis are seronegative because the IgM response has burnt out. Expect these antibodies to decline with appropriate treatment in primary or secondary disease. In late latent disease, some patients are serofast and titers do not decline with treatment.

- 2) **Treponemal tests** (the microhemagglutination assay for antibodies to *Treponema pallidum* [MHA-TP] and the fluorescent treponemal antibody absorption [FTA-ABS] test) detect antibodies that directly react with *T. pallidum*. These are predominantly immunoglobulin G (IgG) antibodies. The tests turn positive after 2–4 weeks and remain positive for life, even with treatment.

Perform a treponemal test to confirm a nontreponemal test because false-positive nontreponemal test results can occur with a variety of other inflammatory and infectious illnesses. If this sequence is followed, patients with a positive RPR test result and a confirmatory positive FTA-ABS test result are considered to have past or present syphilis.

A lumbar puncture (LP) is indicated in patients who have neurologic or ophthalmic manifestations consistent with neurosyphilis, other signs of tertiary syphilis, or serum RPR titers $\geq 1:32$ or who have failed prior appropriate therapy for syphilis. The diagnosis of neurosyphilis should be made if any of the following are found in the CSF: VDRL (+), protein > 45 , or WBC > 5 . RPR testing should not be done on CSF because it has a lower sensitivity than the VDRL test.

RPR and VDRL titers typically decrease with treatment. Expect titers to be positive only in an undiluted specimen, or entirely negative, 1 year after treatment of primary disease, 2 years after treatment of secondary disease, and 5 years after treatment of latent disease. Most treated patients will become seronegative, but some remain seropositive despite cure.

Test all pregnant women with a nontreponemal test in the 1st trimester. If a pregnant patient is at high risk, repeat testing in the 3rd trimester and at delivery. Pregnant patients are treated with the same regimen as nonpregnant patients based on the stage of infection.

The treatment of syphilis is as follows:

- For primary, secondary, and early latent syphilis, give benzathine PCN G 2.4 MU intramuscularly (IM) $\times 1$.
- For late latent syphilis, latency of unknown duration, and nonneurologic tertiary syphilis, give benzathine PCN G 2.4 MU IM every week $\times 3$.

- For neurosyphilis, benzathine PCN G does not reliably cross the blood-brain barrier, so the following must be used:
 - PCN G 18–24 MU IV divided every 4 hours or continuous infusion for 10–14 days
 - Ceftriaxone 2 g/day × 10–14 days (an alternative for PCN-allergic patients; however, cross-reactive allergies may occur)

Doxycycline is an alternative for PCN-allergic patients, except for those with neurosyphilis or who are pregnant. If a patient with neurosyphilis or a pregnant patient is allergic, that patient should undergo desensitization.

Herpes Simplex Virus (HSV)

HSV presents with tender, grouped vesicles on a red base (Figure 4-4) with or without regional adenopathy. Although the appearance is diagnostic, it should be confirmed with PCR serotyping. Treatment is only of benefit for initial infection if given within 72 hours and for recurrent infection if given within 48 hours. Effective agents are acyclovir, valacyclovir, or famciclovir. Patients with frequent recurrences may benefit from chronic suppressive therapy.

Figure 4-4: Herpes simplex
Source: CDC

Other Infectious Genital Ulcers

Chancroid is caused by *Haemophilus ducreyi*, a small gram-negative coccobacillus. Although a much less common ulcerative STI than syphilis in the U.S., it is the most common ulcerative STI in Africa. The initial chancroid lesion transforms from a papule to a pustule to a ragged ulcer, all of which are **painful**, unlike the syphilis chancre. It can progress to secondary chancroid with tender inguinal lymphadenopathy (buboes), which can spontaneously drain. Spread from there (tertiary chancroid) is rare. Diagnose chancroid by the clinical appearance, and confirm the diagnosis by culture. Treat it with a single dose of azithromycin (1,000 mg) or ceftriaxone (125 mg) or give the patient ciprofloxacin 500 mg bid × 3 days.

Lymphogranuloma venereum (LGV) is due to 3 specific serogroups of *Chlamydia trachomatis*: LGV-1, -2, and -3. It is extremely rare in the U.S. (< 500 cases/year) but is endemic in many parts of Asia, Africa, and South America. In the 1st stage, LGV presents with a painless papule and vesicle that eventually form a clean, **painless** ulcer. This stage is present in only 1/3 of infected patients. Most patients present in the 2nd stage with tender inguinal masses on both sides of the inguinal ligament (a.k.a. a groove sign). Diagnose LGV by the clinical appearance and via culture and NAAT. Treatment is with doxycycline for 21 days.

Granuloma inguinale (a.k.a. donovanosis) is very rare. *Klebsiella granulomatis* (formerly called *Calymmatobacterium granulomatis*) is the causative gram-negative organism that produces beefy, oozing, and paradoxically painless genital ulcers (Figure 4-5). Spread to the inguinal area produces bilateral soft tissue granulomas that look like lymphadenopathy (pseudobuboes). Diagnose the infection by its clinical appearance. Culture has a low yield, but a crushed biopsy specimen may show intracellular bacilli (**Donovan bodies**). Treat granuloma inguinale with azithromycin or doxycycline for at least 21 days, until all the ulcers are gone.

Figure 4-5: Genital lesions in granuloma inguinale
Source: CDC

PELVIC INFLAMMATORY DISEASE (PID)

PID can be caused by *Neisseria gonorrhoeae*, *Chlamydia*, or mixed genitourinary flora (aerobes and anaerobes).

Patients present with bilateral lower quadrant pain and fever +/- vaginal discharge. Physical examination commonly reveals bilateral adnexal tenderness, lower quadrant tenderness, and acute cervical motion tenderness. The clinical diagnosis has a positive predictive value (PPV) of < 90%, so use laparoscopy when the diagnosis is uncertain.

If there is no cervical discharge and cervical swabs fail to show WBCs, PID is unlikely. Test these patients for gonorrhea and chlamydia (refer to [Gonorrhea Screening on page 4-15](#) and [Chlamydia Screening on page 4-15](#)). Patients may get an associated perihepatitis (**Fitz-Hugh-Curtis syndrome**) with mild transaminase elevations and RUQ pain.

The CDC recommends empiric therapy for PID if a sexually active woman presents with one of the following findings and no other cause is identified:

- Uterine tenderness
- Adnexal tenderness
- Cervical motion tenderness

Treatment depends on whether the patient requires hospital admission or not. Admit patients if:

- prior oral antimicrobial therapy failed,
- they are unable to follow or tolerate an outpatient oral regimen,
- they have a high-grade fever with abdominal pain or vomiting,

- you suspect or find a tuboovarian abscess, or
- they are pregnant.

If a patient is admitted, the CDC recommends either of the following **inpatient** regimens:

- Cefoxitin or cefotetan IV and doxycycline PO or IV (Substitute azithromycin for doxycycline if the patient is pregnant.)
- Clindamycin and gentamicin IV

Most treatment regimens are designed to ensure treatment of both gonorrhea and chlamydia.

If admission is not indicated, the CDC recommends either of the following **outpatient** regimens:

- Ceftriaxone IM $\times 1$, then doxycycline $\times 14$ days $\pm$ metronidazole $\times 14$ days
- Cefoxitin IM $\times 1$ and probenecid plus doxycycline $\times 14$ days $\pm$ metronidazole

If you suspect the infection is **not** due to *Chlamydia* or *N. gonorrhoeae* based on the lack of STI risk factors, add metronidazole to cover bowel anaerobes.

Follow up with patients treated for chlamydial infections with a test for cure at 3 weeks. The PCR test can remain positive for many weeks.

CERVICITIS

Cervicitis is usually caused by *Chlamydia* (especially if the discharge is mucopurulent) but can also be from *Neisseria gonorrhoeae*, HSV, and *Trichomonas*. Because *Chlamydia* is intracellular, you must have cervical cells for a valid smear/culture (so scrape or use a brush). A Gram stain of cervical secretions is not sensitive or specific in the diagnosis of gonococcal cervicitis (in contrast to male gonococcal urethritis). Empiric treatment for mucopurulent cervicitis is ceftriaxone 250 mg IM $\times 1$ **plus** azithromycin 1 g PO $\times 1$. Dual therapy with ceftriaxone and azithromycin is also recommended in documented gonococcal infection. For patients with uncomplicated genital chlamydial infections, oral azithromycin as a 1 g single dose is preferred; doxycycline (100 mg PO 2 $\times$ /day for 7 days) is an alternative. Treat sexual partners as well.

Because of high rates of reinfection, retest all individuals diagnosed with *C. trachomatis* or *N. gonorrhoeae* for repeat infection 3 months after treatment, but not as a “test of cure” (unless the patient is pregnant).

URETHRITIS

Presentation

Urethritis can be divided into gonococcal and nongonococcal infection. Endocervical, vaginal, urethral (men only), or urine specimens can be tested to detect *Neisseria gonorrhoeae*. Genitourinary infections with *N. gonorrhoeae* can be detected using culture, nucleic acid hybridization testing, and NAAT. With gonococcal urethritis, the patient virtually always has a very painful, **purulent** discharge. The diagnosis is confirmed by either positive

culture results or the finding of gram-negative intracellular diplococci on Gram stain (within PMNs; **Figure 4-6**). Otherwise, consider the infection nongonococcal urethritis, which is generally due to *Chlamydia trachomatis* or, less frequently, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, or HSV. For 35% of cases, the cause is unknown.

Figure 4-6: Gonorrhea (Gram stain)

Patients with nongonococcal urethritis typically have a **clear** urethral discharge, and a Gram stain shows WBCs and **no** bacteria. Gonococcal urethritis has a shorter incubation period (2–6 days vs. 1–2 weeks for chlamydia) and produces a more purulent and more productive discharge.

In all patients, perform a VDRL or RPR test and, if the result is negative, repeat it in 2 months (to allow for possible seroconversion from when blood for the 1st test was drawn). Do HIV testing for all patients with urethritis.

Consider gonococcal disease in sexually active adolescents with acute exudative pharyngitis, especially if the test results for *Streptococcus pyogenes* are negative.

Treatment

Nongonococcal urethritis: Treat with a directly observed single dose of azithromycin 1 g PO. A less desirable option due to compliance concerns is doxycycline 100 mg bid $\times 7$ days. Levofloxacin is also effective, but avoid its use in pregnant patients. Routine cotreatment for gonorrhea is no longer recommended.

Gonococcal urethritis: Resistance to PCNs, tetracyclines, and fluoroquinolones is commonly found. As a result, the CDC recommends **dual** therapy with ceftriaxone + azithromycin for gonorrhea infections of the cervix, urethra, and rectum, hoping that routine cotreatment might hinder the development of further antimicrobial-resistant *N. gonorrhoeae*.

Treat uncomplicated gonococcal infections of the cervix, urethra, rectum, and pharynx with a single dose of ceftriaxone and azithromycin.

For **pregnant women**, do **not** use quinolones or tetracyclines. Use a cephalosporin for gonorrhea and either erythromycin or azithromycin for *C. trachomatis* infection. If the pregnant patient is allergic to cephalosporins, the CDC recommends azithromycin 2 g PO $\times 1$. Perform test of cure for pregnant women 3–4 weeks after treatment.

In addition, as with all patients with documented chlamydia or gonococcal infection, pregnant women should also undergo repeat testing to evaluate for reinfection 3 months following treatment.

Always treat sexual partners of patients with either type of urethritis, even if they are not symptomatic, and always treat suspected cases immediately without waiting for culture results.

DISSEMINATED GONORRHEA

Disseminated gonococcal infection is more predominant in females and typically occurs during menses because this allows the organisms on the cervix to enter the blood stream. The clinical manifestations can consist of a sparse pustular dermatitis, tenosynovitis, as well as a septic arthritis.

Gram stains and cultures of skin lesions have a very low yield (25%), but if specimens are taken from genital, mucosal, and rectal sources, they have an 85% yield.

Treat patients diagnosed with disseminated gonorrhea with a 3rd generation cephalosporin. Include a single dose of azithromycin or levofloxacin or 14 days of doxycycline to treat possible chlamydia coinfection. After 1–2 days, patients can be switched to oral antibiotics based on susceptibilities to complete a 7-day course.

EPIDIDYMITIS

Epididymitis typically presents as unilateral testicular pain and a palpably swollen epididymis. STI pathogens are the most likely cause in sexually active men < 35 years of age. Other pathogens are usually enteric GNBs, most commonly *Escherichia coli*. If *Neisseria gonorrhoeae* is the etiology, urethritis is usually present with the typical findings; otherwise, perform NAAT of urine for *N. gonorrhoeae* and *Chlamydia trachomatis*. Treatment of epididymitis is the same as for gonorrhea in patients at high risk for STIs. For suspected enteric rod infections, use a 10-day course of a fluoroquinolone.

HUMAN PAPILLOMAVIRUS (HPV)

HPV is transmitted by direct contact and causes warts.

Genital warts result in an increased risk of cervical, vaginal, vulvar, penile, and anal cancer. There are many variants, but 15 of these variants found worldwide are designated as being high risk for cancer. HPV-16 and HPV-18 are the most common causes of cervical cancer (with an incidence of 60% and 10%, respectively). The strains that cause cervical cancer are usually subclinical. There's much more information on cervical cancer in the [Oncology](#) section.

HPV-6 and HPV-11 are the most common causes of exophytic, grossly visible genital warts. HPV-6 and HPV-11 carry **little risk** for cervical cancer.

HPV-1, HPV-2, and HPV-5 are common causes of plantar warts.

HPV vaccines contain the most oncogenic serotypes and are recommended for **all** males and females 9–26 years of age.

VAGINITIS

Vaginitis presents with a change or increase in vaginal discharge. There are 3 major causes (in descending order of frequency): bacterial vaginosis, candidiasis, and trichomoniasis. Use a systematic approach to diagnose the etiology. See [Table 4-2](#).

Table 4-2: Vaginitis Diagnostic Tests

	Vaginal pH	Wet Prep	KOH Prep
Bacterial Vaginosis	> 5.0	Clue cells	Fishy odor
Candidiasis	< 5.0	Fungal elements	Fungal elements
Trichomoniasis	> 5.0	Trichomonads	Fishy odor

KOH = potassium hydroxide

Systematic Approach to Vaginitis

Three tests on vaginal secretions/discharge can determine the etiologic agent on initial examination: pH, wet prep, and potassium hydroxide (KOH) prep.

pH: The normal vaginal pH is < 5.0 and remains so with vaginal candidiasis. A pH > 5.0 is seen in bacterial vaginosis and trichomoniasis.

Wet prep (secretions placed in normal saline under microscopy): This reveals epithelial cells studded with causative organisms (i.e., clue cells) in bacterial vaginosis and trichomonads in trichomoniasis. It shows fungal elements in candidiasis.

KOH prep (secretions placed in KOH under microscopy): This yields an amine (fishy) odor in bacterial vaginosis and trichomoniasis. KOH dissolves cellular membranes and debris but not the cellulose in fungi, so it increases the yield of finding yeast forms and pseudohyphae in candidiasis.

Bacterial Vaginosis

Bacterial vaginosis results from the replacement of the normal *Lactobacillus* in the vagina with high concentrations of anaerobic bacteria (e.g., *Mobiluncus*, *Gardnerella vaginalis*). There is a thin, “skim milk,” scanty, foul-smelling, **nonirritating** discharge that has 2 identifying features on testing:

- 1) Clue cells (epithelial cells with many adherent bacteria; [Figure 4-7](#))
- 2) An amine (fishy) odor when mixed with KOH (+whiff/sniff test)

There is no **cervical** discharge.

Treatment is with metronidazole PO × 7 days or vaginal cream × 5 days. Alternately, give tinidazole or 2%

clindamycin orally or as a cream intravaginally $\times 7$ days. Unlike with other vaginal infectious diseases, there is no single-dose therapy.

Oral metronidazole is safe in pregnancy; give this formulation instead of the gel. Bacterial vaginosis increases the risk of preterm labor if not treated orally.

Male sexual partners do **not** require treatment, because bacterial vaginosis is not an STI.

Figure 4-7: Clue cells. Stippled appearance from being covered with bacteria
Source: CDC

Vulvovaginal Candidiasis (VVC)

VVC is almost always caused by the species *Candida albicans*. It presents with adherent white plaques on an erythematous base and is usually pruritic. Remember that this can be a sign of undiagnosed diabetes or HIV, especially if recurrent.

The treatment is as follows:

- For uncomplicated VVC in a nonpregnant patient, give any azole vaginal cream. Oral azoles are equally effective, especially oral fluconazole 150 mg $\times 1$.
- For **recurrent** VVC, weekly topical azole and oral fluconazole 150 mg 1-time doses are equally effective.
- Although systemic or topical fluconazole was previously considered safe in pregnancy, a 2016 study showed that women treated with systemic or topical fluconazole had an increased risk of spontaneous abortion and stillbirth. This does not occur with topical clotrimazole or miconazole, which are the drugs of choice for pregnant women.

Trichomoniasis

Trichomonas vaginalis, a flagellated protozoan, causes vaginitis in women. (Men can also be infected but are typically asymptomatic.) Trichomoniasis presents with a profuse, thin, **frothy**, yellow-green, foul-smelling discharge (which, like bacterial vaginosis, has a +whiff test), vaginal erythema, and a **strawberry cervix**.

Treat trichomoniasis with a single dose of either metronidazole 2 g or tinidazole 2 g. Even though these are the best treatments, they are only moderately effective. Metronidazole is safe in pregnancy. Treat sexual partners as well.

CENTRAL NERVOUS SYSTEM (CNS) INFECTIONS

PREVIEW | REVIEW

- What is the clinical presentation of bacterial meningitis?
- Which organisms are the most common cause of bacterial meningitis in adults?
- What is the standard empiric treatment for bacterial meningitis in adults < 50 years of age?
- To which contacts should you give prophylaxis for meningococcal meningitis?
- Empiric coverage for a patient with a spinal epidural abscess should cover which organism, specifically?
- What are acceptable empiric regimens for a brain abscess?
- Which animals are at high risk for the transmission of rabies?

BACTERIAL MENINGITIS

Untreated bacterial meningitis is a routinely fatal disease. In the U.S., there are 3 main causes of bacterial meningitis in adults:

- *Streptococcus pneumoniae* causes the majority of bacterial meningitis in **all** adult age groups.
- *Neisseria meningitidis* (meningococcus) is more common in young adults until ~ 25 years of age and in adults > 60 years of age.
- *Listeria monocytogenes* meningitis starts at ~ 50 years of age.

Neisseria meningitidis has been declining since the 1990s. It is currently at historic lows (0.1 per 100,000).

Approach to the Patient with Suspected Bacterial Meningitis

Time is of the essence in bacterial meningitis, and an organized approach to diagnosis and treatment is essential to decrease morbidity and mortality. Suspect bacterial meningitis in anyone with a fever, headache, and stiff neck.

The Kernig and Brudzinski signs are very insensitive but highly specific ($> 95\%$). First obtain stat blood cultures, and then perform a lumbar puncture (LP) as soon as possible, but take caution to avoid precipitating herniation in patients who may have a space-occupying CNS lesion. The following parameters are predictive of finding such lesions on a CT scan, and the CT scan should

be performed prior to the LP in these circumstances; however, do not delay the administration of antibiotics while waiting on imaging results for patients with any of the following:

- An immunocompromised state
- Prior CNS disease
- Seizures in the last week
- Altered consciousness
- Papilledema
- A focal neurologic deficit

If a CT is performed and shows no contraindication (e.g., abscess), proceed with the LP. In patients who do not warrant a CT scan, obtain stat blood cultures, give IV dexamethasone and empiric IV antibiotics, and then perform the LP. Doing the LP first is ideal, but **never delay** the administration of antibiotics while waiting on an LP kit delivery or the results.

With the obtained cerebrospinal fluid (CSF), perform a Gram stain, C&S, and cell count with differential and obtain the protein and glucose levels. Rapid antigen testing is not routinely recommended because it uncommonly alters treatment. Typical findings in normal CSF vs. bacterial and viral (aseptic) meningitis are shown in Table 4-3.

Culture results are the gold standard and are positive in the majority of cases.

Antibiotics Used for Bacterial Meningitis

Because the CNS is an immune sanctuary with a decreased ability for complement and immunoglobulin to reach the site of infection, the antibiotics chosen must be **bactericidal**. Classes of antibiotics that are bactericidal are the β -lactams, glycopeptides, fluoroquinolones, and aminoglycosides. In addition, the drugs must be able to cross through the inflamed meninges. This presents a problem for the aminoglycosides, which, if used, may need to be given intrathecally. Selected 3rd generation cephalosporins with vancomycin should be the primary 1st line agents.

Chloramphenicol and TMP/SMX are bactericidal against certain organisms but are 2nd line drugs. Tetracyclines and macrolides are **not** bactericidal; do not use these.

Selecting Empiric Therapy

Age is the most useful predictor of the bacterial etiology of meningitis.

In adolescents and adults < 50 years of age, *S. pneumoniae* and *N. meningitidis* are the predominant organisms. Empiric therapy for this age group is ceftriaxone (which treats > 90% of *S. pneumoniae* strains and 100% of *N. meningitidis* strains) and vancomycin (which treats 100% of *S. pneumoniae* strains).

In adults > 50 years of age, *L. monocytogenes* becomes more common. This bacterium is not routinely susceptible to vancomycin and is resistant to cephalosporins, so add ampicillin empirically until the culture results are known. The CSF WBC count is lower with *Listeria* infection than with other bacterial infections, and the Gram stain is more commonly negative.

Patients with bacterial meningitis after neurosurgical procedures are at risk for staphylococcal and gram-negative aerobic infections; treat these patients with vancomycin and a 3rd generation cephalosporin.

Therapy Based on Gram Stain

Gram stain results allow for the reassessment of therapy within hours. If the CSF Gram stain results show an organism (as in the majority of bacterial meningitis cases), change the empiric therapy based on those results (Table 4-4).

Definitive Therapy

Cultures grow organisms from the CSF in the majority of patients with bacterial meningitis. Use the results to adjust the therapy.

Dexamethasone

Dexamethasone decreases the morbidity and mortality in adults with pneumococcal meningitis. Because > 50% of meningitis is caused by pneumococcus, start dexamethasone empirically 15–20 minutes before antibiotic administration, and continue dexamethasone treatment for 4 days if pneumococci are cultured. Discontinue dexamethasone if another causative agent is found.

Table 4-3: Normal CSF vs. Bacterial and Viral (Aseptic) Meningitis

	Normal CSF	Bacterial Meningitis	Viral Meningitis
WBC Count	< 5 cells/ μ L (0.01×10^9 /L) No PMNs	> 1,000 cells/ μ L (1×10^9 /L) High PMNs	< 1,000 cells/ μ L (1×10^9 /L) PMNs then monocytes
Glucose Level	50–75 mg/dL (2.77–4.16 mmol/L)	Low	Normal
Protein Level	< 45 mg/dL	> 100 mg/dL	< 100 mg/dL

CSF = cerebrospinal fluid PMN = polymorphonuclear leukocyte WBC = white blood cell

Table 4-4: Therapy Based on Cerebrospinal Fluid Gram Stain Results

Gram Stain	Likely Organism	Antibiotics	Comment
Gram-positive cocci	<i>Streptococcus pneumoniae</i>	Vancomycin + ceftriaxone	Until ceftriaxone sensitivity is known
Gram-negative cocci	<i>Neisseria meningitidis</i>	Ceftriaxone or penicillin	
Gram-positive bacilli	<i>Listeria monocytogenes</i>	Ampicillin +/- gentamicin Trimethoprim/sulfamethoxazole if penicillin allergic	
Gram-negative bacilli	Enteric aerobe	3 rd generation cephalosporin or meropenem	Cover for <i>Pseudomonas aeruginosa</i> if postneurosurgical

PREVENTION OF MENINGOCOCCAL MENINGITIS

Give prophylaxis to close contacts of patients with meningococcal bacteremia and/or meningitis to eradicate any possible nasopharyngeal colonization, which increases the risk of subsequent development of invasive disease. Close contacts are defined as:

- persons who have spent > 8 hours within 3 feet of the index case from 7 days prior to 1 day after presentation (e.g., those who live in the patient's household, contacts at day care centers) and
- persons exposed to the patient's oral secretions (e.g., a health care worker who has intubated the patient).

Usual clinical encounters do not merit prophylaxis for health care workers.

To eradicate the carrier state, use **one** of the following:

- Ciprofloxacin 500 mg PO × 1 (for nonpregnant adults)
- Rifampin 600 mg PO bid × 2 days (for children and nonpregnant adults)
- Ceftriaxone 250 mg IM × 1 (for pregnant adults and children < 15 years of age)

Patients with meningococcal disease who are treated with penicillin still need to be given one of these prophylactic drugs prior to discharge because penicillin does not eradicate the carrier state. See [Vaccine Schedules on page 4-86](#) for additional information.

Of the many serotypes of meningococcus, serotypes A, B, C, W, and Y are the main cause of meningitis. As of 2005 there has been a conjugate vaccine against serotypes A, C, W, and Y. In 2014, the FDA approved MenB vaccine against serotype B. Serotype B has been the main cause in the U.S. Recently, serotype Y has increased. Because there is no overlap between the vaccines, decisions on vaccination should be informed by results of serotyping meningococcal meningitis cases in the region.

SETTINGS TO CONSIDER NONBACTERIAL MENINGITIS

Suspect **Cryptococcus** in patients with acquired immunodeficiency syndrome (AIDS), acute lymphocytic

leukemia, or lymphoma or who use corticosteroids, and look for cryptococcal antigen in the blood and CSF.

Consider **amebic meningitis** when the patient has been swimming in freshwater lakes, ponds, or irrigation canals.

ASEPTIC MENINGITIS

The diagnosis of aseptic meningitis is based on clinical and CSF signs of meningeal inflammation (mild CSF pleocytosis and mildly elevated protein) without a clear infectious cause. The vast majority of these cases are due to viral infection. Patient complaints are similar to those for bacterial meningitis, although the symptoms are less acute and severe.

The viruses that cause aseptic meningitis are:

- Enteroviruses (e.g., coxsackievirus, echovirus, enterovirus)
- Arboviruses (e.g., West Nile virus)
- HSV
- Acute HIV infection

Fungal and bacterial causes of aseptic meningitis include:

- Endemic fungi
- Cryptococcal meningitis (seen in AIDS, acute lymphocytic leukemia, and lymphomas)
- *Nocardia*
- *Mycobacterium tuberculosis*
- *Borrelia burgdorferi* (Lyme disease)

TUBERCULOUS MENINGITIS

Tuberculous meningitis causes a thick, basilar meningitis that often causes cranial nerve injury and presents with cranial neuropathy, such as a 6th nerve palsy, and CSF with a lymphocytic pleocytosis, high protein level, and very low glucose level.

LYME MENINGITIS

Lyme meningitis can cause peripheral and cranial nerve palsies, especially of the 7th cranial nerve (Bell's palsy), so think of Lyme disease or HSV infection when a patient presents with an isolated facial nerve palsy. For treatment information, see [Lyme Disease on page 4-51](#).

SPINAL EPIDURAL ABSCESS

Spinal epidural abscesses (pus between the dura and vertebrae) are caused by either hematogenous spread or local extension (e.g., from vertebral osteomyelitis). *Staphylococcus aureus* is the most common cause. Patients can present with the classic triad of fever, back pain, and radiculopathy.

On CSF analysis, a spinal epidural abscess resembles aseptic meningitis, with a moderate pleocytosis, modest protein elevation, normal glucose level, and negative result on Gram stain and culture. If an LP is performed, take care not to go through the area of infection. Obtain an MRI if any 2 of the 3 previously mentioned symptoms occur. CT is not as good as MRI because it is susceptible to bony artifacts. Obtain blood cultures. Drainage is required if technically feasible. Empiric coverage includes drugs effective against staphylococci. Definitive therapy is based on the blood or surgical cultures.

NEUROSYPHILIS

See the prior discussion of neurosyphilis under [Syphilis on page 4-16](#).

BRAIN ABSCESS

Bacteriology of a brain abscess reflects organisms found in sinusitis, dental infections, and otitis media. Postsurgical abscesses can show *Staphylococcus aureus* or GNBs. *Cutibacterium* is a common organism for postneurosurgical abscesses. Common locations from hematogenous sources are the frontal, temporal, and parietal lobes via the middle cerebral artery.

The symptoms are a subacute onset of fever, focal neurologic deficit, and sometimes seizures. Diagnose a brain abscess using a CT scan with contrast or MRI. If accessible, aspirate the abscess and give antibiotic treatment based on the results. An LP is contraindicated if signs of increased intracranial pressure are present, such as papilledema or focal neurologic signs. An LP rarely helps identify the infectious bacteria because the organisms are seldom in the subarachnoid space.

Treatment is initially empiric, followed by definitive therapy for 4–8 weeks if cultures are obtained by drainage. Give ceftriaxone + metronidazole to cover aerobes and anaerobes. Penicillin has been used for anaerobic coverage in the past but there is increasing resistance to this. If you suspect GNBs (e.g., if there is an ear focus), consider an agent with *Pseudomonas* coverage + metronidazole. If there was a history of bacteremia/endocarditis, a neurosurgical procedure, or penetrating head trauma, add vancomycin for MRSA. For postoperative neurosurgical patients, use ceftazidime, cefepime, or meropenem to cover hospital-related gram-negative organisms, including *Pseudomonas*.

VIRAL ENCEPHALITIS

Herpes Simplex Virus Type 1 (HSV-1)

The most common sporadic viral encephalitis is due to HSV-1. The virus enters the CNS via the trigeminal or olfactory tract following an episode of primary or recurrent HSV-1 of the oropharynx or reactivation of latent virus in the CNS without evident oropharyngeal herpes. Disease is usually frontotemporal, and the symptoms range from alterations in behavior, seizures, cranial nerve dysfunction, and hemiparesis to alterations of consciousness, all over a period of < 1 week. Brain imaging is usually abnormal, showing unilateral, sometimes bilateral focal cerebral inflammation. The CSF shows a lymphocytic, aseptic meningitis that is sometimes hemorrhagic. In HSV meningoencephalitis, the CSF glucose is sometimes mildly decreased. The CSF can be normal initially in encephalitis; HSV PCR of the CSF is positive > 95% of the time. Treatment is with high-dose IV acyclovir for ≥ 14 days.

Arboviral Encephalitis

The arboviruses are the most common seasonal viral encephalitides and are named after the geographic location from which they originally came (e.g., West Nile, St. Louis). They are discussed under [Arboviruses on page 4-75](#).

Rabies

Rabies is a preventable but almost always fatal illness that is very rare in the U.S. (< 5 cases a year) but causes ~ 30,000 deaths a year worldwide. Fewer than 20 patients worldwide have survived rabies without treatment. Rabies virus is found in bats, raccoons, skunks, foxes, dogs, cats, and ferrets but not in squirrels, rats, or any other rodents. Worldwide, rabies is primarily transmitted to humans by dogs, but in the U.S., bats are the most common cause. Rabies typically presents within 1–3 months after exposure with a viral prodrome followed by encephalitis, ascending paralysis, neuropathic pain +/- sensorimotor deficits, and eventually hydrophobia, aerophobia, and delirium.

Diagnose rabies by:

- virus-specific immunofluorescent staining of a skin biopsy sample of hair follicles at the nape of the neck,
- detection of the virus from the saliva by reverse transcriptase polymerase chain reaction (RT-PCR), or
- detection of antirabies antibodies in the serum or CSF.

Preexposure prophylaxis is recommended for cave explorers, veterinarians, animal control workers in endemic areas, and anybody who handles bats—but **not** for hunters, mail carriers, or other persons.

Determine the need for postexposure prophylaxis based on the suspected animal source. Bites from bats, raccoons, foxes, and skunks are considered high risk and warrant prophylaxis. Have pet dogs, cats, and ferrets observed for 10 days, and if there are no signs of rabies,

there is no need for prophylaxis. Bites from small rodents never need prophylaxis. Prophylaxis consists of human rabies immunoglobulin (HRIG)—with ~ 50% injected in the tissue around the wound and the remainder administered IM—and vaccination with the rabies human diploid cell vaccine. Give each in a separate site. If a person has been vaccinated previously, administer only a booster vaccine after a bite, not HRIG.

PRION DISEASE

Prions are proteinaceous infectious particles that lack nucleic acid and are destructive to neural tissue.

The most important prion diseases are Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD). In animals, prions cause mad cow disease (bovine spongiform encephalopathy), which is vCJD if transmitted to humans.

CJD is almost always sporadic, but ~ 5% of cases are transmitted from person to person (via, e.g., corneal transplants, cadaveric human growth hormone), and very few cases are genetic. The incubation period is ~ 18 months. Patients with CJD get myoclonus and severe, rapidly progressive dementia. MRI shows diffuse cerebral disease, and electroencephalography (EEG) classically shows periodic synchronous biphasic or triphasic sharp wave complexes. An abnormal amount of 14-3-3 protein may be present in the CSF. The clinical course is one of progressive rapid deterioration, with the majority of patients dying within 6 months of diagnosis. There is no effective therapy.

vCJD is transmitted from eating meat from cattle with bovine spongiform encephalopathy (a.k.a. mad cow disease). No endemic human cases of vCJD have been reported in the U.S., although some veterinary cases have been reported. Patients with vCJD have initial psychiatric symptoms and paresthesias and then ataxia and cognitive impairment. Paresis of upward gaze occurs in ~ 50% of patients. Death occurs in ~ 1 year.

INFECTIVE ENDOCARDITIS (IE)

PREVIEW | REVIEW

- What is the most common organism causing native valve endocarditis?
- What is the usual cause of prosthetic valve endocarditis > 2 months after surgery?
- What are some specific physical examination signs of endocarditis?
- How many sets of blood cultures should be drawn on a patient with suspected endocarditis?
- Which organisms cause culture-negative endocarditis?
- What 2 types of tests make up the major criteria for the diagnosis of endocarditis?

- Know the various regimens to treat endocarditis based on resistance patterns and the type of valve (native vs. prosthetic).
- List the indications for the early surgical treatment of bacterial endocarditis.

OVERVIEW

IE occurs on prosthetic and native valves or other endocardial surfaces. We will specifically discuss culture-negative IE and IE seen in injection drug users. These categorizations are predictive of the microbiology and hence the treatment of the disease. The previous designations of acute and subacute are no longer used.

NATIVE VALVE ENDOCARDITIS (NVE)

NVE is more common on the **left** side of the heart and usually occurs on defective or damaged valves. It can also occur in the path of abnormal flow across a ventricular septal defect (VSD) or patent ductus arteriosus. Over the last half century, the median age of onset has increased and is now around 60 years of age.

The most common organism infecting native valves is *Staphylococcus aureus*, followed by viridans streptococci and then enterococci. Patients with *S. aureus* endocarditis have a higher incidence of embolic phenomena and death. There is a group of organisms that causes a small percentage of IE cases. This group was previously called HACEK but is now called **AACEK**, which stands for the following:

- *Aggregatibacter aphrophilus* (formerly *Haemophilus aphrophilus*)
- *Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*)
- *Cardiobacterium hominis*
- *Eikenella corrodens*
- *Kingella kingae*

These organisms share several commonalities: They take longer to show growth in vitro, cause large vegetations with a high risk of embolization, and are susceptible to PCNs.

Fungal endocarditis is seen in IV drug abusers and patients with central IV catheters.

PROSTHETIC VALVE ENDOCARDITIS (PVE)

Early PVE (occurring within 2 months of valve insertion) is usually due to inoculation during surgery, and staphylococcal species are the most common infecting organisms. PVE is harder to cure than NVE; if there is no response to the 1st round of (adequate) antibiotics, replace the valve. If acute cardiac decompensation occurs, patients need emergent surgical intervention regardless of the duration of prior antibiotics and have a mortality rate of ~ 40%.

Late PVE (occurring > 2 months after valve insertion) is caused by organisms similar to those causing NVE; however, coagulase-negative staphylococci are much more common (~ 15%). If the infecting organisms are viridans streptococci or enterococci, the likelihood of cure with antibiotics is higher than with staphylococci. Better antibiotic treatment success is seen with porcine bioprosthesis than with metal valves.

The valve must be replaced if there is evidence of a valve ring infection, myocardial penetration, or an unstable prosthesis. If you see new heart block or a new bundle branch block, think of this.

HISTORY AND PHYSICAL EXAMINATION

Occasionally IE presents only with signs of embolic events, such as black toes or septic emboli to organs (e.g., embolic stroke, brain abscess, splenic infarct). It can also present as a lingering illness with nonspecific symptoms (e.g., weight loss, fevers, chills, night sweats) or heart failure due to valvular insufficiency.

Focus the history on recent potential exposures to typical organisms:

- Skin infections (staphylococci)
- Dental work (viridans streptococci)
- Genitourinary manipulation or obstruction (enterococci)
- IV catheters (staphylococci)
- Injection drug use (*S. aureus*, GNBs, or yeast)

Also look for clues to uncommon organisms, especially if the blood cultures are negative. Animal exposures predispose patients to *Coxiella*, *Bartonella*, and *Tropheryma whippelii*.

Physical examination may show the following classic stigmata, many of which are part of the Duke criteria used to diagnose the disease:

- Conjunctival hemorrhages
- Petechiae (conjunctival and cutaneous; this is the most common skin finding)
- Splinter hemorrhages (of the fingernails and toenails)
- Janeway lesions (nonblanching, painless, reddish lesions on the hands or feet)
- Osler nodes (painful, purplish lesions on the fingers or toes)
- Roth spots (retinal hemorrhages)

These signs are seen in < 25% of cases. When found, however, they are highly specific for endocarditis. 85% of patients will have a murmur and ~ 20% a changing murmur, but these are less-specific findings.

Systemic involvement commonly includes neurologic deficits (the most common cause of death), infarctions of the spleen and kidneys, immune complex glomerulonephritis, and septic pulmonary infarction in right-sided disease.

LABORATORY EVALUATION

Blood cultures are routinely positive (>95% of the time) for patients with IE. This is because the infection is in contact with the bloodstream.

Blood cultures are vital in diagnosing endocarditis of any type; draw **3 sets before** starting empiric antibiotics.

Additional nonspecific laboratory abnormalities commonly seen in endocarditis include:

- Elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
- Anemia of chronic inflammation
- Leukocytosis or leukopenia
- Thrombocytopenia
- Proteinuria, hematuria, and pyuria
- Evidence of immune activation (low complement levels, cryoglobulinemia, rheumatoid factor [RF], and a +RPR test)

CULTURE-NEGATIVE ENDOCARDITIS

If all 3 blood cultures are negative, there is no history of preculture antibiotic treatment, and the patient meets the clinical criteria for endocarditis, this is called culture-negative endocarditis. Consider the following causative agents:

- Fungi
- Q fever (*Coxiella burnetii*)
- *Bartonella* species
- *Tropheryma whippelii*
- *Chlamydia psittaci*
- *Abiotrophia* species (previously known as nutritionally deficient streptococci)

The following are the appropriate tests/procedures for each cause listed above:

- Fungal blood cultures and urinary antigen testing for *Histoplasma* and *Blastomyces*
- Serologies for *Coxiella*, *Bartonella*, and *C. psittaci*
- Alerting the lab to use special culture techniques to look for *Abiotrophia*

T. whippelii endocarditis is commonly diagnosed in removed valves by using special culture techniques or 16S ribosomal ribonucleic acid (rRNA) testing. If you alert the microbiology lab, it will hold blood cultures longer when culture-negative endocarditis is suspected.

ECHOCARDIOGRAPHY

In NVE, transthoracic echocardiography (TTE) has a sensitivity of up to 75% and a specificity of > 90% for the detection of vegetations. In PVE, the sensitivity drops to 17-36%. Transesophageal echocardiography (TEE) has a sensitivity and specificity of > 90% in NVE and a sensitivity of 86-92% in PVE. The 2015 AHA/ACC Infective Endocarditis in Adults: Diagnosis, Antimicrobial

Therapy, and Management of Complications guidelines recommend the following indications for the use of TTE and TEE in diagnosing endocarditis:

- Use TTE as the initial test to detect vegetations.
- If the TTE is nondiagnostic and there is a moderate to high suspicion of endocarditis, perform TEE. Also use TEE to detect suspected complications (such as abscess) or when intracardiac leads are present.

DIAGNOSIS

The diagnosis is based on fulfillment of the **modified Duke criteria**, which include clinical, laboratory, and echocardiographic characteristics, regardless of whether a patient has native or prosthetic valves.

Definite endocarditis is diagnosed when the patient has any of the following:

- Pathologic evidence of disease
- 2 major criteria (see below)
- 1 major criterion + 3 minor criteria (see below)
- 5 minor criteria

Pathologic evidence is either visible organisms from a vegetation or valve lesion or a positive culture from the same tissue.

Possible endocarditis is diagnosed with either:

- 1 major criterion + 1 minor criterion or
- 3 minor criteria.

The 2 major criteria are:

- 1) **Positive blood cultures.** There are 3 ways that this criterion can be met:
 - The organism is one that typically causes endocarditis and is found in ≥ 2 blood cultures 12 hours apart. These organisms are *S. aureus*, viridans streptococci, *Streptococcus bovis*, enterococci, or the AACEK organisms.
 - If the organism is **not** one that typically causes endocarditis, there must be ≥ 3 positive cultures or the majority of ≥ 5 cultures drawn at least an hour apart from first to last.
 - There is a single positive blood culture for *C. burnetii* (or seropositivity for *C. burnetii*). This is the only organism that meets the criterion with a single positive blood culture.
- 2) **Abnormal echocardiogram** with any of the following:
 - An oscillating mass on a valve or on supporting structures
 - An oscillating mass in the path of a regurgitant jet
 - An oscillating mass on an implanted device
 - An abscess
 - Prosthetic valve dehiscence
 - A new regurgitant valve by echocardiography or auscultation

The 5 minor criteria are:

- 1) A predisposing condition (i.e., valve disease, injection drug use)
- 2) Fever $> 100.4^{\circ}\text{F}$ (38.0°C)
- 3) Vascular phenomena (e.g., arterial emboli, pulmonary infarcts, mycotic aneurysms, stroke, conjunctival hemorrhages, Janeway lesions)
- 4) Immunologic phenomena (e.g., acute glomerulonephritis, Osler nodes, Roth spots, +RF)
- 5) A positive blood culture that does not meet a major criterion

Of note, *S. bovis* has recently been reclassified into 4 species: *S. gallolyticus*, *S. lutetiensis*, *S. infantarius*, and *S. pasteurianus*.

ANTIBIOTIC TREATMENT OF BACTERIAL ENDOCARDITIS

While therapy is based on specific organisms, remember these 5 general concepts:

- 1) Endocarditis requires bactericidal antibiotics because white cells and opsonins have difficulty penetrating to the center of vegetations, so the antibiotic must do the killing.
- 2) With rare exceptions, give antibiotics IV for the duration of treatment.
- 3) Give antibiotics at the appropriate dose to ensure bactericidal levels.
- 4) There are only 3 scenarios in which a 2-week duration is sufficient:
 - For viridans streptococci if an aminoglycoside is added to the regimen
 - For *S. bovis*
 - For uncomplicated right-sided *S. aureus* endocarditis
- 5) Treat all other organisms for a minimum of 4 weeks (Table 4-5 on page 4-28).

Viridans Streptococci and *Streptococcus bovis*

If the organism is susceptible to PCN, give 4 weeks of PCN G, ampicillin, or ceftriaxone (2 g/day). Adding gentamicin can reduce the duration to 2 weeks; however, keep it at 4 weeks if there is an abscess. Gentamicin is not recommended for patients with chronic kidney disease (CKD). Vancomycin can be used for 4 weeks in patients unable to tolerate the β -lactam, but it is **not** preferred for initial treatment.

If there is intermediate resistance to PCN, the regimen is the same except that the dose of PCN G is increased or ceftriaxone is substituted.

Prosthetic valve treatment is generally the same regimen, but the duration of treatment is lengthened.

Table 4-5: Treatment of Bacterial Endocarditis

Organisms	Susceptibility Testing	Drug Regimen	Duration
Viridans streptococci, <i>Streptococcus bovis</i> (See reclassification of this species under <i>Viridans Streptococci</i> and <i>Streptococcus bovis</i> on page 4-27.)	PCN-sensitive	PCN G, ampicillin, or ceftriaxone	4 weeks Prosthetic valve = > 4 weeks
		(PCN G, ampicillin, or ceftriaxone) + gentamicin	2 weeks
		Vancomycin (alternative)	4 weeks
<i>Staphylococcus aureus</i> or coagulase-negative staphylococci	PCN-intermediate	Increased dose of PCN G or ceftriaxone	4 weeks
	Methicillin-susceptible	Nafcillin	6 weeks Prosthetic valve = add rifampin + gentamicin
	Methicillin-resistant	Vancomycin	6 weeks Prosthetic valve = add rifampin + gentamicin
Uncomplicated right-sided staphylococci	Methicillin-susceptible	Nafcillin; if PCN allergic, daptomycin or vancomycin	2 weeks
Enterococci	PCN-sensitive (depending on ampicillin and vancomycin susceptibilities)	(PCN G or ampicillin or vancomycin) + gentamicin	4–6 weeks Prosthetic valve = 6 weeks
	Resistant to ampicillin, PCN G, and vancomycin	Very specialized	Very specialized
AACEK (<i>Aggregatibacter aphrophilus</i> , <i>Aggregatibacter actinomycetemcomitans</i> , <i>Cardiobacterium hominis</i> , <i>Eikenella corrodens</i> , <i>Kingella kingae</i>)		Ceftriaxone	4 weeks Prosthetic valve = 6 weeks

PCN = penicillin

Perform a colonoscopy if endocarditis is caused by what was formerly known as *S. bovis*, given the high prevalence of colon cancer in these patients. (*S. bovis* has been reclassified and consists of 4 species: *S. gallolyticus*, *S. lutetiensis*, *S. infantarius*, and *S. pasteurianus*.)

Staphylococcus aureus without Prosthetics

Methicillin-susceptible *S. aureus* (MSSA) left-sided or right-sided disease with emboli requires nafcillin × 6 weeks. The addition of an aminoglycoside is not recommended, because it does not improve cure rates and it increases nephrotoxicity.

Treat methicillin-resistant *S. aureus* (MRSA) endocarditis with vancomycin × 6 weeks. Alternatively, use daptomycin, especially if the vancomycin MIC is > 1 mcg/mL.

For MSSA uncomplicated right-sided disease, give nafcillin or oxacillin × 2 weeks. For patients with hypersensitivities to the nafcillin or oxacillin, cefazolin × 2 weeks can be used. Daptomycin or vancomycin × 4 weeks are acceptable alternatives for patients with anaphylactic penicillin allergy.

Treat MRSA isolates × 6 weeks with vancomycin or daptomycin only.

Staphylococcus aureus with Prosthetic Valves

For MSSA prosthetic valve disease, give nafcillin + rifampin + gentamicin for ≥ 6 weeks. For MRSA prosthetic valve disease, give vancomycin + rifampin + gentamicin for ≥ 6 weeks. Surgery is almost always indicated.

Enterococci

For native valve endocarditis, based on susceptibilities, if the organism is sensitive to PCN, give gentamicin + PCN or ampicillin or vancomycin × 4–6 weeks.

Prosthetic valve treatment is the same regimen, but the duration of treatment is lengthened to 6–8 weeks.

If the organism is resistant to PCN, ampicillin, and vancomycin, treatment is difficult and specialized, utilizing variations of linezolid or daptomycin (if sensitive) +/- imipenem/cilastatin with either ampicillin or ceftriaxone.

AACEK Organisms

Treat AACEK organisms with ceftriaxone × 4 weeks. Alternatives include ampicillin-sulbactam and ciprofloxacin. If a prosthetic valve is involved, the duration of treatment is 6 weeks.

SURGICAL TREATMENT OF BACTERIAL ENDOCARDITIS

Early surgery (defined as surgery during the initial hospitalization prior to the completion of antibiotic therapy) is indicated in the following situations:

- Heart failure refractory to medical therapy
- Resistant organisms with no available bactericidal therapy
- Development of heart block
- Development of an abscess
- Persistence of positive blood cultures or fever for > 5–7 days into therapy
- A relapse of PVE

A less well-established indication for early surgery is a vegetation > 10 mm.

PREVENTION OF ENDOCARDITIS

Administration of antibiotics to prevent endocarditis is only done under specific circumstances depending on whether the patient is in a high-risk group for endocarditis and if the procedure has a high risk of causing bacteremia.

The only adult patients considered to be at high risk for acquiring endocarditis are those with prosthetic cardiac material (e.g., valves, unrepaired or repaired cyanotic congenital heart disease) or a prior history of endocarditis.

The only procedures requiring prophylaxis are the following:

- Dental procedures that cause bleeding because of manipulation of the gingiva or periapical areas or perforation of the oral mucosa
- Respiratory tract procedures that cut through the mucosa, such as tonsillectomy or bronchoscopy with biopsy

For dental procedures:

- Most patients receive a single 2 g dose of amoxicillin 30–60 minutes prior to the procedure.
- PCN-allergic patients can receive cephalexin, clindamycin, clarithromycin, or azithromycin.
- Those unable to take an oral medication should receive parenteral ampicillin, cefazolin, or ceftriaxone.

For respiratory tract procedures that cut through the mucosa, use the above regimens. If an active respiratory tract infection is the reason for the procedure (e.g., drainage of an abscess or empyema), use one of these antibiotics as part of the treatment regimen. If the patient is known or suspected to be colonized or infected with *S. aureus*, add antistaphylococcal antibiotics.

CARDIAC IMPLANTABLE ELECTRONIC DEVICE (CIED) INFECTIONS

CIED (i.e., pacemaker, implantable cardioverter-defibrillator) infections occur at a rate of ~ 1%. The infection can be limited to the tissue in which the device is placed (i.e., a pocket infection) or involve the leads within the heart, and it can occur as a result of contamination at the time of placement or from bacteremia. *Staphylococcus aureus* and coagulase-negative staphylococci are the main culprits. Risk factors include early device reoperation (posing the highest risk), a longer procedure duration, a device battery change, chronic kidney disease, and immunosuppression (either from an underlying condition or from a medication).

A pocket infection typically presents with pain, erythema, swelling, and sometimes systemic symptoms. A deeper infection presents with systemic symptoms, namely fever, chills, and right-sided endocarditis (refer to [Infective Endocarditis \(IE\)](#) on page 4-25).

Obtain 3 sets of blood cultures separated by at least 1 hour unless the patient is septic, in which case the cultures must be obtained sooner. Perform a TEE (not TTE) as the initial imaging modality.

Treatment of a pocket infection consists of device removal (including leads) and initiation of empiric antibiotics to cover MRSA (e.g., vancomycin). The therapy is tailored to the causative organism once the culture results are known, and the total duration of therapy is 10–14 days. Treat a deeper device infection as you would treat endocarditis (refer to [Infective Endocarditis \(IE\)](#) on page 4-25).

HUMAN IMMUNODEFICIENCY VIRUS (HIV) AND ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

PREVIEW | REVIEW

- What is the viral set point, and what is its significance?
- Patients with immunosuppression from autoimmune deficiency syndrome (AIDS) are at risk for developing infections with which organisms?
- How is human immunodeficiency virus (HIV) infection diagnosed in the acute and chronic stages? What is the utility of measuring HIV ribonucleic acid?
- What is the significance of the CD4 count?
- Which new HIV+ patients should receive resistance testing?
- Which nucleoside reverse transcriptase inhibitor can cause the development of kidney disease?
- Which antiretroviral is teratogenic?

- What is the primary toxicity of nevirapine?
- Jaundice can occur with which antiretroviral drug?
- Which protease inhibitor (PI) is used to boost the drug concentrations of other PIs?
- What is the serious side effect of abacavir, and how can it be screened for?
- Which exposures should receive postexposure prophylaxis for HIV?
- Which pregnant women should be treated for HIV, and with what? What is the treatment goal?
- What are the symptoms of early HIV infection?
- How is *Pneumocystis jiroveci* pneumonia (PJP) best diagnosed?
- Which ancillary treatment should you give to patients who develop severe hypoxemia due to PJP?
- When should you give patients primary prophylaxis for PJP?
- What is the treatment duration for latent tuberculosis in patients with HIV/AIDS?
- How is cryptococcal meningitis diagnosed?
- What is the typical presentation of central nervous system toxoplasmosis?
- Name some of the organisms that can cause chronic diarrhea in patients with AIDS.

OVERVIEW

Changes in the treatment and management of HIV infection are evolving rapidly. The following information covers the basics. Antiretroviral drugs are listed in the contents specifications for the exams, so this information is presented here. Realize, however, that exam questions are more likely to focus on the diagnosis and complications of disease and on side effects of medications than on having you start or change antiretroviral therapy (ART) regimens.

EPIDEMIOLOGY

According to the CDC, as of 2016 in the U.S.:

- There were 1.2 million people living with HIV (~ 15% are unaware).
- There were ~ 38,500 new HIV infections that year.
- Men who have sex with men made up a disproportionate number of the cases, at 63%, as did Blacks, at 44%.
- Heterosexual contact was the transmission category in 25% of cases, and injection drug use was the transmission category in 14% of cases.
- Men represented 80% of cases.
- The most common decile was 20–29 years of age.

HIV PATHOGENESIS

The HIV pathogenesis is relevant to the mechanism of the antiretroviral drugs.

The HIV particle is composed of a dense, single-stranded ribonucleic acid (RNA) core surrounded by a lipoprotein envelope. The RNA contains reverse transcriptase, which allows the RNA to be transcribed into deoxyribonucleic acid (DNA), which is then integrated into the host's genome. The cell then becomes an HIV-producing machine.

The HIV envelope glycoprotein (gp120) binds to the cluster of differentiation 4 (CD4) receptors and coreceptors (such as C-C chemokine receptor Type 5 [CCR5]) on the helper T cells, macrophages, and monocytes. The virus must bind to both the CD4 and CCR5 molecules to fuse with the cell. After fusion, the viral core material enters the cell and is reverse transcribed into DNA that integrates into the human genome and codes for the production of more virion RNA and structural proteins. These proteins, after being cleaved by a protease, then combine with the viral RNA and bud off of the cell using the CD4 cell membrane as a new envelope. This eventually causes destruction of the CD4 cells. The CD4 cells are the major regulator cells in the body; they suppress B lymphocytes and regulate the CD8 suppressor cells.

After initial infection, the virus replicates quickly and robustly until the body controls the infection with cell-mediated immunity. The body establishes a kind of homeostasis with the virus in which the virus is contained to some degree. Some people contain their virus better than others.

The **viral set point** is the viral load that is established after a patient's immune system controls the primary infection; it varies from person to person. When a patient stops ART, the virus typically rebounds to a level that is at the patient's baseline. The higher the viral set point, the faster the CD4 cells are killed and the faster the HIV progresses and the patient becomes ill if not treated.

Continued HIV replication is lytic for CD4+ cells, and B cells also become dysregulated and dysfunctional and are no longer suppressed, causing a polyclonal increase in total serum immunoglobulins but with a decreased ability to create new antibodies. For this reason, infectious diseases in patients with AIDS include not only those occurring from cell-mediated immunodeficiency (e.g., *Pneumocystis* pneumonia, viruses, mycobacteria, fungi), but also those seen with humoral deficiency (e.g., pneumococcus, meningococcus, *Giardia*).

PRESENTATION

Untreated HIV has a long latent period prior to its clinical manifestations unless diagnosed in the acute stage. The acute stage is called symptomatic acute HIV infection, acute retroviral syndrome, or primary retroviral infection. The most common symptoms are rash, sore throat, headache, fever, lymphadenopathy, myalgias, and arthralgias.

The subsequent immunologic decline occurs over several years, and unless screened prior to this, the HIV infection is commonly diagnosed only when the patient presents with symptomatic disease.

SCREENING

Test all persons at least once when they are 13–64 years of age or if they have at-risk behavior outside of this age range. Repeat testing is based on their risk group:

- For high-risk populations (e.g., persons who use IV drugs, men who have sex with men, patients with prior STIs), screen at least annually.
- Screen other populations as the clinical situation warrants. New-onset TB or an STI should trigger screening. Recurrent *Candida* infections or herpes zoster are also examples of situations in which screening is appropriate.

DIAGNOSIS

In the acute and chronic stages, HIV infection is diagnosed by demonstrating the presence of the virus or antibody to the virus. Antibody in acute infection may take up to 3–7 weeks after infection to be detectable.

The presence of HIV can also be detected with tests that measure the actual levels of HIV RNA (the viral load) by amplifying its RNA. These tests are used for initial diagnosis, to assess prognosis, and to monitor the response to ART. Current PCR assays can detect the virus as early as 5 days after infection.

The CDC 2015 Sexually Transmitted Diseases Treatment Guidelines recommend testing with a 4th generation assay, which tests to see if any of the following are present:

- HIV-1 antibody
- HIV-2 antibody
- HIV-1 antigen
- HIV-2 antigen

If any of these are positive, do further testing to see which specific assays are positive to detect chronic infection (antibody present) or acute infection (antigen present).

TREATMENT

Give **all** patients with HIV infection ART with a combination of agents. Adherence to the ART regimen is a key determinant in the degree and duration of viral suppression. The CD4 count is an indication of how immunosuppressed the patient is at the commencement of therapy. The viral load is an indicator of how rapidly the CD4 count will continue to decline if the HIV is left untreated. Therapy is monitored by following the CD4 count and viral load with the goal of getting the viral load to an undetectable level, after which the CD4 count usually increases. Clinical treatment guidelines are released annually by the National Institutes of Health. Prior to treatment, test **all** patients for HIV genotype or phenotype for resistance to antiviral drugs. Repeat testing

if a patient is failing therapy, as indicated by a failure to suppress the viral load below detection when that patient is taking medications reliably.

When the viral load is high and the CD4 count is < 100 cells/ μL ($0.1 \times 10^9/\text{L}$) and decreases rapidly with ART, an **immune reconstitution inflammatory syndrome (IRIS)** can occur. There can be an exacerbation of other preexisting infections that are now unmasked, such as TB, HSV, cytomegalovirus (CMV), and cryptococcal meningitis, because the body now has the ability to mount a response. The overall risk of developing an IRIS is 7–10%. The benefit of starting ART generally outweighs the IRIS risk. If an IRIS develops, the recommendations are to continue with ART and treat the underlying opportunistic infections. In severe situations, corticosteroids can be given for a brief time.

Antiretroviral Drugs

Summary

The classes of anti-HIV drugs are:

- Nucleoside reverse transcriptase inhibitors (NRTIs) and nucleotide reverse transcriptase inhibitors (NtRTIs)
- Nonnucleoside reverse transcriptase inhibitors (NNRTIs)
- Protease inhibitors (PIs)
- Fusion inhibitors (FIs)
- Integrase strand transfer inhibitors (INSTIs)
- CCR5 antagonists
- Postattachment inhibitors

A review of these classes follows, with individual agents highlighted in [Table 4-6 on page 4-32](#).

Nucleoside Reverse Transcriptase Inhibitors (NRTIs)

NRTIs are drug analogs of the deoxynucleotides needed to synthesize viral DNA. They inhibit the replication of HIV by competing with the normal deoxynucleotides. When an NRTI is incorporated into the growing viral DNA, the growing chain terminates, and that DNA cannot be incorporated into the cell's DNA or produce more HIV.

Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)

NNRTIs work very differently from NRTIs. These make the reverse transcriptase ineffective by binding to a different site on the enzyme.

Protease Inhibitors (PIs)

PIs inhibit the HIV protease enzyme that is involved with processing the final assembly of the virion. PIs are typically given with low-dose ritonavir (another PI) because ritonavir interferes with the catabolism of the drug and thus boosts the drug levels of the coadministered PI (which is known as ritonavir boosting). This allows for less frequent dosing.

Table 4-6: Antiretrovirals Used in the Management of Human Immunodeficiency Virus

Drug Class	Drug	Use	Toxicity	Comment
Nucleoside/nucleotide reverse transcriptase inhibitors	Abacavir	1 st line with lamivudine	Severe hypersensitivity reaction if HLA-B*57:01+	Test for HLA-B*57:01 gene prior to administration; once-daily dosing
	Emtricitabine	1 st line with tenofovir	Rare	Cross-resistance with lamivudine; once-daily dosing
	Lamivudine	1 st line with abacavir	Rare	Cross-resistance with emtricitabine; once-daily dosing
	Tenofovir (TDF; newer formulation is TAF)	1 st line	Renal injury and bone density loss with TDF; not seen with the newer TAF formulation; mild gastrointestinal upset	Once-daily dosing
	Zidovudine	Uncommon	Marrow suppression, myopathy	Used only in those who initially responded years ago and in IV form in the perinatal care of HIV-positive mothers
Nonnucleoside reverse transcriptase inhibitors	Doravirine	2 nd line	Rare	P450 interactions
	Efavirenz	2 nd line	Rash, central nervous system toxicity	P450 interactions; once-daily dosing
	Etravirine	2 nd line	Rash	P450 interactions
	Nevirapine	2 nd line	Rash, hepatotoxicity	Initial lead-in phase with lower dose required; once-daily dosing; P450 interactions
	Rilpivirine	2 nd line	Rare	Needs to be taken with food; do not use with viral load > 100,000 copies/mL
Protease inhibitors	Atazanavir	1 st line	Jaundice	Once-daily dosing; P450 interactions
	Darunavir	1 st line	Rare	No cross-resistance with other protease inhibitors; once-daily dosing; P450 interactions
	Lopinavir	2 nd line	Diarrhea	Ritonavir-boosted tablet; P450 interactions
	Ritonavir	1 st line as a booster of another protease inhibitor	Diarrhea, nausea, vomiting	Used only to boost other protease inhibitors; P450 interactions
Fusion inhibitors	Enfuvirtide	Salvage	Local reactions	Subcutaneous administration
Integrase strand transfer inhibitors	Bictegravir	1 st line	Rare	Only available in combination with emtricitabine and tenofovir alafenamide
	Dolutegravir	1 st line	Rare	Blocks creatinine secretion, so can give artifactually elevated creatinine level
	Elvitegravir	1 st line	Rare	Needs to be boosted; needs to be taken with food
	Raltegravir	1 st line	Rare	Twice-daily dosing, but new once-daily form approved in 2016
CCR5 antagonists	Maraviroc	Most commonly 2 nd line	Rare	P450 interactions; twice-daily dosing
Postattachment inhibitors	Ibalizumab-uiyk	Salvage	Rare	IV injection every 14 days
CCR5 = C-C chemokine receptor Type 5		HIV = human immunodeficiency virus	HLA = human leukocyte antigen	IV = intravenous

Fusion Inhibitors (FIs)

FIs bind to and alter the structure of the gp41 glycoprotein on the HIV envelope, which is required for fusion of the virus with the CD4+ cell. FIs have been used infrequently since the introduction of INSTIs.

Integrase Strand Transfer Inhibitors (INSTIs)

INSTIs prevent the HIV integrase enzyme from inserting HIV's reverse-transcribed DNA into an infected cell's own DNA, halting this critical step in the life cycle of HIV. They cause the most rapid decline in viral loads of any agent.

C-C Chemokine Receptor Type 5 (CCR5) Antagonists

CCR5 antagonists prevent the binding of HIV to the CCR5 coreceptor. Not all HIV strains use this coreceptor, so test for this prior to treatment.

Postattachment Inhibitors

Postattachment inhibitors are monoclonal antibodies that bind to the CD4 receptor. They do not prevent HIV from binding to this receptor, but they do prevent subsequent binding to CCR5 and C-X-C chemokine receptor Type 4 (CXCR4) and thus prevent HIV from entering the cell.

Recommended Combination Regimens

According to the 2019 Guidelines for the Use of Antiretroviral Agents in Adults and Adolescents with HIV from the National Institutes of Health, there are 4 preferred initial treatment regimens that all use an INSTI (either bictegravir or dolutegravir) and an NRTI:

- Bictegravir + tenofovir + emtricitabine
- Dolutegravir + abacavir + lamivudine
- Dolutegravir + (emtricitabine or lamivudine) + tenofovir
- Dolutegravir + lamivudine

For the first time, this list includes a 2-drug regimen. Do not use dolutegravir + lamivudine with viral loads > 500,000 copies/mL or in patients with HBV infection.

You must conduct genotypic resistance testing prior to treatment. Many of these drugs are available as combination drugs to facilitate adherence to therapy.

Prior to giving abacavir, test all patients for the HLA-B*5701 allele; if positive, do not give patients abacavir. Such patients are at high risk for a severe hypersensitivity reaction.

When to Change HIV Therapy

It's time to change therapy when:

- the current regimen fails to completely suppress the viral load to an undetectable level on > 1 occasion (assuming the patient is reliably taking the medications),

- the patient becomes intolerant to ≥ 1 of the drugs, or
- there is a rebound in the viral load after it has been suppressed.

Base any changes to therapy on resistance testing done while the patient is still taking the current regimen. Start the patient on a regimen of 3 drugs to which the virus is susceptible and that will not cross-react with side effects from prior medications. If a patient is not taking a medication reliably, the resistance testing may not show any mutations.

Preexposure Prophylaxis to Prevent Sexual Acquisition of HIV

Several studies have shown that once-daily administration of tenofovir-emtricitabine is very effective for decreasing rates of HIV transmission in high-risk populations such as men who have sex with men, heterosexuals with frequent/multiple partners, and HIV-discordant heterosexual couples. In 2012, FDA approved this combination for HIV-negative persons in such risk groups.

Postexposure Prophylaxis for Health Care Workers

Transmission of HIV from patients to health care workers is rare, with the risk from needlestick being 0.33% (1 in 300) and the risk from mucous membrane contact with bloody secretions being 0.09% (1 in 1,100). Transmission has only been documented to occur from bloody fluids and only when these fluids are injected or come into contact with nonintact skin or mucous membranes. If both of these conditions are met, vigorously wash the area with soap and water (flush the mucous membranes with saline) and give postexposure prophylaxis immediately with a 3-drug-combination of 2 NRTIs plus an INSTI. This can be altered based on the index patient's HIV resistance pattern. Treatment is for 4 weeks; test the health care worker for HIV at baseline, 6 weeks, 12 weeks, and 6 months. If the index patient has an undetectable viral load, the risk of transmission is much lower than that stated above.

Pregnancy and Antiretroviral Therapy (ART)

An additional benefit of treating all pregnant women with HIV infection is reducing the risk of vertical transmission from 25% to < 1%. Although initial studies with dolutegravir suggested an increase in neural tube defects, further analysis did not reveal any association. Initial studies of efavirenz also suggested it could cause neural tube defects but sufficient numbers of women have received it in the 1st trimester and this has not been confirmed. Although it is not a 1st line drug for treatment, if a woman is already on efavirenz and becomes pregnant, it is not recommended to discontinue it. For more information, see the [Women's and Men's Health](#) section.

Treat all HIV-infected pregnant women with ART regardless of their CD4 level or viral load. The goal is to make their viral load undetectable. Always do initial resistance testing.

With respect to labor and delivery, give all HIV-infected pregnant women whose viral load is $> 1,000$ copies/mL zidovudine as a continuous infusion during labor in addition to their current ART therapy, and deliver the baby by C-section.

EARLY HIV INFECTION

Early HIV infection is the term used for the first 6 months of infection. The majority of individuals will become ill with a flu-like or mononucleosis-like syndrome that occurs 2-4 weeks after initial infection and lasts 1-2 weeks. Patients with early HIV infection present with some or all of the following:

- Fever
- Lymphadenopathy
- Pharyngitis
- Rash (usually erythematous and maculopapular with lesions on the face, trunk, or extremities; can include the palms and soles)
- Painful, mucocutaneous ulcerations involving the mouth, esophagus, or genitals
- Myalgias or arthralgias
- Aseptic meningitis

The HIV enzyme immunoassay (EIA) antibody test becomes positive at 3-7 weeks after exposure, so it is typically not positive during primary HIV infection. The diagnosis is made by assaying plasma for HIV antigen, which, with current assays, can detect infection as early as 5 days after the patient has acquired the virus. Give all patients with primary HIV infection ART.

HIV / AIDS OPPORTUNISTIC INFECTIONS (OIs) AND OPPORTUNISTIC MALIGNANCIES

Introduction

OIs are caused by microorganisms that do not usually cause disease unless the host is immunocompromised. In the setting of immunosuppression, such as in HIV/AIDS, these microorganisms are able to take advantage of the weakened host. The OIs a patient is at risk for depend on the patient's CD4 cell count. Opportunistic malignancies are those that occur with a markedly higher frequency in HIV-infected persons.

Opportunistic infections in HIV-infected persons typically present in 1 of 4 ways:

- 1) **Pulmonary symptoms:** dyspnea, cough, fever—think of:
 - Bacterial pneumonia
 - Pneumocystosis
 - TB
 - Endemic fungi
- 2) **Systemic symptoms:** fever and wasting—think of:
 - *Mycobacterium avium* complex (MAC) / *Mycobacterium avium* infection
 - CMV

- 3) **CNS symptoms:** altered mental status, focal defects, seizures—think of:

- Cryptococcosis
- Toxoplasmosis
- Progressive multifocal leukoencephalopathy
- Neurosyphilis

- 4) **GI symptoms:**

- Odynophagia—think of:
 - Candidiasis
 - Viral infections (CMV, HSV)
- Chronic diarrhea—think of:
 - Parasitic infections (e.g., *Cystoisospora*, *Cyclospora*, *Cryptosporidium*, *Microsporidium*)
 - Bacterial infections (*Salmonella*, *Shigella*, *Campylobacter*)
 - CMV

Common infections and skin findings in HIV disease include:

- Persistent or recurrent seborrheic dermatitis
- Tinea infections
- Psoriasis
- Molluscum contagiosum
- Folliculitis
- Recurrent HSV and varicella-zoster virus
- Recurrent vaginal and oral candidiasis
- Oral hairy leukoplakia

HIV and Pulmonary Infections

Bacterial Pneumonia

With the successful implementation of primary and secondary prophylaxis against *Pneumocystis*, bacterial pneumonia has become the most common pulmonary infection in HIV-infected persons. The presentation and bacteriology of these infections are similar to those in non-HIV-infected persons and are discussed in the [Pulmonary Medicine](#) section.

Pneumocystis jiroveci Pneumonia (PJP)

PJP (a.k.a. PCP and *Pneumocystis* pneumonia) is a fungal infection acquired via the respiratory route. This pneumonia is the 2nd most common pulmonary infection in patients with HIV and is the presenting illness in 50% of patients with AIDS. 90% of patients with PJP have a CD4 count of < 200 cells/ μ L (0.2×10^9 /L).

Unlike bacterial pneumonia, PJP has an insidious onset of fever, shortness of breath, and dry cough that usually worsens over weeks, not days. There is minimal inflammatory response, which accounts for the lack of sputum production and the rarity of pleuritic pain.

Arterial blood gases typically show a primary respiratory alkalosis. An increased A-a gradient is common along with hypoxia. Lactate dehydrogenase (LDH) is elevated (> 400 U/L [6.68μ kat/L]), and liver enzymes are normal.

The chest x-ray (CXR) usually shows a diffuse, bilateral “batwing” infiltrate, although it is sometimes lobar or unilateral. In 10–15% of patients, the CXR is **normal**, but a CT scan of the chest typically reveals infiltrates.

The best method of diagnosis is by methenamine silver stain (Figure 4-8) or immunostain of pulmonary secretions, either from induced sputum or bronchoalveolar lavage (BAL). Because of the high inoculum of the organism present during active disease, BAL is highly sensitive. PCR assays are also available with similar sensitivity; however, they are less specific in that they may detect colonization instead of infection with the organism.

Figure 4-8: *Pneumocystis pneumonia* methenamine silver stains cyst walls black
Source: CDC

Base treatment on disease severity. Patients with mild to moderate disease have a partial pressure of oxygen (pO_2) > 60 mmHg. Those with severe disease have a $pO_2 < 60$ mmHg.

Treat PJP with high-dose TMP/SMX for 3 weeks. Use oral regimens for mild to moderate disease and the IV form for severe disease. Patients with AIDS have a 15% incidence of sulfa allergy, so 2nd line drugs are often needed. Treat mild to moderate PJP with clindamycin + primaquine or atovaquone. Treat severe disease with IV pentamidine.

Give all patients with an A-a gradient ≥ 35 mmHg or a $pO_2 < 70$ mmHg glucocorticoids concurrently with antibiotics to prevent worsening respiratory failure due to the increased inflammation incited by the killing of the fungal organisms.

TMP/SMX side effects include neutropenia/leukopenia, skin rash, nausea/vomiting, and occasionally fever. TMP/SMX blocks tubular K^+ secretion and can cause severe hyperkalemia, especially at the high doses used to treat PJP.

Possible side effects of pentamidine use include neutropenia/leukopenia, nausea, arrhythmias, renal failure, hypoglycemia, pancreatitis, and hypotension. Long courses of pentamidine may destroy the β cells of the pancreas, causing diabetes mellitus.

Primary prophylaxis is the term used when prophylaxis is given to a patient with no prior history of the OI.

Secondary prophylaxis is what is given when a patient has a history of previous treatment for that OI.

Double-strength (DS) TMP/SMX 1 $\times$ /day or 3 $\times$ /week is the drug of choice. Start primary prophylaxis when the CD4 count is < 200 cells/ μ L ($0.2 \times 10^9/L$). Give secondary prophylaxis after a full course of treatment for PJP. Stop PJP prophylaxis when the CD4 count is > 200 cells/ μ L ($0.2 \times 10^9/L$) for ≥ 3 months in response to ART.

If a patient cannot tolerate TMP/SMX, dapsone or atovaquone are alternative prophylactic agents. Atovaquone is more efficacious than dapsone and has a lower incidence of side effects than TMP/SMX, but it is much more expensive than the other agents. TMP/SMX also provides prophylaxis against toxoplasmosis (see *Toxoplasma gondii* on page 4-59).

Tuberculosis (TB)

Most cases of TB in HIV-infected patients are the reactivation of a prior asymptomatic infection and thus occur in those with the usual risk factors for TB (e.g., homelessness, institutionalization, IV drug abuse, birth in an endemic country). Reactivation occurs at the rate of 3–16% per year in patients coinfecting with HIV and TB.

TB typically presents as a chronic pneumonia but with a presentation different from that in patients without HIV. Specifically, infiltrates can be absent or diffuse, and cavitation is uncommon. Patients can also present with an acute pneumonia, clinically similar to bacterial community-acquired pneumonia. It may also present as cervical lymph node infection, known as scrofula. Disseminated disease is more common in HIV-infected persons.

Diagnose TB in the usual fashion by demonstrating acid-fast bacilli (AFB) by smear or culture of the sputum, of a BAL specimen, a bronchial biopsy specimen, or lymph node biopsy.

Treat patients with a 4-drug regimen of isoniazid, rifampin, ethambutol, and pyrazinamide $\times 2$ months, and then narrow the regimen to isoniazid + rifampin (or rifabutin) $\times 4$ months unless resistance is suspected or proven.

Rifampin may have to be replaced by rifabutin or other drugs in patients with HIV and TB coinfection because of extensive drug interactions with antiretroviral drugs. Rifabutin dosing also needs adjustments because of these drug interactions.

See the **Pulmonary Medicine** section for more information on treatment.

Prevention of active TB in HIV-infected persons is facilitated by annual screening for latent infection with either a TB skin test (purified protein derivative [PPD] test) or an interferon- γ release assay (IGRA). Both can be negative in highly immunocompromised patients.

Give **all** patients with a +PPD (> 5 mm) or +IGRA result without signs of active disease isoniazid for 9 months.

Endemic Fungi

Histoplasma, *Blastomyces*, and *Coccidioides* are the endemic fungi that cause pulmonary infections in HIV-infected individuals. These infections are more likely to be severe as well as to disseminate (in which case they constitute an AIDS-defining illness). These fungi are discussed individually under [Fungal Infections](#) on page 4-53.

Systemic Infections

Mycobacterium avium Complex (MAC) Infection

MAC consists of 10 species, by far the most common of which are *M. avium* and *M. intracellulare*. MAC causes a chronic pulmonary infection in immunocompetent patients. It is ubiquitous in the environment. The infection is acquired by the respiratory or GI route, and when the CD4 count drops to < 50 cells/ μL ($0.05 \times 10^9/\text{L}$), symptoms can occur.

In patients with HIV, MAC usually presents as a disseminated infection, causing a wasting syndrome with fever, weight loss, night sweats, lymphadenopathy, hepatosplenomegaly, diarrhea, and abdominal pain.

Confirm the diagnosis by culturing MAC from blood or body fluids or from biopsies of involved organs, such as the lung, bowel, and lymph nodes.

Treat MAC infection with clarithromycin or azithromycin + ethambutol + rifampin.

Although it was previously recommended to give primary prophylaxis for MAC infection if the CD4 count was < 100 cells/ μL , primary prophylaxis is no longer recommended since the 2018 CDC Guidelines for the Prevention and Treatment of Opportunistic Infections in Adults and Adolescents with HIV. This is because ART can usually produce a rise in CD4 counts above this level in a matter of weeks.

Cytomegalovirus (CMV) Infection

CMV infection can present as diarrhea and/or a wasting syndrome and is by far the most common cause of retinitis in HIV-infected persons (see [Cytomegalovirus \(CMV\)](#) on page 4-71). Most patients with these manifestations have a CD4 count < 50 cells/ μL ($0.05 \times 10^9/\text{L}$). Treatment is with ganciclovir or valganciclovir. Primary prophylaxis is not recommended. Secondary prophylaxis is with valganciclovir.

Central Nervous System (CNS) Infections

Cryptococcus

C. neoformans is endemic worldwide. Although it causes disease in both immunocompetent and immunosuppressed individuals, most HIV-infected patients have a CD4 count of < 100 cells/ μL ($0.1 \times 10^9/\text{L}$) at the time of diagnosis, and the fungus commonly presents as a subacute meningitis with or without disseminated disease.

The most common presentation is a subacute meningitis or meningoencephalitis that is very different than bacterial meningitis. Subtle signs of decreased mental status, personality changes, and memory loss may be the only manifestations and are due to increased intracranial pressure, not invasion of the organism.

Detection of cryptococcal antigen in the CSF or serum is diagnostic and is seen in the vast majority of infected patients.

Treat cryptococcal meningitis in 3 stages:

- 1) Induction with amphotericin B + flucytosine $\times 2$ weeks
- 2) Consolidation with fluconazole 400 mg/day for ≥ 8 weeks
- 3) Maintenance with fluconazole 200 mg/day for ≥ 1 year

Repeat the LP and remove CSF on a daily basis as necessary to obtain normal CSF pressures. If this is not possible or effective, insert CSF shunts.

If the patient presents with a cryptococcal lung infection, you must still perform an LP to investigate for meningitis, even if the patient is asymptomatic.

There is no primary prophylaxis used for this infection. Give secondary prophylaxis as part of the maintenance stage of treatment.

Toxoplasma

T. gondii is the most common cause of focal lesions in the CNS in HIV-infected persons. Typical symptoms of toxoplasmosis are new-onset seizures, focal neurologic deficit, and/or altered consciousness. MRI (which is more sensitive) and CT show multiple ring-enhancing lesions. The main differential diagnoses are primary B-cell lymphoma and brain abscesses that produce focal lesions.

Diagnose toxoplasmosis using imaging that shows multiple bilateral ring-enhancing lesions (often with a predilection for the basal ganglia) in a patient with demonstrable IgG antibody to *T. gondii*. Confirmation is by demonstrating radiographic improvement with empiric treatment. A biopsy is not initially needed if imaging is typical and there is a response to therapy.

Treat toxoplasmosis with pyrimethamine and sulfadiazine. Also give folinic acid (a.k.a. leucovorin) to prevent megaloblastic anemia from the pyrimethamine. Use clindamycin in sulfa-allergic patients. Failure to respond warrants a brain biopsy.

Primary prophylaxis is indicated in patients with a CD4 count < 100 cells/ μL ($0.1 \times 10^9/\text{L}$) and a positive *T. gondii* IgG result. It is accomplished with the same regimen used for PJP prophylaxis (i.e., DS TMP/SMX 1 $\times$ /day or 3 $\times$ /week). Use dapsone in sulfa-allergic patients. In addition, as with primary prophylaxis against PJP, primary prophylaxis for *Toxoplasma* encephalitis can be stopped when the CD4 count is > 200 cells/ μL ($0.2 \times 10^9/\text{L}$) for 3 months.

John Cunningham (JC) Polyomavirus

JC polyomavirus (a.k.a. JC virus) is a commonly acquired asymptomatic infection. If the CD4 count drops to < 100 cells/ μ L (0.1×10^9 /L), JC virus can reactivate and cause a lytic infection in oligodendroglial cells that make myelin. This results in **progressive multifocal leukoencephalopathy (PML)**. PML, because it is multifocal, has varied and widespread presentations. Patients experience altered mental status, motor and sensory changes, and specifically decreased visual acuity.

The diagnosis is suggested by an MRI showing multifocal demyelinating lesions in the white matter and can be confirmed by CSF PCR testing for JC virus, which has a sensitivity of 70–90%.

No specific antiviral therapy is available; however, reconstitution of CD4 cells after ART can reverse some (but not all) symptoms.

Neurosyphilis

Syphilis, even if previously treated, can reactivate in patients with AIDS and cause neurosyphilis. Syphilis and neurosyphilis are treated the same, with or without HIV infection (refer to [Syphilis on page 4-16](#)).

Gastrointestinal (GI) Infections

Esophagitis

Candida albicans is the most common cause of infectious esophagitis in patients with HIV. Viral causes include CMV and HSV. Patients can be infected with more than one of these at the same time. Consider a coexistent viral infection if the symptoms do not improve after empirically treating the *Candida* infection. Because the response to therapy is usually dramatic, no prophylaxis for candidal esophagitis is recommended.

Diarrhea

Chronic diarrhea in patients with AIDS is commonly caused by protozoa: *Cryptosporidium*, microsporidia (includes *Enterocytozoon bienersi* and *Encephalitozoon intestinalis*), *Cyclospora cayentanensis*, and *Cystoisospora belli* (previously known as *Isospora belli*). All of these can also infect the gallbladder and cause acalculous cholecystitis. Bacterial pathogens (e.g., *Salmonella*, *Shigella*, *Campylobacter*) cause an acute diarrhea that may persist and become chronic.

CMV is the only common viral cause of diarrhea.

Stool or bowel biopsy specimens are diagnostic and require modified acid-fast staining to detect *Cryptosporidium*, *Cyclospora*, and *Cystoisospora*. Microsporidia are seen with a modified trichrome stain. PCR assays are now available to detect these organisms in stool.

CMV can be diagnosed by biopsy of the ulcers or erosions during endoscopy. (Remember, if the patient has CMV colitis, check for ocular involvement.)

Treat *Cyclospora* and *Cystoisospora* infections with TMP/SMX. *Cryptosporidium* has a variable response to nitazoxanide. Microsporidia respond to albendazole. Treat *Salmonella*, *Shigella*, and *Campylobacter* infections with ciprofloxacin. Treat CMV with ganciclovir or foscarnet.

Miscellaneous Infections

Hepatitis C Virus (HCV)

Test all HIV-infected patients for HCV. Treat hepatitis C with the current well-tolerated, short-term regimens. HIV is generally treated first. Hepatitis C treatment is covered in the [Gastroenterology](#) section.

AIDS-Defining Malignancies

Although there is evidence that there is a higher frequency of many malignancies in HIV-infected persons, 4 are considered AIDS defining. These are Kaposi sarcoma, cervical cancer, high-grade non-Hodgkin lymphoma, and primary B-cell lymphoma of the brain. These are discussed in the [Oncology](#) section.

FEVER OF UNKNOWN ORIGIN (FUO)

FUO was initially defined as documented fever on several occasions for ≥ 3 weeks with no etiology identified on routine evaluation after 1 week in the hospital. Over the last 50 years, the definition has changed, and a hospital stay is no longer necessary, nor is a several-week course of investigation. Causes vary geographically due to regional exposures, diagnostic tools, and health care availability. They also differ based on the host, especially in HIV-infected persons, and in the elderly. Overall, the most common identifiable causes of FUO are rheumatic diseases (e.g., rheumatoid arthritis, SLE), infections, and malignancies.

Routine evaluation must be unrevealing to diagnose FUO. This includes a history, physical, CBC with differential, comprehensive metabolic panel, blood culture, urinalysis, urine culture, and CXR.

Once FUO is established, further workup may include:

- ESR or CRP
- Serum protein electrophoresis (SPEP)
- RF
- LDH
- Creatine kinase (CK)
- Antinuclear antibody
- HIV
- TB screening
- Heterophile antibody test
- Echocardiogram
- CT scan of the abdomen
- CT scan of the chest
- Gallium or indium WBC scan

Unless a patient is clinically unstable, do not use empiric therapy in cases of FUO; patients are usually stable. Treatment is directed toward the underlying etiology once discovered. The diagnostic evaluation in up to 25% of patients with FUO fails to identify a cause; however, these patients have a good prognosis. If the initial workup is negative and the fever persists, repeat the same workup in several months.

FEBRILE NEUTROPENIA

PREVIEW | REVIEW

- What is the definition of febrile neutropenia?
- What are the empiric treatment options for the febrile neutropenic? When is vancomycin included?
- In the empiric treatment of febrile neutropenia, when would you choose voriconazole over an echinocandin?

EPIDEMIOLOGY AND RISK FACTORS

Neutropenia occurs in the setting of leukemia, bone marrow transplantation, chemotherapy, exposure to drugs or toxins, and bone marrow metastasis. If infection ensues, it is usually caused by colonizing flora that enter the bloodstream across disrupted gut mucosa, via an IV catheter, or through the oropharynx into the lungs and/or sinuses.

Neutropenic sepsis can be caused by both gram-negative and gram-positive bacteria. Of the gram-positives, the most common are *Staphylococcus aureus*, *Staphylococcus epidermidis*, and streptococcal species. Less common are *Corynebacterium* species, *Cutibacterium acnes* (previously known as *Propionibacterium acnes*), *Bacillus* species, and *Leuconostoc* species. These less-common gram-positives are important to remember because they may not be effectively treated with vancomycin. Common gram-negative organisms include *Pseudomonas* species and Enterobacteriaceae, including *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species. Anaerobic bacteria are not commonly seen in neutropenic sepsis.

Fungi, such as *Candida* and *Aspergillus* species, are important pathogens in patients with prolonged neutropenia. Infections with *Fusarium* species and agents of mucormycosis can also occur.

The risk for infection in the patient with neutropenia is directly proportional to the degree and duration of neutropenia.

For an additional discussion of febrile neutropenia, see the [Oncology](#) section.

PRESENTATION

It is important to recognize febrile neutropenia and begin emergent evaluation and empiric antibiotics. The definition of febrile neutropenia is a temperature of $> 101.0^{\circ}\text{F}$ (38.3°C) $\times$ 1 occurrence or 100.4°F (38.0°C) for 1 hour and severe neutropenia, defined as an absolute neutrophil count (ANC) $< 500/\mu\text{L}$ ($0.5 \times 10^9/\text{L}$) or expected to be $< 500/\mu\text{L}$ ($0.5 \times 10^9/\text{L}$) in the next 48 hours.

The decrease in neutrophils creates a blunted inflammatory response, so clinical signs and symptoms that localize the source of infection may be absent. Any localizing symptoms (e.g., sore throat, cough, dysuria, perirectal pain), however, are helpful in determining the source. For the physical examination, concentrate on the upper airway mucosa (looking for mucositis), teeth and periodontal tissues, eyes, and rectum. Any rash or skin ulceration/swelling is potentially significant. Portals that allow infections to enter include catheters and implants.

DIAGNOSIS

Send blood cultures immediately and obtain a CXR. Perform a urine culture if there are UTI symptoms or a bladder catheter is in place. Obtain a sputum culture if there are pulmonary signs or symptoms or if the CXR shows infiltrates. If the CXR is normal in a patient with pulmonary symptoms, obtain a CT scan of the chest. If diarrhea is present, send a stool sample for *Clostridioides difficile* toxin gene PCR testing.

Reserve LP for patients with altered mental status without an identifiable cause or other signs of meningitis. Remember that these patients are usually thrombocytopenic. There should be a low threshold for bronchoscopy for pathology, Gram stains, and bacterial/viral/fungal cultures in patients with undiagnosed pulmonary infiltrates. Open lung biopsy may be needed. Perform skin biopsies for pathology and bacterial and fungal smears and cultures when lesions are present.

TREATMENT

Empiric Treatment

According to the 2011 Infectious Diseases Society of America (IDSA) guidelines, when a neutropenic patient presents with fever, the initial treatment is directed against gram-negative aerobic bacilli, including *Pseudomonas*. The 2018 IDSA clinical practice guideline update adds that oral empiric treatment can be used in patients at low risk of complications, and the regimen of choice is a combination of amoxicillin/clavulanic acid and ciprofloxacin.

Treat patients with fever and neutropenia with one of the following:

- 1) Piperacillin/tazobactam
- 2) A carbapenem (imipenem or meropenem)
- 3) Cefepime

Do **not** include vancomycin as part of the initial regimen **unless** any of the following are present:

- Hypotension or other evidence of severe sepsis
- A positive blood culture for gram-positive bacteria (before the organism or susceptibility is determined)
- Pneumonia documented radiographically
- Persistent fever while on empiric antibiotics
- Obvious skin infection or erythema at the site of an indwelling catheter
- A history of MRSA infection or known colonization
- Severe mucositis

If vancomycin is started, discontinue it after 2 days if there is no evidence of a gram-positive infection.

Persistent Febrile Neutropenia

If the fever and neutropenia persist after 4–7 days on empiric antibiotics (including vancomycin), begin adding empiric antifungal therapy with:

- an echinocandin (caspofungin is the only one approved by the FDA for this indication, but other echinocandins are equally effective) **or**
- voriconazole.

Use voriconazole instead of an echinocandin if there are pulmonary infiltrates, because voriconazole more predictably covers *Aspergillus* infection.

Prophylaxis

Prophylactic antibiotics are given to those at high risk of infection, particularly those with an expected neutropenia duration > 7 days and an ANC $\leq 100/\mu\text{L}$ ($0.1 \times 10^9/\text{L}$) during this time period.

Septic Shock

The management of septic shock is covered in the [Pulmonary Medicine](#) section. The infectious disease workup and treatment are the same for each specific entity that can cause sepsis (e.g., bacteremia, UTI, pneumonia, cholangitis). Sepsis intensifies the urgency of the workup and critical care management.

NOSOCOMIAL INFECTIONS

PREVIEW | REVIEW

- Differentiate the 2 types of nosocomial pneumonias.
- Which organisms usually cause a central line-associated bloodstream infection?

OVERVIEW

Important nosocomial infections include pneumonia (e.g., hospital-acquired, ventilator-associated) and central line-associated bloodstream infections (CLABSIs). UTIs and *Clostridioides difficile* infections were discussed under [Urinary Tract Infections \(UTIs\)](#) on page 4-1 and [Diarrhea due to *Clostridioides difficile*](#) on page 4-12. Standard precautions begin with hand hygiene but may also include gowns, gloves, and respiratory protective equipment.

PNEUMONIA

Hospital-acquired pneumonia is defined as pneumonia occurring > 48 hours after hospital admission (and that was not incubating at the time of admission). **Ventilator-associated pneumonia** is defined as pneumonia occurring > 48–72 hours after intubation. **Health care-associated pneumonia** is no longer recognized as an entity.

These pneumonias are almost always **bacterial** and have the highest mortality rate of all the nosocomial infections. They are most commonly due to gram-negative organisms. The next most common organism is *Staphylococcus aureus*.

The diagnosis is based on a combination of findings, including a new infiltrate on chest imaging, fever, increased and purulent sputum, leukocytosis or leukopenia, and increased oxygenation requirements. Obtain sputum and blood cultures; however, note that the former can be nonspecific, especially if prior antibiotics were administered.

For empiric therapy, include a drug that is active against MRSA (e.g., vancomycin) and a broad-spectrum gram-negative antibiotic (e.g., piperacillin/tazobactam, cefepime, a carbapenem). Adjust the antibiotics if an organism cultured from the sputum or blood is resistant to the empiric therapy.

CENTRAL LINE-ASSOCIATED BLOODSTREAM INFECTIONS (CLABSIs)

Central line infections are usually due to *Staphylococcus epidermidis* and *Staphylococcus aureus*, but almost any organism can cause infection, including GNBs, *Candida* species, and *Corynebacterium jeikeium*. An IV-catheter-related infection presents as sepsis without symptoms localizing to the line or as a localized infection of the subcutaneous tunnel and/or of the exit site with purulence and erythema at the site. Septic thrombophlebitis of the catheterized vein and/or right-sided endocarditis can also occur and result in septic pulmonary emboli.

When a CLABSI is suspected, obtain 2 blood cultures from 2 sites, with at least one of these sites being peripheral. Remove the infected line when possible, and culture the catheter tip. The diagnosis of a CLABSI is confirmed if both the catheter tip **and** the blood cultures grow the same organism.

If the catheter is retained (and you are therefore unable to culture the tip), the hub can be cultured, and this culture can be compared with the peripheral blood culture(s). A CLABSI is then diagnosed if the hub and peripheral blood cultures show the same organism **and** if quantitative cultures of the hub:

- are ≥ 3 -fold that of the blood cultures or
- turn positive ≥ 2 hours prior to the blood cultures.

If the hub culture is positive but the blood cultures are sterile, this is consistent with catheter colonization only. If the hub culture is negative but the blood cultures are positive, the bacteremia may be unrelated to the line.

In addition to antibiotics, a key decision in treating CLABSIs is whether or not to remove the line. Remove the catheter if a CLABSI occurs with any of the following conditions:

- Severe sepsis
- Hemodynamic instability
- Metastatic infection (e.g., meningitis, osteomyelitis, endocarditis)
- Suppurative thrombophlebitis
- Blood cultures remaining positive > 72 hours after appropriate antibiotic therapy

In addition, remove lines for infections with *S. aureus*, *Pseudomonas aeruginosa*, fungi, or mycobacteria. In the case of enterococci, GNBs, or coagulase-negative staphylococci, remove short-term catheters; salvage of long-term catheters can be attempted.

Empiric antibiotic treatment is with vancomycin alone, with the following 2 exceptions:

- 1) Give gram-negative coverage (that includes *P. aeruginosa*) if there is neutropenia or severe sepsis, the patient is known to be colonized with a resistant GNB, or the patient has a femoral line, which predisposes that patient to a fecal flora infection.
- 2) Give antifungal therapy with an echinocandin if the patient has previously been on broad-spectrum antibacterials, has more than one site colonized with *Candida* species, has a hematologic malignancy, is on total parenteral nutrition, or has a femoral line.

Treat infections for 14 days after line removal. In cases of *S. aureus* infections of long-term catheters, give antibiotics for 4–6 weeks.

INFECTION CONTROL AND ISOLATION

Health care workers are a risk for acquisition of pathogens from patients and the environment. This topic deals with a review of the types of precautions.

Needlesticks and HIV were discussed under [Human Immunodeficiency Virus \(HIV\) and Acquired Immunodeficiency Syndrome \(AIDS\) on page 4-29](#).

For other needlesticks, obtain hepatitis B and C and HIV serologies from the index patient. The health care worker should have been vaccinated against hepatitis B; if not, administer vaccination. If the index case is positive, give hepatitis B immunoglobulin as well. Obtain the same serologies from the health care worker, and follow up with laboratory studies based on the serologic test results from the index patient and health care worker. There is no prophylaxis for hepatitis C.

Standard precautions: All health care workers must wash their hands with soap and water or gel before **and** after entering a patient's room. Use soap and water for *Clostridioides difficile*, norovirus, and rotavirus.

In addition to the standard precautions, take the following precautions depending on the scenario:

- **Contact precautions** (gloves and gown): *C. difficile*, scabies, norovirus, MRSA colonization
- **Droplet precautions** (mask): influenza, *Neisseria meningitidis*, pertussis, coronavirus
- **Airborne precautions** (private room, negative pressure, and N95-type mask): TB, varicella, measles
- **Contact and droplet precautions:** parainfluenza
- **Contact and airborne precautions:** disseminated zoster

Isolation for *C. difficile* was discussed under [Diarrhea due to *Clostridioides difficile* on page 4-12](#). In general, isolate patients with multiple antibiotic-resistant bacteria as appropriate for the site of infection (e.g., contact isolation, droplet isolation).

ORGANISM-BASED REVIEW

BACTERIA

PREVIEW | REVIEW

- What is the clinical presentation of toxic shock syndrome?
- Which antibiotics are recommended to treat skin and soft tissue staphylococcal infections?
- How do blood culture results differ between staphylococcal and streptococcal toxic shock?
- When should you use 2 antibiotics to treat enterococcal infections? Which drugs would you choose?
- Which patient populations are at risk for *Listeria*, and how do you treat *Listeria*?
- If a pathology report describes beaded, branching, mildly acid-fast, filamentous organisms, which organism is likely?
- When should you suspect *Pseudomonas* as a cause of infection?
- Which form of plague is transmitted person to person?
- Which associated symptoms are often observed with *Legionella* pneumonia?
- Which geographic locations have the most cases of tularemia?
- What are the manifestations of bartonellosis?
- Name the clinical signs and symptoms of Rocky Mountain spotted fever. Which drugs are used for treatment?
- What is Q fever? How is it treated?
- How does *Mycobacterium marinum* infection present?
- Which associated symptoms are often seen in respiratory infections due to *Chlamydia pneumoniae*?

GRAM-POSITIVE BACTERIA

Staphylococci

Staphylococcus aureus, which on Gram stain shows cocci in grapelike clusters, colonizes the anterior nares of ~ 20% of humans, and coagulase-negative staphylococci are ubiquitous on human skin. *S. aureus* is the most common cause of soft tissue infections and causes purulent infections that manifest as folliculitis, furuncles (boils) and carbuncles (Figure 4-9), and impetigo. Patients often inaccurately report a spider bite when in fact they have a staphylococcal abscess. Treatment is based on the clinical presentation (see [Common Skin and Soft Tissue Infections](#) on page 4-6).

S. aureus is also an important cause of bacteremia, especially among those exposed to needles, such as IV drug abusers, insulin-using diabetics, hospitalized patients, and hemodialysis patients. *S. aureus* is never considered a skin contaminant when it is seen in blood cultures. In addition, it is a leading cause of central line-associated bloodstream infection (CLABSI). Infection with *S. aureus* can also result in toxic shock syndrome and staphylococcal scalded skin syndrome (Figure 4-10). The latter

Figure 4-9: Carbuncle on buttock

Figure 4-10: Staphylococcal scalded skin syndrome

does not occur in adults unless they have chronic kidney disease because the toxin is otherwise easily excreted through the kidneys. Remember that with influenza, there can be a bacterial superinfection with *S. aureus*.

S. aureus also commonly causes osteomyelitis. The ABCs of diabetic foot ulcer infections is a way to remember their management: antibiotics, bone imaging (e.g., MRI, nuclear scan), cultures (blood, wound), Doppler scan of leg arteries, erythrocyte sedimentation rate/C-reactive protein, and foot doctor/podiatry.

Pathogenicity of *S. aureus* results from a variety of toxins. Only rare isolates are susceptible to PCN, and ~ 50% of isolates are methicillin-resistant *S. aureus* (MRSA) regardless of whether they are acquired from the community or in a health care setting. Methicillin resistance connotes resistance to all other β -lactam antibiotics, with the exception of ceftaroline.

Toxic Shock Syndrome (TSS)

An important complication of *S. aureus* infection is TSS. Staphylococcal TSS presents with red skin (sunburn-like rash), hypotension, and fever along with ≥ 3 signs of organ system involvement: GI (e.g., vomiting, diarrhea), muscle (myalgia or elevated creatine kinase), acute kidney injury, liver (transaminase or bilirubin elevation), thrombocytopenia, or altered consciousness. Hypocalcemia can also occur. Bacteremia is uncommon. A strawberry tongue may be seen on exam, which can also be seen in scarlet fever and Kawasaki disease. The classic association is with retained tampon use during menses; however, currently the majority of cases are not related to menstruation. Tampon use is still a risk factor, albeit a small one, as there is a decrease in cases associated with tampon use. The

majority of cases are caused by colonization of other foreign bodies (e.g., nasal packing) or *S. aureus* infection (e.g., cellulitis, pneumonia). Treatment is with fluids and pressors, source control, and antistaphylococcal antibiotics with consideration of clindamycin to inhibit toxin production.

Streptococcal TSS is the other classic form of TSS. See [Streptococcus pyogenes \(Group A\)](#) for more on that topic.

Treatment

Bacteremia and other serious *S. aureus* infections are initially treated with vancomycin until sensitivity results are available. If isolates are methicillin susceptible, then change therapy to an antistaphylococcal PCN (e.g., nafcillin) or a 1st generation cephalosporin. Otherwise, continue vancomycin. Very few cases of vancomycin-resistant *S. aureus* are reported worldwide. Additional drugs with predictable activity against MRSA include linezolid, tedizolid, tigecycline, ceftaroline, daptomycin, telavancin, dalbavancin, and oritavancin. Be aware that most of the additional drugs have no approved indication for bacteremia or serious disease.

Treat milder infections, including skin and soft tissue infections, with TMP/SMX or doxycycline, to which ~ 90% of strains remain susceptible, especially if known to be MRSA. Clindamycin has higher resistance rates so is a limited option for empiric treatment, but if susceptibilities are known, then it would be an option. Additionally, there can be inducible resistance with clindamycin. The erythromycin-clindamycin D-zone test evaluates for the capacity for the isolate to express inducible resistance genes in the presence of clindamycin; therefore, clindamycin would not be an option if there is a positive D-zone test. If MSSA, can use PCN or cephalosporin.

Avoid quinolones due to increasing resistance and the ability of the organism to acquire resistance while the patient is on therapy plus additional recognized toxicities. Delafloxacin was approved in 2017 with an indication for treating MRSA skin infections and is the only quinolone with reliable MRSA activity.

Staphylococcus epidermidis and *S. saprophyticus*

S. epidermidis and *S. saprophyticus* are 2 species of coagulase-negative staphylococci that on Gram stain are seen in irregular clusters. *S. epidermidis* is usually methicillin resistant. It is the most common cause of both catheter-related bacteremia and bacteremia occurring post-op when a foreign body (e.g., prosthetics [including heart valves and joints], pacemakers, shunts) is placed. Treat with vancomycin. Add rifampin and gentamicin for prosthetic valve endocarditis.

S. saprophyticus causes cystitis in young women and, unlike other coagulase-negative staphylococci, is usually susceptible to antistaphylococcal PCNs and ampicillin.

Streptococcus pneumoniae

S. pneumoniae (pneumococcus) is the most common cause of bacterial meningitis and community-acquired bacterial pneumonia in adults. The former is discussed under [Bacterial Meningitis on page 4-21](#), and the latter is discussed in the [Pulmonary Medicine](#) section. On Gram stain, *S. pneumoniae* appears as lancet-shaped diplococci. A history of splenectomy is a risk factor for infections due to encapsulated bacteria (e.g., *S. pneumoniae*). Remember that with influenza, there can be bacterial superinfection with *S. pneumoniae*.

Resistance to PCN occurs in ~ 5% of *S. pneumoniae* isolates, but all isolates are susceptible to vancomycin. Ceftriaxone sensitivity is > 95%. Do not use vancomycin for bacteremia unless resistance to other agents is present. Pneumonia is commonly treated with ceftriaxone or levofloxacin.

Streptococcus pyogenes (Group A)

S. pyogenes is the **only** group A β -hemolytic *Streptococcus* species. On Gram stain, it appears in chains. It causes:

- **Pharyngitis** ([Figure 4-11](#); Centor criteria: fever, sore throat, exudative pharyngitis, anterior cervical lymphadenopathy, absence of cough; see [Pharyngitis on page 4-5](#).)
- **Scarlet fever** (may have strawberry tongue as seen with TSS and may see circumoral pallor, Pastia lines, and desquamation)
- **Toxic shock syndrome (TSS)**
 - This rapidly invasive infection can occur following minor trauma, recent surgery, or pharyngitis. Fever and pain can occur at the inoculation site, followed by hypotension.

Figure 4-11: Streptococcal pharyngitis
Source: James Heilman, MD

- In contrast to TSS related to *S. aureus*, **bacteremia** occurs in ~ 60% of cases of streptococcal TSS.
- The most common entry sites are mucous membranes and skin. Chickenpox lesions can become superinfected with group A strep with bacteremia and, less commonly, toxemia. Since use of the vaccine (released in 1995), the incidence has dropped significantly.
- Streptococcal TSS is rapidly progressive with shock and multiorgan failure. The mortality rate is 30–60%. Empiric therapy is clindamycin plus either a carbapenem or a PCN plus β -lactamase inhibitor until the etiology is confirmed.
- Rapidly progressive cellulitis that spreads through superficial cutaneous lymphatics (i.e., **erysipelas**; [Figure 4-12](#)) or along fascial planes (i.e., **necrotizing fasciitis**; discussed under [Rapidly Progressive Cellulitis on page 4-7](#)). *S. pyogenes* necrotizing fasciitis may develop after trauma and present with pain out of proportion to exam and may have crepitus or bullous lesions.

Figure 4-12: Erysipelas
Source: CDC

Immune reaction to a cell surface protein called the **M protein** can lead to rheumatic fever or poststreptococcal glomerulonephritis. This organism has yet to acquire PCN resistance.

Streptococcus agalactiae (Group B)

S. agalactiae (group B) is more common in the elderly, **especially** if they are alcoholic or diabetic. It appears on Gram stain in long chains. In pregnant women, *S. agalactiae* causes UTIs and is a cause of postpartum endometritis and bacteremia. It originates from a GU reservoir, although many cases of bacteremia have an unclear source. Treat with PCN or ampicillin; in PCN-allergic patients, treat with clindamycin or vancomycin.

Streptococcus dysgalactiae Subspecies *equisimilis* (Groups C and G)

Streptococci that react to groups C and G Lancefield typing sera are considered to be a single species and subspecies: *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE). This is part of the normal flora of the upper airway, skin, GI tract, and female GU tract. It can cause pharyngitis, soft tissue infection, septic arthritis, and endocarditis. It is universally susceptible to PCNs and cephalosporins. Diabetes and malignancy are risk factors.

Group D Streptococci

Group D streptococci includes 4 species previously grouped as *S. bovis* (*S. gallolyticus*, *S. lutetiensis*, *S. infantarius*, and *S. pasteurianus*) that are inhabitants of the GI tract and cause bacteremia and endocarditis. Group D *Streptococcus* bacteremia is seen in conjunction with colon cancer in 20–30% of cases; therefore, positive blood cultures from this organism warrant a colonoscopy.

Enterococci

Enterococci are gram-positive cocci that are difficult to distinguish from streptococci under the microscope. Like streptococci, they occur in pairs and short chains. Two species normally inhabit the intestines, with a higher amount of *Enterococcus faecalis* (95%) than *Enterococcus faecium* (5%). Thus, *E. faecalis* causes the vast majority of enterococcal infections (which include UTIs, bacteremia from lines, endocarditis, and intraabdominal polymicrobial infections). Asymptomatic enterococcal bacteriuria is managed similar to other cases of asymptomatic bacteriuria, which is generally treated only in the setting of pregnancy, those about to undergo urological procedures, and in the first 3 months after a kidney transplant.

All enterococci are resistant to cephalosporins and penicillinase-resistant PCNs. They are moderately resistant to the aminoglycosides, such as gentamicin, but these drugs are often used for synergy in the treatment of endocarditis.

E. faecium is resistant to imipenem and commonly exhibits high-level resistance to vancomycin (vancomycin-resistant *Enterococcus* [VRE]).

Single antibiotics are used to treat mild to moderate infections (UTIs and uncomplicated bacteremia) and include PCN G, ampicillin, or vancomycin, depending on sensitivities. If VRE, then additional antibiotic options include linezolid, daptomycin, and tigecycline depending on location of the infection.

Combination treatment must be used for complicated bacteremia and endocarditis because single drugs are not bactericidal. In these cases, check the isolate for gentamicin susceptibility and, if susceptible, add low-dose gentamicin. According to 2015 Infectious Diseases Society of America endocarditis guidelines, use ampicillin combined with ceftriaxone as a treatment that is less nephrotoxic than using ampicillin combined with gentamicin.

Listeria monocytogenes

Listeria monocytogenes, an aerobic gram-positive rod, causes infection in patients with decreased **cellular** immunity, such as from AIDS, lymphoma, or leukemia, and in the elderly, alcoholics, and pregnant women.

Drugs that depress cellular immunity (e.g., glucocorticoids, transplant drugs) increase the risk for infection.

Listeria is one of the most virulent foodborne pathogens, with a mortality rate of ~ 15%. It can be found in deli meats, hot dogs, milk, soft cheeses, poultry, and even fruit.

Listeria can cause neonatal meningitis via transvaginal inoculation and can affect the fetus. For this reason, pregnant women are cautioned against eating soft cheeses, unpasteurized milk, and other high-risk foods.

Like enterococci, *Listeria* is resistant to all cephalosporins, so you must include ampicillin in the empiric treatment of meningitis in the elderly, the immunosuppressed, or neonates. Treat mild to moderate cases of listeriosis with PCN or ampicillin. Give PCN-allergic patients TMP/SMX. Vancomycin and chloramphenicol are 3rd line drugs. Although no randomized trials have been conducted, an aminoglycoside is often added to treat meningitis.

Corynebacterium diphtheriae* and *C. jeikeium

Corynebacterium diphtheriae (Figure 4-13) cause diphtheria. They are pleomorphic gram-positive rods that, on microscopy, may group together in patterns that somewhat resemble Chinese characters. Diphtheria is an upper respiratory infection with a gray-white **pharyngeal pseudomembrane** (Figure 4-14) that occurs along with hoarseness, sore throat, and a **low-grade fever** (< 101.0°F [38.3°C]). Toxin production causes myocarditis with heart failure and polyneuritis. Treat with erythromycin; 2nd choice is PCN. Diphtheria equine antitoxin is **always** given with the antibiotic.

Corynebacterium jeikeium (JK) is a multidrug-resistant strain that colonizes and infects neutropenic patients and/or bone marrow transplant patients, where it causes IV catheter-related infections. Vancomycin is the only reliably effective antibiotic.

Figure 4-13: *Corynebacterium diphtheriae*
Source: CDC

Figure 4-14: Pharyngeal pseudomembrane

Arcanobacterium haemolyticum

Arcanobacterium haemolyticum causes pharyngitis in adolescents with a desquamative scarlatiniform rash and lymphadenitis. Treat with PCN, erythromycin, or tetracycline.

Bacillus anthracis* and *B. cereus

Bacillus anthracis is a large, gram-positive rod that causes anthrax, a potential agent of bioterrorism.

There are 3 main clinical manifestations:

- 1) Cutaneous (95%)
- 2) Inhalation (e.g., wool hides, terrorism)
- 3) GI

Inoculation occurs from handling naturally contaminated hides/wool, ingestion, or maliciously contaminated sources (e.g., mail, aerosol). Unlike plague (discussed under *Yersinia* on page 4-12), anthrax is **not** transmitted from person to person. All forms can lead to a hemorrhagic meningitis, but this is more common with inhalation type.

Cutaneous anthrax starts as a painless papule that vesiculates and forms an ulcer (Figure 4-15), then becomes a painless black eschar, often with nonpitting, painless induration (Figure 4-16). Treat with an oral fluoroquinolone for 60 days.

Figure 4-15: Anthrax ulcer (painless)

Figure 4-16: Anthrax later-stage eschar

Inhalation anthrax presents similarly to influenza with malaise, fever, cough, and myalgias. After 2–3 days, there is a dramatic worsening of symptoms with hypoxia, hypotension, and death. Rather than causing a pneumonia, it causes a necrotizing mediastinitis that appears as mediastinal widening on imaging.

GI anthrax is acquired by eating undercooked, contaminated meat. Patients get pharyngeal eschars and/or GI ulcerations.

Until susceptibilities are known, treat systemic disease with 3 drugs: ciprofloxacin, meropenem, and linezolid. There are 2 FDA-approved monoclonal antibodies (oblitoximab and bezlotoxumab). One of these should be given for inhalation or disseminated disease.

Bacillus cereus is a close relative of *B. anthracis*. Found in the normal flora of the skin, *B. cereus* causes a benign food poisoning if its toxins are ingested. This is further discussed under [Food Poisoning on page 4-10](#). The majority of the time when it is found in a blood culture, it is a contaminant, but on rare occasions, it is the culprit in line sepsis. It can also cause endophthalmitis if inoculated into the eye by trauma, especially in contact lens wearers. It is universally susceptible to vancomycin.

Clostridioides difficile

Clostridioides difficile (*C. difficile*; formerly known as *Clostridium difficile*) is a cause of toxin-producing diarrheal illness usually precipitated by antibiotic exposure and/or health care exposures. Any antibiotic can precipitate *C. difficile* colitis, but fluoroquinolones, clindamycin, and β -lactams have a higher propensity than others. Diagnosis is made with stool polymerase chain reaction (PCR)/toxin (see [Diarrhea due to *Clostridioides difficile* on page 4-12](#)).

Clostridium

Clostridium species (there are > 100) are anaerobic, gram-positive rods that cause a wide variety of human illnesses:

- *C. difficile*, now classified as *Clostridioides difficile*, is discussed under [Clostridioides difficile](#).
- *C. botulinum* produces the most potent human toxin known. It works by blocking presynaptic acetylcholine release, causing a descending motor paralysis and parasympathetic cranial nerve dysfunction that results in dilated pupils, dry tongue, and dysphagia with death from respiratory arrest if untreated. It does not enter the CNS, and thus there is no alteration of consciousness. The toxin is usually acquired via the ingestion of contaminated food (typically from people who do their own canning) but can be from a wound source. It is the only disease other than diphtheria for which we still use an equine antitoxin. PCN is given to eradicate a wound source. Honey is a source of infant botulism.
- *C. perfringens* is one of the most common causes of food poisoning in the U.S. and presents as a diarrheal illness similar to the enteric form of *B. cereus*. It manifests as watery diarrhea and crampy abdominal pain. It also causes a rapidly progressive cellulitis. See [Necrotizing Fasciitis on page 4-7](#).
- *C. septicum* is a gut organism, and the majority of persons with infection from this organism have an associated GI malignancy. Thus, persons with bacteremia should undergo upper and lower GI endoscopy.
- *C. tetani* causes tetanus. There are < 50 cases/year in the U.S. See [Approach to Tetanus Prevention on page 4-88](#).

Clostridium species are susceptible to PCNs, cephalosporins, and clindamycin. The latter is useful when treating *C. perfringens* cellulitis to inhibit the organism's ability to produce its numerous toxins. Again, remember the antitoxin properties of clindamycin.

Nocardia

Nocardia species: *Nocardia asteroides* and *Nocardia brasiliensis* are 2 examples of pathogenic species. These are aerobic, weakly acid-fast, beaded, branching, filamentous, gram-positive rods.

N. asteroides usually starts as a lung infection, commonly causing a thin-walled cavitory lesion. It can cause focal brain abscesses and chronic **neutrophilic** meningitis—most chronic meningitides are lymphocytic. Nodular skin lesions are common. *Nocardia* are slow growers on culture medium. The usual setting is in patients with impaired cell-mediated immunity.

Usual treatment is high-dose sulfonamides or TMP/SMX. In severely ill patients, imipenem or amikacin is added. Minocycline can be used for sulfa-allergic patients. Treat for at least 3 months; 6–12 months may be required. Resistance testing is important for *Nocardia* species.

N. brasiliensis is in the soil. Like *M. marinum* and *Sporothrix schenckii*, if inoculated into the skin, it causes nodular lesions that spread along lymphatic channels. Treat with sulfonamides or TMP/SMX.

Actinomyces israelii

Actinomyces israelii is an anaerobic, gram-positive, beaded rod that causes an infection in which yellow sulfur-like granules can be visualized, which are actually clusters of organisms. The usual presentation of actinomycosis is cervicofacial involvement (“lumpy jaw”; Figure 4-17). *A. israelii* is part of the normal bowel flora and thus can be a participating organism in intraabdominal abscesses and pelvic inflammatory disease. Treatment is PCN or ampicillin; 2nd choice is tetracycline.

Figure 4-17: Cervicofacial involvement in actinomycosis
Source: CDC

GRAM-NEGATIVE BACTERIA

Neisseria

Neisseria meningitidis (meningococcus) is a gram-negative diplococcus that is carried in the human nasopharynx in 5–10% of healthy persons. It typically does not cause disease because specific antibodies and complement lyse the organisms as they enter the bloodstream.

Thus, patients with complement deficiency or asplenia are especially prone to meningococcal sepsis (a.k.a. meningococcemia), which presents with fever, hypotension, and skin signs that vary from petechiae (early disease) to diffuse purpuric lesions and DIC (later disease). Bloodstream infection can occur with meningococcal meningitis.

The diagnosis and treatment of bacterial meningitis are discussed under [Bacterial Meningitis on page 4-21](#).

Prophylaxis to prevent meningococcal disease is discussed under [Prevention of Meningococcal Meningitis on page 4-23](#).

Neisseria gonorrhoeae is a gram-negative diplococcus that causes gonorrhea, which is discussed under [Sexually Transmitted Infections \(STIs\) on page 4-15](#).

Moraxella catarrhalis

Moraxella catarrhalis is a gram-negative coccobacillus that causes otitis, sinusitis, and respiratory illness including exacerbations of COPD and pneumonia. All strains produce penicillinases but are usually susceptible to amoxicillin/clavulanate, a 2nd or 3rd generation cephalosporin, TMP/SMX, macrolides, and quinolones.

Pseudomonas aeruginosa

Pseudomonas aeruginosa is a gram-negative rod (GNR) that is a ubiquitous water organism and a common cause of hospital-acquired infections. There are several clinical presentations suggestive of infection with this organism:

- **Tennis shoe cellulitis and/or osteomyelitis**—*P. aeruginosa* survives in the moisture-absorbing middle layer of tennis shoes and can be inoculated into soft tissue or bone after the wearer steps on a nail.
- **Otitis externa**—both benign and malignant; discussed under [Otitis Externa \(Swimmer's Ear\) on page 4-4](#)
- **Ecthyma gangrenosum**—a round, indurated, necrotic lesion with central ulceration (Figure 4-18) seen in neutropenic patients with *Pseudomonas*
- **Hot tub folliculitis** (hot tub rash)—from improperly chlorinated hot tubs. This is a self-limited inflammation from *P. aeruginosa* entering the base of hair follicles in the submerged areas.

Figure 4-18: Ecthyma gangrenosum
Source: Kimberly Salkey, MD

There is no single antibiotic to which all *P. aeruginosa* are universally susceptible. Therefore, it is reasonable to treat invasive infections with 2 antipseudomonal antibiotics from different classes (i.e., piperacillin/tazobactam plus a fluoroquinolone or an aminoglycoside) until you know the susceptibility pattern.

The most active drugs include:

- Carbapenems (except ertapenem)
- Aztreonam
- Fluoroquinolones
- Aminoglycosides
- Ceftazidime
- Cefepime
- Ceftolozane/tazobactam
- Ceftazidime/avibactam
- Piperacillin/tazobactam
- Colistin

Enterobacteriaceae

Enterobacteriaceae is a family of aerobic GNRs that includes *Escherichia coli*, *Klebsiella*, *Proteus*, *Salmonella*, *Shigella*, *Yersinia*, *Citrobacter*, *Serratia*, and *Enterobacter*. *Salmonella* and *Shigella* are discussed under [Bacterial Diarrhea on page 4-10](#).

Yersinia

Yersinia pestis is a gram-negative, rod-shaped coccobacillus that causes plague. Wild rodents are the reservoir. *Y. pestis* is transmitted by fleas or direct contact with an infected animal, and mortality is high if not properly treated.

The **bubonic** type causes large, localized lymphadenopathy (buboes) that suppurates at the site of the inoculation. If not treated, it can lead to sepsis and death. The **pneumonic** form occurs after inhalation of the organism via aerosols from infected animals or from other humans with pneumonic plague. Only a small inoculum is required, which can lead to epidemics and makes it a potential agent of bioterrorism.

Plague and tularemia present similarly (adenopathy after hunting), except that the geographic locations are different—Desert Southwest for plague vs. Arkansas, Missouri, and Oklahoma for tularemia. There is more on tularemia under [Francisella tularensis on page 4-48](#).

Diagnose plague by aspirating lymph nodes or obtaining sputum specimens that reveal bipolar-staining GNRs (safety pin shape) and growth of *Y. pestis*.

Plague is 1 of 2 infectious diseases for which an aminoglycoside is the drug of choice; the other is tularemia. Streptomycin is the aminoglycoside of choice, but if it is not available, gentamicin is an acceptable alternative. 2nd line choices are tetracycline, doxycycline, or quinolones.

Citrobacter

Citrobacter species (especially *C. freundii*, *C. koseri*, and *C. amalonaticus*) are GNRs that colonize the human gut and cause UTIs as their most common disease manifestation. They can be part of a polymicrobial intraabdominal abscess after bowel perforation or bowel necrosis but rarely cause other illnesses. They

are universally resistant to ampicillin and 1st generation cephalosporins but are usually killed by other generations of cephalosporins, carbapenems, fluoroquinolones, and TMP/SMX.

Escherichia

E. coli is the most common GNR aerobe in the bowel. It is the most common cause of community- and health care-associated UTIs. It causes diarrheal disease via several mechanisms (see [Bacterial Diarrhea on page 4-10](#)): intraabdominal infection, primary peritonitis, a minority of bacterial pneumonias (typically nosocomial or aspiration), a minority of endocarditis (usually on a prosthetic valve), and, rarely, osteomyelitis. Resistance to ampicillin, TMP/SMX, and quinolone is commonly > 25%, and extended-spectrum β -lactamase (ESBL)-containing organisms are becoming prevalent. These are sensitive to carbapenems.

Klebsiella

Klebsiella pneumoniae and *K. oxytoca* are GNRs and normal flora of the bowel that can cause UTI, intraabdominal infection, primary peritonitis, and nosocomial pneumonia. All strains are resistant to ampicillin, but almost all strains are killed by carbapenems. Susceptibility to cephalosporins and quinolones is variable.

Some strains of *Klebsiella*, known as *Klebsiella pneumoniae* carbapenemases (KPCs), are carbapenemase-producing strains. These are frequently encountered in residents of nursing homes or long-term care facilities. KPCs are resistant to carbapenems and all other β -lactams. They are frequently resistant to other antibiotic classes as well. Options for therapy can include colistin, tigecycline, or aminoglycosides, depending on the susceptibility of each strain.

Proteus

Proteus mirabilis and *P. vulgaris* are normal flora of the bowel and cause urinary tract and intraabdominal infections. They are GNRs. They produce urease, which splits urea in the urine, releasing ammonium. This creates an alkaline environment that facilitates stone formation. These stones can be a nidus for recurrent UTI. *P. mirabilis* is usually susceptible to ampicillin-sulbactam, piperacillin/tazobactam, and all cephalosporin generations. Resistance to TMP/SMX is common. *P. vulgaris* is often resistant to multiple β -lactams and fluoroquinolones.

Serratia

Serratia marcescens is a GNR found in the environment but does not often colonize the human microbiome. When it does, it can cause UTIs and nosocomial pneumonia. It can also cause septic arthritis and bacteremia in drug abusers. All isolates are resistant to ampicillin

and 1st generation cephalosporins but are usually susceptible to 3rd generation cephalosporins, aminoglycosides, and piperacillin/tazobactam.

Enterobacter

Enterobacter cloacae and *E. aerogenes* are GNRs and the 2 most common species infecting humans. They are part of normal gut flora, and due to their resistance to commonly used antibiotics (e.g., ampicillin-sulbactam and cefazolin), they can become predominant species in patients receiving these drugs and cause nosocomial UTIs, pneumonia, and complicated intraabdominal infection. Both species are almost always susceptible to cefepime and aminoglycosides, and most are susceptible to TMP/SMX and fluoroquinolones.

Legionella

Legionella species are aerobic GNRs (but show up poorly on Gram stain) and require special media for culture (charcoal yeast extract). Obtaining a urine *Legionella* antigen is a good rapid test. *Legionella* has > 19 known pathogenic species, but *Legionella pneumophila* causes 80–90% of human infections. *Legionella* species easily colonize standing water and enter the lungs via inhalation, causing pneumonia.

L. pneumophila causes **legions** of problems with multisystem manifestations as the rule. Patients often present with diarrhea, hyponatremia, hypophosphatemia, and CNS symptoms (headache, delirium, and confusion) in addition to the pneumonia.

Treat with a fluoroquinolone or a macrolide. Tetracyclines also have activity. Add rifampin for severe disease.

Brucella

Brucella is an aerobic gram-negative bacillus. *B. melitensis* causes brucellosis in goats, sheep, and camels. Other strains are *B. abortus* (cattle), *B. suis* (pigs), and *B. canis* (dogs). These are transmitted to humans via unpasteurized milk or cheese or by inhalation (work related).

Acute **brucellosis** is a nonspecific febrile disease—with night sweats (often with a foul, moldy odor), diarrhea, myalgias, arthralgias, and fatigue—that is difficult to pinpoint unless there is an occupational or travel exposure history to assist. Think “BruSmella” to help remember the association of *Brucella* with smelly sweat. If inhaled, *Brucella* pneumonia occurs. A small percentage of patients have diffuse rash, orchitis, or uveitis.

Localized infection can ensue and manifest as osteomyelitis, tissue abscesses, or endocarditis (that can initially be culture negative because the organism takes weeks to grow).

Because cultures can take up to 6 weeks to grow, confirming the diagnosis is difficult. Diagnosis can also be made via acute and convalescent serum titers, as well as PCR.

Treatment requires 1 of the following regimens:

- 1) Doxycycline + aminoglycoside (streptomycin or gentamicin) × 4 weeks
- 2) Doxycycline + rifampin × 6–8 weeks
- 3) Avoid doxycycline in pregnant women; treat with rifampin 900 mg daily for 8 weeks.

Francisella tularensis

Francisella tularensis is a small, gram-negative, pleomorphic bacillus that causes **tularemia**. It is found in many animals, particularly rabbits (“rabbit fever”). *Francisella* is transmitted by ticks and bloodsucking flies, but the organism can also be ingested, transmitted by contact with animal skins, or inhaled. It is seen most often in Arkansas, Missouri, and Oklahoma. It has 6 distinct forms: ulceroglandular (the most common type), glandular, oropharyngeal, oculoglandular, typhoidal, and pneumonic.

Patients with the ulceroglandular form of tularemia present with a history of sudden onset of fever, chills, myalgias, and arthralgias, as well as a single, red papuloulcerative lesion with a central eschar at the site of the tick bite. Additional symptoms can develop, based on portal of entry. Regional lymphadenopathy can develop, and these nodes can necrose and suppurate. If pneumonia occurs, it demonstrates hilar adenopathy, nodular infiltrates, and pleural effusion similar to pneumonic plague.

The diagnosis is based on the clinical and epidemiological presentation. Serologic testing for *F. tularensis* is confirmatory, but it usually takes > 2 weeks to turn positive. Culture apparently infected tissue, but know that these cultures have a very low yield.

Treat with streptomycin or gentamicin. Doxycycline or ciprofloxacin can be used if the patient is not severely ill.

Bartonella henselae

Bartonella henselae (cats are the natural reservoir, especially kittens) causes **cat scratch disease** or, in the immunocompromised patient, **bacillary angiomatosis**. Cat scratch disease has a macule → papule → pustule at the site of the infection (**Figure 4-19**) with painful regional lymphadenopathy. Often the site of inoculation is no longer visible when the patient presents with lymphadenopathy. Rarely it can cause encephalitis or endocarditis. It is a very slow-growing GNR. Treatment with azithromycin decreases the duration of illness and is recommended, although it may be a self-limited process.

Figure 4-19: Catscratch disease primary lesion
Source: CDC

Helicobacter pylori

Helicobacter pylori is a gram-negative, spiral, flagellated bacillus. It causes gastritis and peptic ulcer disease (PUD) and is a risk factor for adenocarcinoma of the stomach and GI lymphoma. Further discussion about *H. pylori* is in the [Gastroenterology](#) section.

RICKETTSIA

Rocky Mountain Spotted Fever (RMSF)

Rickettsia rickettsii is a poorly staining gram-negative coccobacillus that causes RMSF. This tickborne disease has a 5–10% mortality rate. Classic signs and symptoms include a rash, fever, severe headache, arthralgias (but not overt arthritis), and history of recent exposure to ticks in endemic areas (predominantly southeastern United States). The rash ([Figure 4-20](#)) occurs on the distal extremities. It progresses from maculopapular to petechial. Patients sometimes also present with diarrhea and abdominal pain.

Figure 4-20: Rash in Rocky Mountain spotted fever

Labs show leukopenia or leukocytosis, thrombocytopenia, hyponatremia, and increased transaminases. PT, aPTT, and fibrin split products are often increased, although the condition does not often result in true DIC. The increase in these parameters is thought to be due to organism-induced local injury in the blood vessels.

It is important to diagnose this infection presumptively on clinical grounds (especially the distinct rash) to allow emergent treatment. The **quickest** confirmation of the diagnosis is via immunofluorescent staining of a biopsy sample of a petechial lesion. Serology eventually turns positive but is often negative on presentation.

Treat with doxycycline or chloramphenicol.

Endemic Typhus

Rickettsia typhi causes endemic typhus, which presents with fever, headache, myalgia, a faint rash, and transaminase elevation. In the U.S., the opossum is the reservoir, and it is transmitted by the cat flea. A history of cat ownership with opossums in the neighborhood is helpful. The diagnosis is made serologically, and the treatment is doxycycline. The disease will eventually resolve, but doxycycline shortens the course of the illness.

Q Fever

Q fever (*Coxiella burnetii* infection) is a zoonosis transmitted mainly by inhalation of the aerosol released from the infected animal. Q fever is seen in abattoir (**slaughterhouse**) workers and people exposed to an infected animal's products of conception during **birthing**. It usually presents as a flu-like febrile illness, with or without pneumonia and/or hepatitis. Headache is common. ~ 5% of infections become chronic and manifest as a fever of unknown origin or culture-negative endocarditis.

Diagnose with serology, particularly Phase II IgG (acute Q fever) and Phase I IgG (chronic Q fever). Treat chronic Q fever or endocarditis with doxycycline and hydroxychloroquine.

Ehrlichia and *Anaplasma*

Ehrlichia and *Anaplasma* are small, obligate, intracellular gram-negative organisms that cause ehrlichiosis and anaplasmosis, respectively. Ehrlichiosis is called "**spot-less**" Rocky Mountain fever even though ~ 30% have a rash. Like RMSF, ticks are the transmission vectors, and also like RMSF, ehrlichiosis and anaplasmosis predominantly occur in the eastern half of the U.S. ([Figure 4-21](#) and [Figure 4-22 on page 4-50](#)).

Figure 4-21: Annual reported incidence (per million population) for *Ehrlichia chaffeensis*, 2018
Source: CDC

Figure 4-22: Annual reported incidence (per million population) for anaplasmosis, 2018

Source: CDC

The 2 species of *Ehrlichia*, *E. chaffeensis* and *E. ewingii*, cause **human monocytic ehrlichiosis** (HME), mainly in Missouri and Arkansas.

Anaplasma phagocytophilum causes **human granulocytic anaplasmosis** (HGA), mainly in the Northeast and upper Midwest U.S.

Patients with either illness present similarly with fever and severe headache. Both HME and HGA can cause thrombocytopenia, leukopenia, and pancytopenia. Rash is present in ~30% of HME patients but rare in HGA patients. Definitive diagnosis is established by finding intracytoplasmic inclusions (**morulae**) in white blood cells (Figure 4-23 and Figure 4-24).

These inclusions are found within PMNs in HGA and within monocyte cells in HME. Serologies are available but require a 4-fold change in titer and thus are not useful at presentation.

Treat all patients suspected or proven to have ehrlichiosis or anaplasmosis with doxycycline just like with RMSF.

Because the same ticks are vectors for all 3 illnesses, coinfection with *Ehrlichia/Anaplasma* and *Babesia microti* (an intra-RBC protozoan parasite) or *Borrelia burgdorferi* (Lyme disease) can occur in endemic northeast areas.

Figure 4-23: Ehrlichia morula

Figure 4-24: Anaplasma morula
Source: CDC

MYCOBACTERIA

All mycobacteria are **acid-fast**—they do not lose their stained color when exposed to acids (red on a green background). As a rule, treat mycobacterial infections with a **prolonged multidrug regimen**.

M. tuberculosis is a prominent global cause of pulmonary infection and death. In addition, it can cause myriad extrapulmonary infections in any organ. See more on TB in the **Pulmonary Medicine** section.

Mycobacterium avium complex (MAC; a.k.a. *M. avium-intracellulare* [MAI]) causes a chronic pulmonary infection with either *M. avium* or *M. intracellulare*. Immunocompromised (especially HIV) patients are at risk for disseminated disease. Older women and patients with COPD can also present with an indolent pneumonia (Lady Windermere syndrome). Treatment includes a macrolide (clarithromycin or azithromycin) plus ethambutol and rifampin. For severe or refractory disease, aminoglycosides may be necessary. Remember that for **MAC**, you need a **MACrolide** antibiotic.

M. leprae causes leprosy. Transmission is primarily via respiratory droplets from person to person, although it can also occur from direct contact on open wounds. The majority of the population is genetically not susceptible to infection. Armadillos serve as a reservoir of *M. leprae* in the southern U.S. Presentation is with nodular, hypopigmented, and anesthetic skin lesions and sometimes palpable peripheral nerves. Biopsy of affected areas can demonstrate the organism with Fite stains. PCR can also be used.

M. marinum is the so-called fish-tank bacillus. It causes nonhealing skin ulceration in people working around fish tanks, in addition to being associated with aquatic trauma involving saltwater. It causes strings of lesions or nodules along the lymphatic channels. (Similar lesions occur with *Nocardia brasiliensis* and *Sporothrix schenckii*.) If mild, treat with doxycycline, TMP/SMX, or clarithromycin. Treat more serious disease with clarithromycin + either rifampin or ethambutol for 1–2 months after symptoms resolve.

Other nontuberculous mycobacteria (NTM) include *M. kansasii* (pneumonia in patients with COPD) and *M. abscessus* (chronic pulmonary infections in patients with underlying lung disease).

CHLAMYDIA AND CHLAMYDOPHILA

Chlamydia and *Chlamydophila* are obligate, intracellular bacteria. *Chlamydia psittaci*, *Chlamydia trachomatis*, and *Chlamydophila pneumoniae* (formerly TWAR) are pathogenic in humans.

C. psittaci is found in psittacine (e.g., parrots, parakeets, macaws, cockatoos) and other birds and causes psittacosis: pneumonia and **splenomegaly**. Any pneumonia associated with poultry contact, especially with splenomegaly, strongly suggests *C. psittaci*. (Differential diagnosis: *Histoplasma* also causes pneumonia and

splenomegaly; it is found in patients with contact with bird and bat droppings; difficult to distinguish based on presentation while awaiting evaluation, but psittacosis may be more severe with onset over a shorter period of time.) Onset of psittacosis presents with myalgias, rigors, headache, and high fever—to 105.0°F (40.6°C).

C. trachomatis causes GU infections and **trachoma** (chronic, anterior eye infection causing cataracts but **not** glaucoma; found especially in Asia and Africa). ~ 5% of pregnant women have *C. trachomatis* in their genital tracts. The same *C. trachomatis* also causes neonatal pneumonia. Lymphogranuloma venereum is an STI caused by the same *C. trachomatis* but a different immunotype. See [Sexually Transmitted Infections \(STIs\)](#) on page 4-15.

Chlamydomydia pneumoniae (formerly *Chlamydia* but found to have different DNA and antigen) causes community-acquired pneumonia in adults who typically have **not** been exposed to birds; i.e., person-to-person spread. Bronchospasm is particularly prominent, as is an association with early pharyngitis and laryngitis.

Treatment is with doxycycline, macrolides, or fluoroquinolones.

SPIROCHETES

PREVIEW | REVIEW

- What are the clinical presentations of leptospirosis?
- Which symptoms manifest in the various stages of Lyme disease?
- What are the treatments for Lyme disease?

SYPHILIS

Syphilis is discussed under [Infectious Genital Ulcers](#) on page 4-16.

LEPTOSPIROSIS

Leptospirosis is a spirochetal disease caused by *Leptospira interrogans* and transferred by contact with infected animals or contaminated water. It is seen in association with exposure to rodent urine. Leptospirosis is considered the most widespread zoonosis in the world. It is common in Hawaii (~ 50% of all U.S. cases) and can be seen after recreational water exposures (e.g., in whitewater rafters, adventure racers, surfers, swimmers, triathletes).

Leptospirosis has a wide range of signs and symptoms, from myalgias, fever, and headache (with or without aseptic meningitis) to Weil disease (severe hepatitis with renal failure, pneumonitis, and hemorrhagic complications).

Conjunctival suffusion (Figure 4-25) is highly specific because it is rarely seen in other infectious diseases.

The hepatitis is characterized by the bilirubin being disproportionately elevated compared to the liver transaminases. The variety of presenting symptoms makes for a high incidence of initial misdiagnoses.

Figure 4-25: Leptospirosis conjunctival suffusion
Source: James Heilman, MD

Diagnose by CSF cultures on special media within the first 10 days of illness. After that, culture the urine and send serum for antileptospiral IgM, and check urine antigen.

Treat with PCN or doxycycline.

LYME DISEASE

Borrelia burgdorferi causes Lyme disease. It is transmitted by the *Ixodes scapularis* tick in the mid-Atlantic, Midwest, and Northeast U.S. and by the *Ixodes pacificus* tick in California. The protozoan *Babesia* (see [Babesia](#) on page 4-62) and the agents of ehrlichiosis and anaplasmosis are also transmitted by this tick.

Ixodes ticks have 3 stages of development: larva, nymph, and adult. Ticks transmit Lyme disease most efficiently during the nymphal stage. Nymphs are more likely to feed on humans and are rarely noticed because they are very small (< 2 mm).

Ticks require **at least 36-48 hours** of attachment before transmission of infection occurs. A tick found walking on the skin is not transmitting infection.

Manifestations

Stages of Lyme disease:

- Stage 1—**early localized**: **Erythema migrans** (EM) is the pathognomonic skin lesion of Stage 1 disease; it starts at the site of the bite and is a slowly spreading, circular, erythematous lesion, usually with a lighter center (Figure 4-26 on page 4-52). Other Stage 1 symptoms include myalgias, arthralgias, fever, headache, and lymphadenopathy. ~ 50% of patients have secondary skin lesions.

- Stage 2—**early disseminated**: Weeks to months later, Stage 2 disease occurs with **neurologic** symptoms (i.e., lymphocytic meningitis, cranial or peripheral neuritis) and/or **heart** infection (i.e., myocarditis with transient 1st, 2nd, or 3rd degree heart block). A peripheral 7th nerve palsy (Bell's palsy) is not uncommon and, if bilateral from an endemic area for Lyme disease, is diagnostic.
- Stage 3—**late**: Months to years later, Stage 3 occurs with a mono- or oligoarticular **arthritis**. This is not to be confused with so-called chronic Lyme disease, which is generally not recognized as being a real entity.

Figure 4-26: Erythema migrans
Source: CDC

Diagnosis

A diagnosis can be made in 2 ways:

- 1) presence of EM or
- 2) ≥ 1 Stage 2 or 3 manifestations and positive serology (an enzyme immunoassay [EIA] test, followed by a Western blot only if the EIA is positive).

There are a few important caveats about testing for Lyme disease:

- Do not perform serology if there are no Lyme symptoms. Patients with seropositivity and no symptoms have had prior asymptomatic exposure, but they do not warrant and do not benefit from treatment.
- Do not perform serology in patients with EM. It is diagnostic of Lyme disease and most patients are seronegative in Stage 1.
- Reserve serology for persons from endemic areas with symptoms consistent with Stage 2 or 3 Lyme disease.

Treatment

Treatment depends on the stage and type of manifestation:

- Treat Stage 1, Bell's palsy, and asymptomatic 1st or 2nd degree heart block with oral doxycycline or amoxicillin $\times$ 10–21 days.
- Treat symptomatic heart block and neurologic disease with ceftriaxone 2 g or PCN G 20 MU IV in divided doses $\times$ 14–21 days. Typically only temporary pacing is required for symptomatic heart block.
- Treat arthritis with oral doxycycline or amoxicillin $\times$ 28 days, but you may need to repeat the oral regimen or use IV ceftriaxone if there is recurrence after the initial oral regimen.

Although patients previously treated for Lyme disease more commonly have chronic neuromuscular symptoms (e.g., muscle and joint pain, fatigue, trouble with memory and formulating ideas) than do patients never infected with *B. burgdorferi*, several studies have confirmed that there is no benefit in giving additional courses of antibiotics to these individuals.

Prevention

Because transmission does not occur until at least 36–48 hours of attachment, the best prevention is to keep ticks off the body with clothing treated with insect repellents and to find and remove the *Ixodes* tick from the skin. When ticks are embedded in the skin, they should be removed by grasping them with tweezers placed on their mouthparts and pulling them straight up from the skin.

Postexposure prophylaxis: Give a single dose of doxycycline 200 mg PO if an embedded tick is found on the skin and all of the following are true:

- The tick is in the nymph or adult stage.
- The tick was attached at least 36 hours and is engorged.
- The patient presents within 72 hours of tick removal.
- The local rate of tick infection with *B. burgdorferi* is $\geq 20\%$, such as in New England, mid-Atlantic states, and parts of Minnesota and Wisconsin.

FUNGAL INFECTIONS

PREVIEW | REVIEW

- In a febrile patient who is receiving intravenous hyperalimentation, which fungal bloodstream infection might you suspect?
- When can you disregard *Candida* as a blood culture contaminant?
- What is the treatment of candidemia when a line is present?
- Which patient population typically develops hepatosplenic candidiasis?
- Patients with candidemia should have what kind of referral?
- What are the cerebral spinal fluid abnormalities in cryptococcal meningitis?
- Initial treatment for cryptococcal meningitis includes which drugs?
- Where is *Coccidioides immitis* geographically found?
- What are the clinical presentations of histoplasmosis?
- Which tests are best for diagnosing histoplasmosis?
- What are the clinical manifestations of disseminated blastomycosis?
- Which patient groups are at risk for mucormycosis?

OVERVIEW

Fungi are divided into 2 morphologic types: **yeasts** and **molds**. There are also **dimorphs** that change from a yeast to mold, and vice versa, depending on temperature. The dimorphs are the type most likely to cause **systemic** disease in the nonhospitalized, immunocompetent host. The dimorphic fungi are transmitted by spores that convert to yeast at body temperature.

Some of the clinically relevant fungi include:

- *Candida* species
- *Cryptococcus* species
- *Aspergillus* species
- Endemic fungi (*Histoplasma*, *Blastomyces*, and *Coccidioides*; found in specific regions of the U.S.)
- Dermatophytes (cause tinea capitis, tinea corporis, tinea pedis, and tinea cruris)
- *Sporothrix schenckii*
- Zygomycetes (e.g., *Mucor*, *Rhizopus*, and *Rhizomucor*)

CANDIDA

Outpatient *Candida* infections are usually caused by *Candida albicans*.

People who have recently spent time in nursing homes and have lines and tubes that go into their body, such as breathing tubes, feeding tubes, and central venous catheters, seem to be at highest risk for *Candida auris* infection. Limited data suggest that the risk factors for *C. auris* infections are generally similar to risk factors for other types of *Candida* infections. These risk factors include recent surgery, diabetes, broad-spectrum antibiotic and antifungal use. Infections have been found in patients of all ages, from preterm infants to the elderly. Further study is needed to learn more about risk factors for *C. auris* infection. Infections with this organism are more likely to occur in patients who:

- are immunosuppressed,
- are on antibacterials,
- have indwelling catheters,
- are receiving IV hyperalimentation,
- have uncontrolled diabetes, or
- have HIV infection.

Presentations vary. Disease can be localized to mucosal surfaces of the mouth (thrush), esophagus, and vagina (candidal vaginitis). Disseminated disease manifests as candidemia that can produce endocarditis, endophthalmitis, hepatosplenic infection, and renal infection. Usually, candidemia, either from an infected vascular catheter or from overgrowth of *Candida* in the gut, is the source of dissemination to these other organ systems.

Physical exam findings: Limited mucosal *Candida*, such as thrush, is visible as whitish plaques with an underlying erythematous base. Patients who have odynophagia and oral thrush can be assumed to have esophageal candidiasis; endoscopy is not required to make the diagnosis. Vulvovaginal candidiasis presents as a thick, whitish discharge along with intense vaginal itching (see [Vulvovaginal Candidiasis \(VVC\)](#) on page 4-21).

C. auris is an emerging multidrug-resistant yeast with outbreaks in health care settings. Patients with lines going into their body (e.g., feeding tube, central catheter) are more susceptible. Known risk factors for *C. auris* are the same as those for *C. albicans*. The most reliable antifungal options are the echinocandins.

Candidemia

Signs and symptoms of disseminated disease are fever; rash or painless, erythematous papules/pustules; visual complaints; and multiorgan involvement. *Candida* species grow readily in routine blood culture bottles. *Candida* in a blood culture is **never** a contaminant; it represents real disease, even if the patient is relatively asymptomatic. It can take days to grow the organisms out of the blood. If the patient is ill, consider empiric antifungal treatment (e.g., in a neutropenic patient with a prolonged fever).

Non-*albicans Candida* are common in hospitalized and immunocompromised patients. They are often resistant to fluconazole.

Treatment of candidemia includes removal of any infected catheters and administering a systemic antifungal. An echinocandin (i.e., caspofungin, micafungin, anidulafungin) is 1st line therapy in all patients, pending identification and susceptibility. Fluconazole can be considered once speciation is known.

Chronic Disseminated Candidiasis

Chronic disseminated candidiasis (a.k.a. hepatosplenic candidiasis) is seen in leukemic patients as they recover from a period of neutropenia. Symptoms include fever and pain in the right upper quadrant.

Labs show increased alkaline phosphatase +/- increased transaminases and bilirubin. Contrast CT of the abdomen shows multiple small abscesses in the liver and spleen.

As with candidemia, the main therapy is an echinocandin (i.e., caspofungin, micafungin, anidulafungin). Note that the echinocandins end in "-fungin."

Ocular Candidiasis

Ocular candidiasis presents with altered visual acuity and can manifest as endophthalmitis or chorioretinitis. Disease can occur as a result of fungemia and seeding of the eye or after cataract surgery. Early disease (especially with chorioretinitis) can be relatively asymptomatic, so any patient who develops candidemia should have a dilated eye exam by an ophthalmologist. The most common symptom is painless loss of visual acuity, and exam may show fluffy chorioretinal lesions or fungus balls in the vitreous.

Treat chorioretinitis without vitritis with systemic azoles (fluconazole or voriconazole), unless there is azole resistance, and then liposomal amphotericin should be used. If there is also macular involvement, give intravitreal amphotericin B or intravitreal voriconazole. If chorioretinitis with vitritis is present, treatment may entail vitrectomy in addition to systemic and intravitreal antifungals.

Genitourinary Candidiasis

Candiduria is fairly common, especially in hospital settings, and it often represents colonization, especially if the patient has had a urinary catheter.

Be concerned about repeatedly positive urine cultures for *Candida* in patients with diabetes or recent urinary manipulation and patients with systemic signs of infection. Urinalysis showing pyuria is not sensitive or specific for true infection. In the evaluation, include renal imaging with either ultrasound or CT of both the bladder and the kidneys.

Manage asymptomatic candiduria with negative imaging by changing the urinary catheter if present. Antifungal therapy is **not** indicated unless the patient is neutropenic or will be undergoing urologic manipulation.

Treat symptomatic candiduria with a systemic antifungal based on culture results. Fluconazole is preferred if the isolate is susceptible.

Lipid amphotericins are not excreted in high enough concentrations in the urine to be useful in treating *Candida* UTIs. Echinocandins are also not recommended, for the same reason. Bladder irrigation also is not recommended for cystitis, although it has some use in treating upper tract disease complicated by fungus balls.

Surgically remove any fungus ball if no improvement after amphotericin B upper tract irrigation.

CRYPTOCOCCUS

In immunocompetent patients, *Cryptococcus neoformans* usually causes minimally symptomatic, self-limited infection after entering via the respiratory route. Patients can have a low-grade fever, pleuritic pain, cough, and a pulmonary infiltrate. Form of treatment depends on level of symptoms. Although it is found in pigeon droppings, most patients have no recollection of being in contact with birds. Cryptococcal pneumonia can form cavitory lesions and peripheral "cannon ball" lesions. Lumbar puncture is recommended in pulmonary cryptococcosis, even if without CNS symptoms, as cryptococcal meningitis may be subtle.

Dissemination is more likely with *Cryptococcus gattii*, a related species, in immunodeficient patients (e.g., AIDS, corticosteroid therapy, Hodgkin disease, acute lymphocytic leukemia, diabetes, after organ transplant). These patients are especially likely to get **cryptococcal meningitis**—the most common presentation of severe cryptococcal infection. *C. gattii* is found in northern California and the Pacific Northwest.

Suspect cryptococcal meningitis in any immunosuppressed patient who has headache +/- skin lesions and/or pulmonary lesions +/- fever. More specific meningeal symptoms (e.g., stiff neck, photophobia) are rare. Lumbar puncture commonly shows increased CSF opening pressure, usually > 200 mmH₂O. The rest of the spinal fluid analysis may be remarkably benign with minimal leukocytosis and protein elevation. India ink testing is relatively nonspecific and insensitive and has generally been replaced by cryptococcal antigen testing.

Treatment is long term and occurs in 3 stages:

- 1) Induction with amphotericin B + flucytosine for 2 weeks
- 2) Consolidation with fluconazole 400 mg/day for ≥ 8 weeks
- 3) Maintenance with fluconazole 200 mg/day for ≥ 1 year

Additionally, daily repeated lumbar punctures are recommended in those with increased intracranial

pressure (> 200 mmH₂O) or with associated headache, clouded sensorium, visual/hearing loss, or cranial nerve palsies. Sometimes, if these do not reduce pressure, shunts are required.

Patients with AIDS require secondary prophylaxis with chronic fluconazole.

ASPERGILLOSIS

Aspergillus species are ubiquitous in the environment. *A. fumigatus* is the most commonly isolated pathogen and can cause severe infections, mostly in immunocompromised hosts. Aspergillosis can present with a spectrum of disorders spanning the following:

- Allergic bronchopulmonary aspergillosis (ABPA), an allergic reaction to colonization with *Aspergillus* (clinical presentation similar to asthma; more in the [Pulmonary Medicine](#) section)
- Aspergilloma (a fungus ball in a previously formed cavity; [Figure 4-27](#))
- Invasive aspergillosis can be an acute destructive pulmonary process in immunocompromised patients (acute invasive pulmonary aspergillosis) or chronic in those who are immunocompromised (chronic necrotizing aspergillosis) or immunocompetent (chronic cavitary aspergillosis leading to chronic fibrosing aspergillosis).

Figure 4-27: *Aspergillus* fungus ball
Source: CDC

Invasive aspergillosis can be rapidly fatal and requires prompt diagnosis and treatment. Diagnose by lung biopsy and demonstration of the organism invading the lung and on culture. Use caution in interpreting expectorated sputum and bronchoalveolar lavage (BAL) specimens because the organism is common in the environment and may represent colonization. Alternatively, measure *Aspergillus* galactomannan antigen in the blood or the BAL fluid. This test is most useful in immunocompromised hosts (particularly patients with hematologic malignancy and stem cell transplant recipients), which is also true for 1,3-β-D-glucan, which is a serum test that may support the diagnosis of invasive aspergillosis.

Treat ABPA with steroids +/- voriconazole. Aspergillomas can be observed, but if symptomatic (hemoptysis), resect. 1st line treatment for the invasive forms of aspergillosis is voriconazole.

ENDEMIC FUNGI

The American endemic fungi are *Coccidioides*, *Histoplasma*, *Blastomyces*, and *Cryptococcus gattii* (discussed in [Cryptococcus](#)). They have the following characteristics in common:

- They are found in specific areas of the U.S., and a patient becomes infected only after visiting or living in the area where the organism is endemic and participating in activities that encounter the organism.
- They are acquired by inhalation.
- They most commonly cause asymptomatic or mild, self-limited pulmonary disease.
- Less frequently, they cause significant pulmonary disease requiring medical treatment.
- Least commonly, they cause disseminated disease.
- Significant pulmonary disease and dissemination are much more common in immunodeficient patients.
- Mild disease is treated with azoles. Severe or CNS disease is treated with amphotericin B.

Coccidioidomycosis

Coccidioides immitis and *Coccidioides posadasii* cause coccidioidomycosis ([Figure 4-28](#)). The spores (arthroconidia) are highly infectious at a very low inoculum.

Figure 4-28: Geography of coccidioidomycosis, 2018
Source: CDC

C. immitis is found in the soil of the arid southwest U.S. and northern Mexico. This disease is frequently called **valley fever** because it is endemic to the San Joaquin Valley and Death Valley.

When inhaled, the arthroconidia convert to their yeast form that, days to weeks later, causes a self-limited, flu-like illness with arthralgias, erythema multiforme, and/or erythema nodosum. Disease can result in a pulmonary "coin lesion." People at highest risk for severe infection include Asians and African Americans, pregnant women, and the immunosuppressed.

Extrapulmonary coccidioidomycosis can involve bone, skin, or the CNS. Coccidioidomycosis and ABPA are the only 2 fungal diseases that cause peripheral **eosinophilia**.

Demonstration of spherules in body fluids or tissue is diagnostic (Figure 4-29). Culture is also diagnostic, and the organism grows well on almost all media in ~ 1 week. IgM serology is available but takes 1-3 weeks to turn positive.

Figure 4-29: Coccidioidomycosis spherules

Most patients have self-limited disease and do not require treatment. If needed, nonmeningeal, less severe infections can be treated with fluconazole or itraconazole. Treat severe cases with amphotericin B. When treatment is indicated, continue for a prolonged duration (6-12 months).

Histoplasmosis

Histoplasma capsulatum causes histoplasmosis and is found predominantly in the Mississippi and Ohio River valleys (Figure 4-30).

Figure 4-30: Geography of histoplasmosis, 2018
Source: CDC

H. capsulatum is especially prevalent in bat and bird droppings. Conidia or mycelial fragments are the infectious form.

Immunocompetent patients typically have a self-limited, flu-like illness with or without mild pulmonary infiltrates. *Histoplasma* can present with pneumonia, mediastinal adenopathy, superior vena caval obstruction, palate ulcers, and hepatosplenomegaly. Radiographically, it can mimic cancer, sarcoid, or TB.

In the immunocompromised patient (especially HIV/AIDS), *H. capsulatum* can disseminate, causing a rapidly progressive sepsis and/or multisystem involvement.

Demonstration of characteristic yeast forms with narrow-based budding (Figure 4-31) that are often intracellular is diagnostic. They are not as commonly detected

Figure 4-31: Histoplasmosis narrow-based budding
Source: CDC

as is the granuloma on biopsy. Serum and urine antigen detection is diagnostic and has the highest yield in immunocompromised hosts and/or those with disseminated disease. Antigen detection tests cross-react with *Blastomyces dermatitidis*, which diminishes the specificity of these tests.

Acute, nonsevere pulmonary disease requires no therapy. More severe but localized histoplasmosis can be treated with itraconazole. Disseminated disease requires amphotericin B (either deoxycholate or liposomal formulations; liposomal formulations are preferred because they are relatively less nephrotoxic) followed by itraconazole.

Blastomycosis

Blastomycosis is caused by *Blastomyces dermatitidis*, which, in vivo, is a broad-based budding yeast (remember the 4 Bs: blasto, broad-based, budding).

Blastomycosis was primarily seen in states bordering the Mississippi and Ohio River basins and the basins near the Great Lakes and along the St. Lawrence River but has since expanded to cover almost all of the eastern half of the U.S. (Figure 4-32).

Figure 4-32: Geography of blastomycosis, 2018
Source: CDC

Initial infection is often asymptomatic; otherwise it commonly presents as a flu-like illness. This can progress to a lobar pneumonia that is unresponsive to antibacterial agents. If it disseminates from the lung, it typically does so to the skin, usually causing verrucous (warty) lesions with central ulceration. Septic arthritis and osteomyelitis can also be seen.

Demonstration of the yeast form with its broad-based buds in secretions or tissue is diagnostic (Figure 4-33). Cultures require fungal media and turn positive in 1-4 weeks. Urinary antigen and serum antigen are usually positive in disseminated disease, with the urine being a more sensitive test.

Figure 4-33: Blastomycosis; giant cell with broad-based budding

Treat mild to moderate disease with itraconazole. Severe or CNS disease requires amphotericin B.

SPOROTRICHOSIS

Sporotrichosis (a.k.a. rose gardener's disease) is caused by *Sporothrix schenckii*—a ubiquitous dimorphic fungus found in soil and plants. Gardeners are prone after being pricked by a thorn. Of the 4 clinical presentations, the cutaneous and the lymphangitic (nodules form on the skin over lymph channels) types are treated with itraconazole, and the rare pulmonary and disseminated types are treated initially with lipid amphotericin B. The disseminated type is more common in those with immunodeficiency. *Mycobacterium marinum* and *Nocardia brasiliensis* cause similar lesions over lymphatic channels.

MUCORMYCOSIS

Mucormycosis (previously zygomycosis) is caused by fungi in the order Mucorales. *Mucor*, *Rhizopus*, or *Rhizomucor* are the most common species of Mucorales that cause human disease.

Rhizopus thrives in acidic and high-glucose conditions. These conditions occur in patients with iron overload on deferoxamine chelation, in patients with diabetes, and in those with primary or secondary hemochromatosis. The severely immunosuppressed are also at risk.

Disease can present as invasive pulmonary or rhinocerebral infection. Rhinocerebral mucormycosis presents as a black necrotic spot on the paranasal skin, nasal mucosa, or paranasal sinuses that can extend intracranially. Necrotic areas can also be seen on the hard palate. It has a poor prognosis.

Pulmonary mucormycosis presents as a necrotizing, cavitating pneumonia, similar to aspergillosis. Consider mucormycosis in a patient on voriconazole treatment or prophylaxis with new or worsening pulmonary disease.

Diagnosis is made by biopsy showing broad, nonseptate hyphae with right-angle branching that are described as “ribbon-like” (Figure 4-34).

Treat with correction of predisposing factors (e.g., diabetic ketoacidosis), aggressive surgical resection, and lipid amphotericin B. Use posaconazole or isavuconazole in those who cannot tolerate amphotericin B or for salvage therapy. The other azoles (fluconazole, itraconazole, voriconazole) do not have activity against mucormycosis.

Figure 4-34: Right-angle branching in mucormycosis pneumonia

DERMATOPHYTES

Dermatophytes infect keratinized structures, such as skin and hair.

The names of the diseases caused by dermatophytes begin with “tinea” and end with the location of their infection: tinea corporis, tinea capitis, tinea pedis, and tinea cruris. See the Dermatology section.

Treat ringworm (tinea corporis) with topical clotrimazole, topical terbinafine, or undecylenic acid. Then, if there is no success, use an oral agent; the preferred ones are itraconazole and terbinafine. Infection of hair follicles (tinea capitis) requires treatment with oral agents, such as terbinafine, itraconazole, and fluconazole.

PARASITES

PREVIEW | REVIEW

- How is a *Giardia* infection diagnosed?
- What is kala azar?
- Which form of malaria is associated with banana-shaped gametocytes?
- For travel to chloroquine-resistant areas, which drugs are used for malaria prophylaxis?
- What is the presentation of *Babesia* infection?
- *Strongyloides* hyperinfection syndrome can be seen in which patient population?
- What is visceral larva migrans?
- What are the clinical manifestations and treatment of neurocysticercosis?

There are 2 main types of parasites, protozoa and helminthic organisms.

PROTOZOA

Protozoa are single-celled and can replicate within the body. With the exception of *Cystoisospora*, protozoa do not cause eosinophilia.

There are 3 types of protozoa:

- 1) Sporozoa (*Toxoplasma*, *Cryptosporidium*, *Cystoisospora* [previously *Isospora*], microsporidia, *Plasmodium*, *Cyclospora*, *Babesia*)
- 2) Amebas (*Entamoeba histolytica*, *Naegleria fowleri*)
- 3) Flagellates (*Giardia*, *Trichomonas*, *Trypanosoma*, *Leishmania*)

We classify the protozoan parasites in terms of the systems they affect (Figure 4-35 on page 4-58).

Figure 4-35: Classification of parasites—protozoa

Intestinal Protozoans

Giardia

Giardia lamblia (a.k.a. *Giardia duodenalis*, *Giardia intestinalis*) is an intestinal protozoan that infects the duodenum and proximal jejunum by adhering to the mucosa. Infected persons are asymptomatic in 75% of cases. Distribution is worldwide; it is the most common intestinal parasite in North America. Infection occurs through ingestion of infectious cysts via contaminated food, water, or fomites. Cysts turn into trophozoites in the gut, and look like a face with flagella legs when viewed under the microscope.

Groups of people at increased risk for *Giardia* infections include:

- Campers/backpackers (drinking unfiltered water)
- Travelers to endemic regions
- Young children in day care (and their parents also)
- HIV-infected persons
- Men who have sex with men, or anyone who performs oral-anal contact
- IgA deficiency (Remember: IgA is actively secreted across mucosal barriers, so this makes sense.)

Infection may be asymptomatic, posing infectious risk to others. If symptoms are present, they include foul, floating, watery diarrhea; sulfur-tasting burps; and flatulence associated with a malabsorption syndrome. A helpful distinguishing feature is prolonged diarrhea, with flatulence, frequently associated with weight loss. *Giardia* can sometimes cause a chronic syndrome of diarrhea, malabsorption, and weight loss. Diagnose by microscopic examination of fresh stool samples, antigen detection, or nucleic acid amplification assays, with the latter being the most sensitive. Excretion of the organism is intermittent, so up to 3 stools may be needed to make the diagnosis. Treat with tinidazole, metronidazole, or nitazoxanide.

Entamoeba

Human amebiasis is caused by the protozoan *Entamoeba histolytica*. Distribution is worldwide, though primary burden of disease occurs in developing countries. There are 30–50 million cases per year around the world, and it is the 3rd most common parasitic disease in the United States. Transmission occurs through ingestion of infectious cysts, typically via the fecal-oral route (e.g., food, waterborne). Acquisition through oral-anal sexual contact also occurs. In the U.S., the most commonly affected population groups include the institutionalized, immigrants, travelers, and men who have sex with men.

There are 4 major clinical syndromes:

- 1) **Asymptomatic cyst-passing carrier state** (80% of cases): risk to community
- 2) **Amebic diarrhea without dysentery**: diarrhea without mucus or blood
- 3) **Amebic dysentery** (< 20% of cases): subacute (3–4 weeks) progressively worsening diarrhea with mucus, or visible/microscopic blood, usually with abdominal pain; fever uncommon
- 4) **Amebic liver abscess** (< 1% of cases): seeded via portal system; usually presents as subacute RUQ pain, most commonly occurs in adult men; typically a solitary abscess

Diagnosis of intestinal disease is by stool for ova and parasites. Amebic liver abscesses often show no amebas or PMNs. These cases can be diagnosed by serology.

Treat with metronidazole or tinidazole for both forms of the disease. Although metronidazole treats amebas that have invaded, it does not kill intraluminal cysts. This must be accomplished with the administration of paromomycin, diiodohydroxyquin, or diloxanide furoate. Typically, amebic liver abscesses do not require percutaneous drainage, as opposed to pyogenic liver abscesses (which most commonly do).

Cryptosporidium

Cryptosporidium parvum and *Cryptosporidium hominis* are acid-fast, intestinal protozoans that cause enteric infections. *Cryptosporidium* is found worldwide. Infection occurs after ingestion of oocysts, usually from fecally contaminated water. *Cryptosporidium* is quite hardy and unique from other intestinal pathogens in that it can be acquired after swimming in recreational, chlorine-treated water, such as swimming pools or water parks. The patient's immune response influences the severity and duration of illness, as well as response to therapy. *Cryptosporidium* typically causes watery diarrhea for 1–2 weeks in immunocompetent patients, but can be quite severe and protracted (sometimes with biliary involvement) in immunocompromised patients. Patients with advanced HIV/AIDS are particularly at risk for severe disease. Diagnosis can be difficult but is typically made by stool microscopy, aided by acid-fast staining, as well

as other special stains. Additional methods, such as stool antigen detection and PCR, may be used to improve sensitivity. Therapy involves supportive care, consideration of nitazoxanide, and (if applicable) reduction of immune suppression or initiation of antiretroviral therapy.

Cystoisospora belli and *Cyclospora cayetanensis*

Cystoisospora belli (previously *Isospora belli*) and *Cyclospora cayetanensis* are two partial acid-fast protozoans that cause a secretory, self-limited diarrhea in immunocompetent patients, and more severe chronic forms of diarrhea in patients with compromised immune systems (especially those with advanced HIV/AIDS). Infections occur worldwide, though more commonly in tropic/subtropic regions. Infection develops after fecal-oral ingestion of oocysts. *Cyclospora* in particular is often the cause of outbreaks related to imported fruits or vegetables from Central America. Extraintestinal manifestations, particularly acalculous cholecystitis, sometimes occur in immunocompromised patients with severe disease. A clue to all of these intestinal protozoan infections is a longer duration of illness than most bacterial GI infections. Diagnosis is made via stool microscopy and aided by modified acid-fast staining (plus other special stains). Multiple stool samples might be needed to improve detection sensitivity. Treat with TMP/SMX—or, in the sulfa-allergic patient, use ciprofloxacin or nitazoxanide.

Microsporidia

The phylum Microsporidia encompasses a large group of organisms. They are intracellular parasites, recently reclassified as fungal organisms rather than protozoans; however, they can be thought of as protozoan-like and most commonly cause diarrhea, though they can infect any organ system. Water contact is a risk factor for acquisition. The most common microsporidia infecting humans are *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. These organisms cause disease predominantly in the immunosuppressed patient (particularly advanced HIV/AIDS). The diagnosis is made by demonstrating spores in the stool by trichrome staining or PCR assay. Bowel disease is patchy, so biopsy does not increase the yield. Albendazole is the treatment of choice.

Tissue Protozoans

In addition to the tissue protozoans described here, *Entamoeba histolytica* can also manifest as tissue disease (see *Entamoeba*).

Toxoplasma gondii

Toxoplasma gondii is a tissue protozoan that causes toxoplasmosis. Cats are the definitive host (i.e., the host in which the adult parasite lives); they excrete the oocysts. After oocysts are ingested by other animals, they encyst in the muscles. Undercooked muscle from these animals (mainly pigs, lambs, and cattle) is then ingested

by humans, the organism excysts, and tachyzoites are released that circulate through the blood stream and infect any nucleated cell—with a predilection for neural tissue. ~ 20% of pork and lamb and 10% of beef contains *T. gondii* cysts. Thus, consumption of undercooked meat and outdoor cat contact/ownership are the modes of acquisition. Infection is common in the U.S., with 1/3 of adults demonstrating seropositivity to the organism.

There are 4 clinical presentations of toxoplasmosis:

- 1) Immunocompetent host
- 2) Congenital
- 3) CNS
- 4) Ocular

Immunocompetent hosts are usually asymptomatic, but toxoplasmosis may cause fever, lymphadenopathy, and atypical lymphocytosis similar to infectious mononucleosis; pharyngitis is conspicuously absent. Diagnose by demonstrating the presence of IgM antibody. It is self-limited and requires no treatment.

If acquired during pregnancy, *T. gondii* can infect the fetus and cause **congenital toxoplasmosis**, with a combination of necrotizing chorioretinitis, hydrocephalus, intracranial calcifications, and intellectual disabilities (see the [Women's and Men's Health](#) section).

CNS toxoplasmosis occurs in immunocompromised patients (particularly those with AIDS) from reactivation of previous infection. These patients present with new onset of seizures, neurologic deficit, and/or altered consciousness. Diagnosis is made by brain imaging revealing multiple, bilateral, ring-enhancing lesions with a predilection for the basal ganglia. When considering CNS toxoplasmosis, the other main differential diagnosis to consider in a patient with AIDS and ring enhancing lesions is primary CNS lymphoma (though lymphoma lesions are typically single). Because this is a reactivation disease, IgM antibody is not present—but IgG is. However, a negative IgG does not necessarily exclude infection in the immunocompromised patient because of difficulty making antibodies. Treat with pyrimethamine, sulfadiazine, and leucovorin. Substitute clindamycin for sulfadiazine in the sulfa-allergic patient.

Ocular toxoplasmosis causes retinal lesions that appear as yellow-white cotton patches, irregular scarring, and pigmentation. There is also reactivation in the immunocompromised host. Treat with pyrimethamine and a sulfadiazine for 3 weeks.

Naegleria fowleri

Naegleria fowleri is a free-living amoeba found worldwide in warm freshwater (not saltwater). It causes primary amoebic meningoencephalitis, a rare but rapidly fatal disease that occurs when infested water comes in contact with nasal mucosa and the cribriform

plate, usually after extensive exposure through swimming, diving, waterskiing, and surfing. The disease is rare because the risk of infection is < 1 in 2.5 million exposures.

Typical cases involve a young, previously healthy patient, ~ 2–5 days after recreational water exposure, presenting with a rapidly progressive meningoencephalitis that is almost universally fatal within 2 weeks. Spinal fluid shows a polymorphonuclear pleocytosis and is often hemorrhagic. The diagnosis can be made by demonstrating the motile organisms on a centrifuged CSF specimen.

Because of the rarity of the disease and the high mortality rate, there are no convincing trials to determine optimal therapy.

Trypanosoma

Trypanosoma is a tissue/blood protozoan that causes two distinct diseases, Chagas disease (American trypanosomiasis) and African sleeping sickness.

Chagas disease is caused by *Trypanosoma cruzi* and is transmitted to humans via the triatomine bug (a.k.a. reduviid bug or kissing bug). It has a large impact on health and wellness, affecting 6–8 million people worldwide with 50,000 deaths per year. It occurs primarily in Central and South America. Acute illness is nonspecific with fever, lymphadenopathy, and hepatosplenomegaly. There is an intermediate phase without symptoms, followed by a chronic phase with predominately GI and cardiac involvement, causing congestive heart failure and ventricular arrhythmias in particular. Congenital infection occurs as well. Make the diagnosis by microscopic identification of organisms from the buffy coat of blood during acute disease, and by tissue biopsy in chronic disease. Treat acute illness, congenital infection, reactivation in the immunosuppressed, and young people (< 18 years of age) who are asymptomatic. Do not treat people with advanced heart disease, those who are pregnant, or patients with multi-organ failure.

African sleeping sickness, caused by *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*, is much less common, affecting ~ 10,000 people per year worldwide. It is transmitted by the bite of the Tsetse fly in East, Central, and West Africa. A painful chancre develops at the bite, after which organisms disseminate to lymphatics, then blood, then finally to the CNS, where neuropsychiatric symptoms and sleep disturbances can occur. Death and coma will occur if left untreated. It is important to always rule out CNS disease with a lumbar puncture. Diagnosis is made by microscopy. Treat with pentamidine or suramin, depending on the causative species.

Leishmania

Leishmaniasis is caused by any of the following 4 species of the *Leishmania* protozoa: *L. donovani*, *L. tropica*, *L. mexicana*, and *L. braziliensis*. It is spread via the sand

fly in tropical and subtropical regions around the world. It is characterized by a chronic, progressive course with 3 main phenotypes:

- 1) **Cutaneous** (painless ulcer)
- 2) **Mucocutaneous** (destructive lesions in oral/nasal mucosa)
- 3) **Visceral** (a.k.a. Kala-Azar; hepatosplenomegaly, pancytopenia)

Of note, there is a higher susceptibility for leishmaniasis in HIV-infected patients who travel to endemic areas. Diagnosis is made by histologic examination of infected tissues for cutaneous and mucocutaneous disease, and the highest yield for visceral disease is a bone marrow biopsy. Treatment varies from observation, to local therapies, to systemic therapy, depending on the extent of disease, location, and host immune status.

Blood Protozoans

In addition to the blood protozoans described here, *Trypanosoma* and *Leishmania* can also manifest as blood disease. They are described under Tissue Protozoans in *Trypanosoma* and *Leishmania*.

Plasmodium (Malaria)

Malaria—an acute febrile illness of varying severity caused by a blood protozoan—is a very old disease, described by ancient civilizations. There are 5 clinically relevant species within the genus *Plasmodium*:

- 1) *P. falciparum*
- 2) *P. vivax*
- 3) *P. ovale*
- 4) *P. malariae*
- 5) *P. knowlesi*

The clinical significance of malaria cannot be understated. According to the WHO World Malaria Report, there were 228 million cases of malaria with 405,000 deaths in 2019 alone. Africa carries the highest burden of disease and highest mortality, which is typically attributed to *P. falciparum*.

The basic life cycle of malaria is important to consider in order to understand the disease. The female *Anopheles* mosquito releases sporozoites during a blood meal. Sporozoites travel to the liver and mature. *P. vivax* and *P. ovale* can form hypnozoites and “sleep” in the liver, allowing for recurrent infection unless appropriately treated. After maturation in the liver, merozoites are released into the blood stream and continuously infect, mature, then rupture red blood cells. In RBCs, merozoites mature into ringed trophozoites, which is the form that is typically identified on microscopy. Some merozoites in the bloodstream form gametocytes, which transmit back to uninfected *Anopheles* mosquitos and then infect additional people.

Consider malaria in any febrile traveler returning from an endemic region. Geographic hot spots include sub-Saharan Africa and tropical regions of South America, Asia, and Indonesia.

Malaria typically presents as an acute febrile illness with chills, rigors, profound fatigue, and splenomegaly. Fevers can be very high ($> 40^{\circ}\text{C}$, 104°F) and may be spaced in regular intervals, correlating with cycles of RBC rupture. In endemic regions, due to partial immunity, symptoms can be milder or more indolent. *P. falciparum* deserves special attention because it causes the majority of severe malaria due to its ability to lodge in microvasculature and obstruct blood flow. Look out for cerebral malaria (seizure, coma), shock, acidosis, severe anemia, respiratory distress (ARDS), hypoglycemia, and renal failure. Anemia occurs through a combination of hemolysis and bone marrow suppression.

Diagnosis is made by microscopic analysis of blood smears. Thick blood smears analyze a larger volume of blood by lysing RBCs and looking for parasites. Thin blood smears are used to make a species diagnosis based on the stage and appearance within intact RBCs.

Appropriate treatment of malaria depends on 3 factors:

- 1) Species
- 2) Geographic region
- 3) Illness severity

As we go through the following discussion, refer to Table 4-7.

Plasmodium falciparum

P. falciparum causes the most severe malaria and is the cause of virtually all fatal malarial infections. It has widespread chloroquine resistance.

Differentiating this species from the others is critical because *P. falciparum* causes the large majority of the mortality attributed to malaria throughout the world. *P. falciparum* has several unique findings on blood smears that facilitate this identification: banana-shaped

gametocytes (Figure 4-36); double chromatin knobs (giving the parasite the appearance of headphones); > 1 parasite per cell; and the number of infected RBCs being $> 5\%$.

Figure 4-36: *P. falciparum* banana-shaped gametocytes
Source: CDC

Treatment for *P. falciparum* malaria depends on the country of acquisition. Chloroquine-susceptible regions are still present in 4 parts of the world. Malaria acquired from these areas can safely be treated with chloroquine:

- 1) Central America north of Panama
- 2) Haiti
- 3) Dominican Republic
- 4) Middle East

P. falciparum from other areas must be assumed to be chloroquine resistant. Treat nonsevere disease (i.e., no end-organ damage) with artemether/lumefantrine (Coartem) or atovaquone/proguanil. Treat patients with severe disease with artesunate.

Non-*P. falciparum*

Assume *P. vivax* from Papua New Guinea, Indonesia, and Southeast Asia is chloroquine resistant; otherwise, all non-*P. falciparum* species are chloroquine sensitive, so treat with chloroquine.

Table 4-7: Treatment and Prophylaxis of Malaria

Type of Malaria	Treatment	Prophylaxis
Non- <i>falciparum</i> malaria	Chloroquine, followed by primaquine	Chloroquine 500 mg (300 mg base) weekly; give daily in endemic areas, and continue for 4 weeks after return.
<i>P. falciparum</i> Chloroquine-sensitive	Chloroquine Atovaquone/proguanil	Choose any 1 of the following: • Chloroquine • Atovaquone/proguanil • Mefloquine • Doxycycline
<i>P. falciparum</i> Chloroquine-resistant Not severe	Atovaquone/proguanil or Mefloquine	
<i>P. falciparum</i> Chloroquine-resistant Severe	Artesunate Artemether/lumefantrine Alternative: IV quinidine gluconate with either doxycycline or clindamycin	Atovaquone/proguanil 1 dose daily, including 1–2 days before travel and 7 days after return, or Mefloquine 1 dose weekly, including 1 week before and 4 weeks after, or Doxycycline 100 mg 1–2 days before and continued 4 weeks after

Treat resistant isolates with artemether/lumefantrine (Coartem), atovaquone/proguanil, quinidine + doxycycline, or mefloquine.

Primaquine is adjunctive medication for infections with *P. vivax* and *P. ovale* to eradicate hypnozoites in the liver. Hypnozoites are the malarial forms responsible for relapse. Remember that primaquine induces hemolytic anemia in glucose-6-phosphate dehydrogenase (G6PD)-deficient persons, so you must screen for G6PD deficiency before prescribing it.

Prophylaxis

In chloroquine-sensitive areas: Use chloroquine. Start it 1–2 weeks before the patient departs to the endemic area and continue 4–6 weeks after they leave the area.

In chloroquine-resistant areas: Use mefloquine or atovaquone/proguanil. Start 2 weeks prior or 2 days prior to travel, respectively. Atovaquone/proguanil is preferred because of the easier dosing schedule and lack of neurologic side effects.

Doxycycline has activity against chloroquine-sensitive and chloroquine-resistant malaria, and it can be used for prophylaxis at a dose of 100 mg daily. The advantage is that it is very inexpensive; the disadvantages are that it can cause photosensitivity, must be taken daily, and must be taken for 4 weeks after leaving the endemic area.

Malaria in pregnancy can be particularly severe, so prevention is key. Deferment of travel should be considered. If travel cannot be delayed, practice mosquito avoidance in combination with chemoprophylaxis. For chloroquine-sensitive regions, use chloroquine. For chloroquine-resistant regions, use mefloquine.

Babesia

Babesia microti is an intra-RBC protozoan parasite indigenous to the U.S. that causes babesiosis. Similar to malaria, it causes a febrile hemolytic anemia, and asplenic patients are at increased risk for severe disease.

The organism is transmitted via the *Ixodes* tick, as is the spirochete *Borrelia burgdorferi*, which causes Lyme disease. It is most prevalent in the northeast U.S. and upper Midwest, usually in summer or early autumn. The primary animal hosts are the white-footed mouse and white-tailed deer. Rare cases result from blood transfusion.

Symptoms, which can persist for months, include fever, profuse sweats, myalgias, and shaking chills. Severe cases cause liver, renal, and neurologic failure and death. Hemoglobinuria is a predominant sign.

Diagnosis is made by thick and thin blood smears. These may need to be repeated if tests are initially negative but there is high clinical suspicion. Serologies and

serum PCR can be helpful with low level parasitemia and when differentiating from malaria is difficult. Travel history is important for the microbiology lab because babesiosis can be misdiagnosed as malaria.

B. microti distinguished from *Plasmodium* by being pear-shaped. *B. microti* occasionally form a tetrad, appearing as a Maltese cross.

Figure 4-37 shows the *Babesia* parasites in both ring and tetrad forms.

PCR assays are available and more sensitive than peripheral smears.

Mild babesiosis infections are usually self-limited. Treat moderate infections with atovaquone + azithromycin and severe cases with clindamycin + quinine and consider an exchange transfusion.

Figure 4-37: *Babesia* parasites in both tetrad and ring forms

Genitourinary (GU) Protozoans

Trichomonas vaginalis

Trichomonas vaginalis causes trichomoniasis, an STI. Treat with metronidazole. See more about this under Trichomoniasis on page 4-21.

HELMINTHIC ORGANISMS

Helminthic organisms are multicellular worms that cause eosinophilia. Helminthic organisms consist of roundworms (nematodes) and flatworms, which are divided into tapeworms and flukes. With the exception of *Strongyloides*, helminthic organisms do not replicate in the human host.

In Figure 4-38, we classify the helminthic parasites in terms of the systems they affect.

Roundworms (Nematodes)

Nematode infections are listed in Table 4-8 on page 4-64.

Intestinal Roundworms

Ascaris lumbricoides (Roundworm)

- Cause ascariasis
- Epidemiology: Worldwide, > 1 billion people are infected—predominantly in tropical and subtropical regions with poor hygiene. Humans are the sole host. In the U.S., 2% overall are infected (worse in the rural South), with up to 30% of young children affected in some areas.

Figure 4-38: Classification of parasites—helminths

- Life cycle: Eggs (Figure 4-39) are ingested and hatch in the small intestine; the larvae penetrate the intestinal wall and migrate to the lungs, where they mature over 10 days. Then they ascend the bronchial tree, which generates a cough reflex, and are then swallowed. They mature into adult worms in the small intestine, and eggs are excreted in the stool. Eggs can live for up to 10 years in dark, moist conditions. Worms may migrate into the biliary tree and the appendix.
- Presentation (if symptomatic): pulmonary eosinophilic syndrome (a Löffler-type syndrome) in early phase of infection, malnutrition, acute appendicitis, biliary obstruction including ascending cholangitis
- Diagnosis: microscopy, demonstrating eggs (and rarely, worms) in stool
- Treatment: albendazole or mebendazole

Figure 4-39: Roundworm egg
Source: CDC

Trichuris trichiura (Whipworm)

- Epidemiology: Worldwide, > 1.5 billion people are infected (~ 25% world's population), mainly children. Found in warm, moist places with poor sanitation, similar to *Ascaris*; coinfection is not uncommon.
- Life cycle: Eggs are ingested, hatch in small intestine, and mature in caecum and ascending colon where they embed in epithelial layer; eggs are excreted in stool. There is no lung stage.
- May present with eosinophilia

- Presentation (if symptomatic): chronic colitis in children, *Trichuris* dysentery syndrome (diarrhea with mucus, blood, tenesmus, abdominal pain, and rectal prolapse)
- Diagnosis: stool microscopy demonstrating eggs in stool
- Treatment: albendazole for 3 days; repeat Rx prn.

Necator americanus and *Ancylostoma duodenale* (Hookworm)

- Epidemiology: *Necator* is endemic in the U.S. but can be found throughout the Americas, India, Africa, and Indonesia. *Ancylostoma* is found in the Mediterranean, Iran, India, Pakistan, and the Far East. Acquisition requires coming into barefoot contact with larvae in the soil that have hatched from eggs excreted by humans. People walking barefoot or with open sandals in contaminated areas are at risk.
- Life cycle: Larvae penetrate the skin, migrate to the lungs and up the bronchial tree, cough reflex occurs, and then the larvae are swallowed. Once in the small intestine, they mature and attach to the intestinal wall, where they feed. Eggs are excreted in stool.
- Presentation (if symptomatic): cutaneous itching at the site of larval entry (ground itch) and serpiginous eruption along the course of the larvae's migration (cutaneous larval migrans [CLM]). Pneumonitis can occur during pulmonary migration, although it is less severe than that of *Ascaris*. Chronic infection leads to iron deficiency anemia from chronic GI blood loss and hypoalbuminemia in persons already malnourished. Persistent eosinophilia may also be present.
- Diagnosis: stool microscopy demonstrating eggs in stool
- Treatment: single dose of albendazole

Table 4-8: Nematode Infections

Genus	Common Name	Route of Acquisition	Life Cycle in Humans	Signs and Symptoms*	Diagnosis	Treatment
<i>Ascaris</i>	Ascariasis	Ova ingestion	Eggs → larvae through lungs → swallowed → adults in bowel	PES; can obstruct bile duct or appendix	Stool ova	Albendazole or mebendazole
<i>Trichuris</i>	Whipworm	Ova ingestion	Eggs ingested → hatch in small intestine → mature in caecum and ascending colon → excrete eggs in stool	Diarrhea; abdominal pain; blood in stool; rectal prolapse	Stool ova	
<i>Ancylostoma</i> ; <i>Necator</i>	Hookworm	Larvae enter through skin	Soil larvae → penetrates skin → through lungs → swallowed → adults attach and feed in bowel	Ground itch; CLM; iron deficiency; hypoalbuminemia	Stool ova	
<i>Strongyloides</i>	Strongyloidiasis	Larvae enter through skin; only spp. to autoinfect	Soil larvae → penetrates skin → through lungs → swallowed → adults attach, mate in bowel, produce more larvae → cycle repeats	Ground itch; CLM; PES; abdominal pain; N/V/D; immunocompromised hyperinfection with multiorgan invasion and shock	Stool larvae, serology in immuno-competent	
<i>Enterobius</i>	Pinworm; threadworm	Ova ingestion	Eggs → hatch to adults → lay perianal eggs	Perianal itch	Tape test	Albendazole
<i>Trichinella</i>	Trichinellosis	Cysts in undercooked meat ingested	Excyst → adult releases larvae → blood → muscle	Muscle pain; high worm burdens can affect the CNS, lungs, heart, and kidneys	Muscle biopsy; serology	Albendazole with glucocorticoids
<i>Wucheria</i> ; <i>Brugia</i>	Filariasis	Mosquito injects larvae	Larvae in lymphatics → adult → releases microfilaria → ingested by next mosquito	Acute fever; microfilaria in lungs cause wheezing; lymphedema	Blood smears for microfilaria; best around midnight	Diethyl-carbamazine (only available from CDC)
<i>Toxocara</i>	Toxocariasis	Ova ingestion	Eggs → larvae migrate through tissues	Hepatomegaly; myocarditis; PES; eosinophilic meningitis; myalgia; ocular lesions	Serology	Albendazole
<i>Angiostrongylus</i>	Rat lungworm; angiostrongyliasis	Ingestion of larvae in snails and others	Larvae enter blood → CNS or mesenteric arteries	Headache; eosinophilic meningitis or abdominal pain; N/V; GI bleed and perforation	Organisms in CSF (rare) or on bowel biopsy (rare)	No drug available; surgery for ocular complications

*if present

CLM = cutaneous larval migrans

N/V/D = nausea, vomiting, and diarrhea

PES = pulmonary eosinophilic syndrome (fleeting infiltrates, cough, wheeze, and eosinophilia)

Strongyloides stercoralis (Strongyloidiasis)

- **Epidemiology:** endemic in soil throughout tropical regions of the world and in parts of the U.S. It is the only helminthic organism that can complete its life cycle within the human body, resulting in **autoinfection** and persistence of infection. The filariform larvae penetrate the perianal or colonic mucosa to complete the autoinfection cycle. This can lead to overwhelming worm burden in immunocompromised patients. Patients who are immune suppressed are at greatest risk for hyperinfection syndrome, including steroid use, HTLV infection, advanced HIV/AIDS, organ or bone marrow transplantation, and chemotherapy.
- **Life cycle:** Like hookworm, the *Strongyloides* larvae penetrate the skin (usually after walking barefoot on feces-contaminated ground) and migrate to the lungs. They then migrate up the tracheobronchial tree, produce a cough reflex, and are swallowed. Once in the small intestine, they attach to the mucosa and mature. Adult female worms produce eggs that hatch into **noninfectious** rhabditiform larvae, which are mostly excreted in the stool. However, some of these noninfectious larvae convert to infectious filariform larvae while still within the small intestine. These larvae penetrate the wall of the colon or perianal skin to hematogenously travel to the lung, just like exogenously introduced larvae do.
- **Presentation (if symptomatic):**
 - Like hookworm, itching at the site of larval entry (ground itch) and a fast-moving serpiginous eruption along the course of the larvae's migration (larva currens) can occur; this is pathognomonic.
 - Pulmonary eosinophilic pneumonitis can occur, causing a Löffler-like syndrome.
 - GI symptoms include abdominal pain, nausea, vomiting, and diarrhea.
 - ***Strongyloides* hyperinfection syndrome** is seen in immunocompromised hosts. Those who receive high-dose steroids, and those with advanced HIV or HTLV-1 are at particular risk. This represents an augmented and accelerated autoinfection cycle. As worms migrate out of the GI tract, they can bring bacteria with them—think of this with polymicrobial GNR bacteremia or community-acquired GNR meningitis. Perhaps counterintuitively, peripheral eosinophilia may be **absent** in these patients due to blunted immune response.
 - **Diagnosis:** Larvae in the stool are diagnostic but are seen in < 50% of those infected. Serology is useful in immunocompetent patients. In hyperinfection syndrome, many larvae can often be seen in respiratory samples. *Strongyloides* are sometimes encountered incidentally on a culture plate; see Figure 4-40.
- **Treatment:** Ivermectin is the drug of choice; albendazole is a less effective alternative. Repeat treatment after 2 weeks for eradication.

Figure 4-40: *Strongyloides* (serpiginous trail wandering around bacterial colonies)

Source: Nathaniel Warner, MD

Enterobius vermicularis (Pinworm, Threadworm)

- **Epidemiology:** **most common** helminthic infection in the U.S.; humans are the only host. Occurs commonly in school-aged children and their families.
- **Life cycle:** Eggs (Figure 4-41) are ingested and hatch in the small intestine. Gravid females migrate to the rectum and, at night, lay eggs in the perianal area. Autoinfection is possible (i.e., scratch anal area with hands and ingest eggs via contaminated hands).
- **Presentation (if symptomatic):** perianal itching
- **Diagnosis:** microscopic exam of transparent tape that was touched upon the perianal area demonstrating eggs and sometimes female worms (Scotch tape test)
- **Treatment:** single dose of albendazole, followed by repeat dose in 2 weeks to kill worms from hatched eggs. Strict hand hygiene. Treat the entire household.

Figure 4-41: Pinworm eggs

Source: CDC

Tissue Roundworms

Trichinella spp. (Trichinellosis)

- Epidemiology: ~ 10,000 cases worldwide are reported per year. *T. spiralis* is the most common *Trichinella* species in the U.S. The main sources of the disease are undercooked wild game (e.g., bear, wild boar) and domesticated pigs (pork). In the U.S., ~ 20 cases are reported each year, although there is a much higher incidence seen on autopsy.
- Life cycle: Cysts in undercooked meat are ingested then excyst and mature into adults in the small bowel, where they release larvae that invade via the blood into the muscle, where they burrow and encyst in a muscle cell.
- Presentation (if symptomatic):
 - Intestinal phase (week 1): invade small bowel mucosa, patients may experience watery diarrhea, abdominal pain
 - Muscle phase (> week 1): hematogenous dissemination and encystment into striated muscle; muscle pain, fevers, splinter hemorrhages
 - Eosinophilia is common. High worm burdens can affect the CNS, lungs, heart (e.g., fatal cardiomyopathy), and kidneys.
- Diagnosis: Serology is available and turns positive after several weeks. Muscle biopsy may be performed to look for cysts. High-grade eosinophilia is almost always present.
- Treatment for mild cases is supportive. For systemic infections, treat with albendazole for 10–14 days. Give glucocorticoids to suppress the inflammatory consequences of worm death.

Wuchereria bancrofti, *Brugia malayi*, and *Brugia timori* (Lymphatic Filariasis)

- Epidemiology: > 100 million people worldwide are infected, and 1/3 of those infected are symptomatic. These worms are transmitted via mosquito bites. Most cases occur in sub-Saharan Africa, Southeast Asia, Indian subcontinent, and Pacific islands. Epidemiology may change as countries adopt mass drug administration campaigns.
- Life cycle: A mosquito introduces larvae into the skin during feeding. Larvae enter the lymphatics and mature over 9 months. Adult worms then produce microfilariae that migrate into the cutaneous blood vessels, with timing synchronized to the specific mosquito species involved. The microfilariae are ingested by another mosquito, develop into larvae, and can be transmitted to another human.
- Presentation (if symptomatic)—primarily related to lymphatic obstruction:
 - Acute infection causes a nonspecific febrile illness in a traveler (**filarial fever**) that can be similar to malaria. There may be associated tender lymphadenopathy, which is called acute adenolymphangitis.

– **Tropical pulmonary eosinophilia** is due to microfilariae trapped in the lungs and causes nocturnal wheezing.

- Chronic infection leads to lymphatic obstruction, scarring, and severe lymphedema (**elephantiasis**).
- Diagnosis: blood smears (best obtained around midnight) to identify microfilariae from blood
- Treatment: Diethylcarbamazine kills the larvae and adult worms. It must be obtained from the CDC.

Toxocara canis and *Toxocara cati* (Toxocariasis, Visceral Larva Migrants)

- Epidemiology: *T. canis* (the dog ascarid) is more common than *T. cati* (the cat ascarid). It occurs worldwide, with a 14% prevalence in the U.S. Humans are not normal hosts for these helminths and are not a required part of their life cycle.
- Life cycle: The adult worm sheds eggs in the stool of its animal host. If humans ingest these eggs, they hatch into larvae that travel through tissue and elicit an immune response. The larvae subsequently die.
- Presentation (if symptomatic): Migrating larvae (**visceral larva migrants**) can cause injury to the liver (causing hepatomegaly), heart (causing myocarditis), lungs (fleeting pulmonary infiltrates, shortness of breath, cough, wheeze), brain (eosinophilic meningoencephalitis), muscle (myalgias), and eyes. Presentation is typically accompanied by eosinophilia.
- Diagnosis: ELISA IgG serology is available.
- Treatment: Self-limiting; antiparasitic typically not required. If necessary, give albendazole for 5 days.

Angiostrongylus cantonensis and *Angiostrongylus costaricensis* (Angiostrongyliasis, Rat Lungworm)

- Epidemiology: *A. cantonensis* is endemic in southeast Asia and tropical Pacific islands and is the most common parasitic cause of eosinophilic meningitis. *A. costaricensis* is endemic in Latin America and the Caribbean. The parasite is passed between rats and mollusks (e.g., slugs, snails) to complete its life cycle; humans are accidental hosts.
- Life cycle: *A. cantonensis* eggs found in rat stool are ingested by snails and slugs. If the snail or slug is eaten by humans, the larvae can migrate to the central nervous system, causing eosinophilic meningitis.
- Presentation (if symptomatic): *A. cantonensis* causes symptoms typical of meningitis that can be self-limiting or neuroinvasive. Headache is the most prominent symptom, and LP yields an eosinophilic inflammatory response. *A. costaricensis* causes abdominal pain, fever, and vomiting and can progress to GI bleeding and perforation.
- Diagnosis: *A. cantonensis* is rarely visualized in the CSF, so diagnose based on the presence of eosinophilic meningitis in the appropriate epidemiologic setting.

- Treatment: *A. cantonensis*—the disease is self-limited, and no antiparasitic drugs have been shown to be effective. *A. costaricensis*—antiparasitic drugs are not effective and may cause worm migration and worsening symptoms. Perform surgery for ocular complications.

Flatworms

Tapeworms (Cestodes)

Clinically important tapeworms include *Taenia solium* (pork tapeworm), *Taenia saginata* (beef tapeworm; usually asymptomatic), *Diphyllobothrium latum* (fish tapeworm; occasionally causes vitamin B₁₂ deficiency because it competes with the ileum for absorption), and *Echinococcus*.

T. solium is endemic in many regions of Central and South America, sub-Saharan Africa, India, and Asia. Although it is called the pork tapeworm, humans are the definitive host. It is important to recall the life cycle of *T. solium* in order to understand the 2 manifestations of human disease it causes: extraintestinal disease (in its larval form) and intestinal disease (when it is an adult worm).

Extraintestinal Tapeworm Disease (Larval Form)

If *T. solium* eggs are ingested, they hatch in the bowel and become oncospheres that invade the bloodstream to encyst in tissues (most commonly the central nervous system) as cysticerci—causing **neurocysticercosis**. CNS cysticerci can be in the parenchyma or be extraparenchymal in the CSF, where they usually lodge in the aqueduct of Sylvius. Cysticerci are able to suppress the human host response and thus remain asymptomatic until the organism dies, when an inflammatory response ensues. The most common presentation is seizure, followed by hydrocephalus, depending on the location of cysts within the brain or ventricles. Intraocular, subarachnoid, and extra-CNS cysts occur as well.

Patients with suspected neurocysticercosis should have a head CT as well as an MRI. Diagnosis is typically made based on characteristic findings of cysts, and confirmed with serologic testing. Screen patients who will require steroids for latent tuberculosis and *Strongyloides* to prevent reactivation and hyperinfection while on steroids. Prior to starting antiparasitics, do a dilated funduscopic exam to rule out intraocular disease.

Treatment of neurocysticercosis is complex and frequently requires a multidisciplinary approach. Type and timing of treatment depends on location, viability, and number of cysts, as well as the presence of CNS edema and hydrocephalus.

Treatment is recommended in patients presenting with seizures. For < 2 viable intraparenchymal cysts, use albendazole. If > 2 intraparenchymal cysts are present, add praziquantel to albendazole. Corticosteroids are recommended to reduce risk of seizures during therapy. Antiparasitic therapy is **not** recommended if

only calcified, nonviable cysts are present—or if cerebral edema, untreated hydrocephalus, or intraocular lesions are present. These cases are typically treated with a combination of steroids and surgery, in collaboration with infectious disease and neurosurgical specialists. Cutaneous and intramuscular disease can be treated with analgesics.

Echinococcus species also cause an extraintestinal disease—**hydatid disease**—in which hydatid cysts proliferate throughout the body. It is acquired after ingesting food contaminated with feces from the definitive hosts, which are other mammals (e.g., sheep, dogs, rodents, foxes). Most cases are diagnosed in immigrants from endemic regions (i.e., Asia, Europe, South/Central America, the Middle East); hunters and veterinarians are also susceptible. The initial phase of infection is typically asymptomatic, and most people are infected as children. The liver is the most common organ affected (especially with *E. granulosus*), followed by the lungs (especially with *E. multilocularis*). The right lobe of the liver is most commonly affected, and generally presents as a single large cyst. Complications can occur due to mass effect of the cyst, cyst rupture into the biliary tree or peritoneum, or cyst infection. Ultrasound or other imaging is diagnostic and can be confirmed with a serologic test, usually ELISA. Treatment with surgical techniques is evolving, but open surgery is recommended for large cysts (> 10 cm). Therapy with albendazole before and after surgery is useful.

Intestinal Tapeworm Disease (Adult Worm Form)

If *T. solium* cysts are ingested from undercooked pork, the organism excysts and grows into the adult tapeworm in the gut (taeniasis). A person carrying a tapeworm then starts shedding eggs. Most people with a tapeworm have no symptoms. Niclosamide is the usual treatment for all intestinal tapeworms, including beef and fish tapeworm.

Flukes (Trematodes)

Fluke common names are based on the part of the body in which the adult worm resides. In humans, there are blood, liver, and lung flukes. Liver and blood flukes increase risk of cancer. [Table 4-9 on page 4-68](#) summarizes them all.

Blood Flukes (Schistosomes)

There are 5 species of schistosomes: *Schistosoma mansoni*, *japonicum*, *haematobium*, *intercalatum*, and *mekongi*. The latter 2 species are geographically limited, uncommon, and will therefore not be discussed further.

S. mansoni is endemic to Africa, South America, and the Caribbean. *S. japonicum* is in East Asia. *S. haematobium* is found in Africa and the Middle East.

The infectious form for all species is cercariae, which are released from snails in fresh water and can penetrate intact skin. These lose their tails and become schistosomula, which migrate to the liver where they mature into

Table 4-9: Fluke Infections

Genus	Common Name	Route of Acquisition	Life Cycle in Humans	Signs and Symptoms	Diagnosis	Treatment
<i>Clonorchis</i> , <i>Opisthorchis</i> , <i>Metorchis</i> , <i>Fasciola</i>	Liver flukes	Ingestion of metacercariae in raw fish; water vegetables	Metacercariae → biliary tree → adult fluke resides	Biliary obstruction, cholangiocarcinoma	Stool or bile ova	Praziquantel; triclabendazole
<i>Paragonimus</i>	Lung flukes	Ingestion of metacercariae in crabs and crayfish	Metacercariae penetrate bowel → cross diaphragm to lung → adult fluke resides	Cough, hemoptysis, pleuritic pain, fever	Sputum/BAL ova, stool ova	Praziquantel
<i>Schistosoma</i>	Blood flukes	Cercariae enter through skin	Cercariae migrate to liver → adult fluke can then → enter mesenteric veins or vesicular plexus	Swimmer's itch, Katayama fever (fever, chills, myalgias, abdominal pain, lymphadenopathy, hepatosplenomegaly, eosinophilia), bladder cancer, portal hypertension, cirrhosis, and esophageal varices	Stool ova; urine ova (<i>S. haematobium</i> only)	Praziquantel

motile adult flukes. From there, they swim upstream through the portal vein to spend their adult lives in their preferred venous system: *S. mansoni* in the inferior mesenteric vein, *S. japonicum* in the superior mesenteric vein, and *S. haematobium* in the vesicular venous plexus.

Initial penetration of the cercariae can produce local inflammation and itching after swimming in fresh water (swimmer's itch). If large numbers invade, an acute syndrome (**Katayama fever**) occurs 3–8 weeks after inoculation. This presents with fever, chills, myalgias, abdominal pain, lymphadenopathy, hepatosplenomegaly, and marked eosinophilia. This spontaneously resolves.

The flukes themselves do not cause symptoms, but the eggs they shed do. *S. haematobium* eggs cause inflammation and fibrosis of the bladder wall with symptoms of UTI, and they predispose to bladder cancer. *S. mansoni* and *S. japonicum* shed eggs into the portal venous system, leading to portal hypertension, cirrhosis, and esophageal varices.

Diagnose by finding the eggs in the stool or urine, depending on the species. Treat with a 1-day course of praziquantel.

Liver Flukes

Clonorchis sinensis is the Chinese liver fluke, which is endemic in the Far East. *Opisthorchis felinus* and *viverrini* are endemic in Eastern Europe and Asia. *Metorchis conjunctus* is endemic in Canada. Infection from all ensues after eating the metacercariae in raw fish, which mature to adult flukes that live in the biliary tree and can cause biliary obstruction and cholangiocarcinoma. Diagnose by finding eggs in bile (from an ERCP) or stool. Treat with praziquantel. *Fasciola hepatica* is a fluke that infects livers of mammals. Its primary hosts are cattle and sheep throughout most temperate zones in the world.

Eggs shed by these develop into metacercariae that encyst on nearby watercress and, if ingested, become mature flukes in the human biliary tree. The mature fluke can obstruct or migrate through the liver. Treat with triclabendazole (available through the CDC under investigational protocol) or, as 2nd line, nitazoxanide. Praziquantel is not effective.

Lung Flukes

Paragonimus westermani is the human lung fluke. It is endemic in the Far East and West Africa but also is found in the Americas. It is acquired by ingestion of metacercariae in crabs and crayfish. They penetrate the duodenum into the abdominal cavity and then penetrate the diaphragm and pleura to enter the lung parenchyma, where they mature into adults that lay eggs. They are coughed up and then swallowed and defecated back into the environment. If symptomatic, the predominant symptoms are cough, hemoptysis, pleuritic chest pain, and fever. Pleural effusions, if they occur, are eosinophilic. Diagnose by finding the ova in sputum, BAL, or stool. Treat with praziquantel.

VIRUSES

PREVIEW | REVIEW

- Multinucleated giant cells can be seen with which viral infections?
- What is the most sensitive and specific method for diagnosing herpes simplex virus encephalitis?

HERPES SIMPLEX VIRUS (HSV)

HSV (a DNA virus) is spread person to person, usually through asymptomatic shedding. Both HSV-1 and HSV-2 cause vesicular lesions, with HSV-1 predominating in the orofacial area and HSV-2 in the genital area. If the virus is in its preferred location, it is more likely to recur.

HSV-1 causes orofacial infections in ~ 40% of the population, although the seropositivity rate is much higher. In the primary infection, the vesicular lesions and ulcers are usually localized to the oral mucosa, lips, and surrounding skin and are commonly accompanied by constitutional symptoms. Recurrent infection ulcers are typically just on the outer lip. It is possible to autoinoculate the virus, so the infection can spread, for example, from the lips to the eyes of a patient.

Recurrent HSV-1 eye infection resulting in keratitis is the most common infectious cause of blindness in industrialized nations. See the [General Internal Medicine](#) section.

Tzanck smears are performed by scraping down to the bottom of a vesicle, placing the material on a slide, then staining with either Giemsa or Wright stain. In herpes simplex and varicella-zoster virus infections, it shows **multinucleated giant cells** (Figure 4-42). However, in current clinical practice, PCR and direct fluorescent antibody (DFA) are the most commonly used diagnostic tests and should be done to confirm the diagnosis if the clinical picture is not diagnostic.

HSV-2 causes ~ 75% of HSV genital infections—the rest are due to HSV-1. The prevalence of HSV-2 is 1 in 6 Americans 14–49 years of age. Most cases of neonatal

Figure 4-42: Multinucleated giant cell

HSV are from intrapartum contact, so a C-section is recommended if the mother has symptoms or signs of genital herpes or has a typical prodrome at the time of delivery. HSV reactivates in 2/3 of seropositive transplant patients within 6 weeks of transplant, but this rate is drastically **lower** in patients receiving antiviral prophylaxis.

HSV encephalitis is the most common cause of sporadic viral encephalitis and causes the highest number of deaths due to viral encephalitis in adults. Patients with HSV encephalitis usually present with fever, altered mental status, seizures, and/or focal neurologic deficits. The virus has a predilection for the frontal and temporal lobes. Prognosis is poor, and > 60% have neurologic sequelae. MRI is usually abnormal, potentially showing hemorrhage in the temporal lobe. Do not delay LP and empiric treatment to obtain an MRI. CSF typically shows increased protein, lymphocytic pleocytosis, and increased red cells, but it can be normal in early infection. Diagnosis of HSV by PCR in CSF is the most sensitive (98%) and specific (97%) test. False negative testing can occur early in clinical course, so if high clinical suspicion remains despite a negative test, consider repeating CSF HSV PCR 3–7 days later before stopping IV acyclovir.

HSV is one of many causes of erythema multiforme. See the [Dermatology](#) section.

Treatment of HSV: Initial or recurrent mucocutaneous HSV can be treated with acyclovir PO, but this is beneficial only if treatment is given within the first 72 hours. Famciclovir and valacyclovir are similarly effective but more expensive—although they have more convenient dosing. Give acyclovir after 72 hours if the patient is immunocompromised. For HSV encephalitis, give IV acyclovir for 14–21 days. Give IV acyclovir if there is disseminated HSV (e.g., lung, skin, liver). Acyclovir (or famciclovir or valacyclovir) can also be given in low doses chronically to suppress infection in those with frequent recurrences. Use foscarnet to treat those with HSV resistant to acyclovir; ganciclovir is **not** used because cross-resistance is common in acyclovir-resistant strains.

VARICELLA-ZOSTER VIRUS

Varicella-zoster virus (VZV; a DNA virus) causes varicella (chickenpox) when initially acquired and herpes zoster (shingles) if it recurs.

Varicella (Chickenpox)

Varicella is an airborne, highly contagious disease that causes a characteristic pruritic, vesicular eruption that comes in successive crops. On exam, these skin lesions are typically found in various stages, from new erythematous papules to vesicles to crusted-over lesions—this is in contrast to smallpox, where lesions are all in the same stage of development (Figure 4-43 on page 4-70).

Figure 4-43: Chickenpox lesions in various stages

Patients are contagious for 1–2 days before eruption and stay contagious until the last lesion has crusted over. These pox marks do not leave scars unless superinfected or manipulated.

Patients have a characteristic prodromal phase with fever, malaise, pharyngitis, myalgias, nausea, and headache.

Varicella symptoms are usually mild in children but can be severe in adolescents and adults, especially in pregnant women, in whom pneumonia is more likely to occur.

Diagnosis is made clinically based on the classic appearance of the rash. DFA or PCR can be used for atypical-appearing rashes.

Treat all adult patients with PO acyclovir if they present within 24 hours of rash onset. This treatment decreases the number of lesions and the duration of disease. Give IV acyclovir for noncutaneous organ involvement and to patients who are immunocompromised.

Patients at increased risk of developing severe varicella infection are those who are:

- not currently immune because they have never had varicella or the vaccine,
- currently immunocompromised, or
- pregnant.

There are two varicella (chickenpox) vaccines on the market: a single antigen varicella vaccine (Varivax), and a combination measles, mumps, rubella, and varicella vaccine. Vaccination is recommended in all infants > 12 months, children, and adults who do not have immunity to varicella.

Herpes Zoster (Shingles)

Herpes zoster manifests as grouped vesicles along a dermatome with focal pain. Older age and immunosuppression (e.g., HIV) are risk factors.

Zoster is caused by reactivation of the varicella-zoster virus. After the initial infection, the virus becomes dormant and asymptomatic in sensory ganglia neurons until it is reactivated and spreads down the nerve, causing a painful rash.

Reactivation causes a prodromal phase with constitutional symptoms followed by hyperesthesia and a burning, frequently lancinating pain over the dermatome. This is followed by the characteristic vesicular skin rash localized to that dermatome.

The most common dermatomes involved are the thoracic dermatomes. Usually 1 thoracic dermatome is involved, but occasionally it involves 1–2 more. If there are > 3 dermatomes involved, or > 30 lesions outside of the primary dermatomes, it is considered disseminated zoster.

In ~ 10–20% of patients, the ophthalmic branch of the trigeminal nerve is involved, which can be sight-threatening if zoster keratitis results. Consider this in a patient with the classic vesicular lesions appearing on one side of the face anywhere on the forehead, nose, and periorbital area. This requires emergent treatment and referral.

Herpes zoster oticus (**Ramsay Hunt syndrome**) affects several cranial nerves; it presents with vesicles in the external auditory canal and tympanic membrane, along with ipsilateral facial paralysis and ear pain.

As with varicella, zoster lesions are contagious until crusted over, and they can give a nonimmune person varicella. Unlike varicella, there is no respiratory transmission with shingles; if the patient is hospitalized, use standard precautions alone, unless the lesions are disseminated.

Rash duration is ~ 2–4 weeks. If there are any new lesions after 7–10 days, consider underlying cell-mediated immunodeficiency. Immunocompromised patients are at increased risk for dissemination, which can include internal organ involvement (e.g., CNS, lung, liver). Shingles recurs in < 5% of immunocompetent patients.

Postherpetic Neuralgia

Postherpetic neuralgia (PHN) is the most common complication (~ 10% overall) of zoster, and it is more likely to occur with increasing age (20% in those > 80 years of age). It can cause a lancinating, sometimes debilitating pain for many months to years.

Treatment

If started within 72 hours of onset, antiviral therapy with acyclovir, famciclovir, or valacyclovir decreases disease duration of disease, severity of the initial pain, and incidence of PNH.

Adding prednisone provides no additional benefit and may prolong the course of herpes zoster in immunosuppressed patients.

For pain control, tricyclic antidepressants, gabapentin, pregabalin, and lidocaine patches have some efficacy. Opiates can be useful but remain controversial due to dependency. Capsaicin cream is useful after the lesions have healed.

Regarding work restrictions for health care personnel, the following apply:

- Any health care worker with disseminated zoster should stay home until lesions are fully scabbed over.
- Immunocompromised health care personnel with dermatomal zoster (as well as immunocompetent healthcare personnel with dermatomal zoster who work with immunocompromised patients) should not return to work until all lesions are fully crusted over.
- Health care personnel with dermatomal zoster who are immunocompetent and do not work with immunosuppressed patients can return to work, as long as they can cover up their lesions with a bandage and clothing.

Vaccination for Herpes Zoster

The most recent zoster vaccine, called recombinant zoster vaccine (RZV; Shingrix), was approved by the FDA in October 2017. It is a recombinant vaccine as opposed to the previous live attenuated vaccine (Zostavax). The Advisory Committee on Immunization Practices (ACIP) and the CDC recommend the recombinant vaccine for all healthy adults > 50 years of age. The ACIP also recommends that those who received the earlier zoster vaccine be revaccinated with the newer version.

In those 50–69 years of age, recombinant zoster vaccine (RZV; Shingrix) has an effectiveness of 97% and 91% in preventing herpes zoster and PHN, respectively. At > 70 years of age, this falls a little to 91% and 89%. This is much better than Zostavax (attenuated live vaccine), with an overall effectiveness of only 50% and 75%. The longer-term immune response of Shingrix also appears to be much better.

As opposed to the first vaccine, with only 1 dose required, Shingrix requires 2 total doses repeated 2–6 months apart.

CYTOMEGALOVIRUS (CMV)

Cytomegalovirus (CMV; a DNA virus) is in the herpes virus family. CMV infection in the normal population is fairly common; 50% of the population has anti-CMV antibodies by 35 years of age.

CMV infection in the immunocompetent population is typically asymptomatic, but ~ 10% have a mononucleosis-type illness with fever, sore throat, adenopathy, fatigue, and hepatitis. Exudative pharyngitis is rare. Think of this in a monospot-negative adult with these symptoms, especially in younger to middle-aged individuals, because EBV mono usually occurs more often in adolescents. Also consider acute HIV with this presentation.

CMV is a very common infection in patients with decreased cellular immunity (e.g., posttransplant, AIDS). Pretransplant donor and recipient CMV IgG serologies are very important to guide use of antiviral prophylaxis after transplant. For example, of seronegative transplant recipients, 75% get CMV disease if the

donor is seropositive. In organ transplant recipients there are 3 main presentations:

- 1) CMV DNAemia: CMV in the blood (PCR-positive) without any attributable signs or symptoms of disease
- 2) CMV syndrome: CMV in the blood (PCR-positive) with attributable signs/symptoms of systemic disease, but no evidence of end-organ disease (e.g., colitis, pneumonitis). Typical signs and symptoms include fever, profound fatigue, and leukopenia.
- 3) Tissue-invasive CMV disease: end-organ disease due to CMV, typically (but not always) accompanied by CMV in the blood (PCR-positive). Typical signs and symptoms depend on the organ that is involved (e.g., colitis = diarrhea, pneumonitis = shortness of breath and bilateral infiltrates, chorioretinitis = decreased vision and fluffy retinal lesions).

HIV/AIDS: When the CD4 count is < 50 cells/ μ L (0.05×10^9 /L), CMV can cause chorioretinitis, pneumonitis, esophagitis, and colitis. Patients with CMV retinitis may initially complain of floaters and will then gradually lose vision. CMV retinitis is distinctive; it has both retinal blanching and hemorrhage and follows along the path of the retinal arteries. Diagnosis is typically made by an ophthalmologist based on appearance. CMV serologies and serum PCR do not play a role in diagnosing CMV retinitis. CMV esophagitis and colitis are diagnosed by endoscopy and tissue pathology.

Diagnose acute CMV infection in immunocompetent hosts by serologies, either a 4-fold rise in convalescent serologies or positive IgM. Serologies have no role in the diagnosis of active CMV disease in immunosuppressed patients. CMV DNAemia and CMV syndrome are diagnosed by demonstrating DNA in peripheral blood. For tissue invasive disease, get a biopsy of the tissue involved for pathology—the tissue will demonstrate cytopathic viral effects combined with positive immunohistochemical stains. Most patients with end-organ disease have an accompanying viremia, but not all. Always try to get tissue samples if possible (e.g., colonoscopy).

Treat susceptible CMV infection with valganciclovir or ganciclovir. For resistant virus, use foscarnet or cidofovir.

EPSTEIN-BARR VIRUS (EBV)

Epstein-Barr virus (EBV; a DNA virus) causes infectious mononucleosis. The incubation period is 1–2 months, and it is usually acquired in adolescence through contact with others who are asymptotically shedding the virus in their secretions (the so-called kissing disease).

The vast majority of adults have been infected, but most acute EBV infections are asymptomatic. If symptomatic, > 90% have pharyngitis, which is typically exudative. Tonsillitis, fever, lymphadenopathy, and elevated transaminases also occur. Splenomegaly

may be seen. A maculopapular rash occurs in ~ 20% of symptomatic patients; however, if patients are given ampicillin, 90% develop a similar rash. This can occur if the exudative pharyngitis is mistakenly treated as an *S. pyogenes* infection.

Symptomatic patients typically develop extreme fatigue, which can occasionally persist months after the initial symptoms disappear.

Lymphocytosis is found in acute EBV infection, usually with > 10% atypical lymphocytes on peripheral blood smear. Atypical lymphocytes (Figure 4-44) are enlarged T cells actively trying to fight EBV-infected B cells. They have abundant cytoplasm, vacuoles, and indentations of the cell membrane.

Figure 4-44: Atypical lymphocyte

Confirm diagnosis of infectious mononucleosis with serology. Heterophile antibody titers (monospot) are nonspecific antibodies that cross-react with RBCs of other mammals. They are absent ~ 25% of the time in the 1st week of illness (heterophile-negative mononucleosis). Thus, the most common cause of heterophile-negative mononucleosis of 1-week duration is still EBV. Diagnose by testing for IgM capsid antibody in these patients. Other causes of heterophile-negative mononucleosis are CMV, toxoplasmosis, acute HIV, and HHV-6 infection.

Treatment of acute EBV infection remains supportive because of its excellent prognosis and the unavailability of any antivirals active against EBV. If splenomegaly is present, patients should avoid contact sports.

EBV causes oral **hairy leukoplakia**, which can be seen as an early manifestation of HIV disease. These are white lesions on the lateral tongue (Figure 4-45) that, unlike thrush, do not scrape off.

Chronic fatigue syndrome has **no** proven association with EBV.

EBV is oncogenic and can result in nasopharyngeal carcinoma, non-Hodgkin lymphoma—specifically Burkitt lymphoma—and posttransplantation lymphoproliferative disorders (PTLD).

RUBELLA (GERMAN MEASLES)

In adults, the typical rash of rubella (a.k.a. German measles; an ssRNA virus) may be preceded by up to 5 days of fever, generalized malaise, headache, sore throat, arthralgias, cough, and coryza. The illness in adults is typically a fairly mild viral illness. Associated clinical signs

Figure 4-45: Oral hairy leukoplakia

Source: CDC

include posterior cervical, postauricular, and suboccipital lymphadenopathy and an enanthem in 20% of cases (**Forchheimer sign**) characterized by soft palate petechiae and/or larger, reddish spots. Despite its mild course in adults, if acquired by a pregnant patient in the 1st trimester, there is up to a 90% chance that the baby will develop congenital rubella syndrome (e.g., deafness, cataracts, cardiac disease).

Rubella is diagnosed by demonstrating rubella-specific IgM at least four days after development of a rash. In pregnant patients, it can be diagnosed via PCR from nasopharyngeal swab. In infants, virus can be detected from cord blood or placenta.

Due to a successful vaccination program, rubella has been declared eliminated in North and South America but is still seen elsewhere.

RUBEOLA (MEASLES)

Rubeola (an ssRNA virus) causes measles. Outbreaks continue to occur in at-risk persons who have not been vaccinated. This is one of the most contagious diseases known.

After an incubation period of 1–3 weeks with a median of 2 weeks, measles begins with a prodromal phase of fevers, malaise, and the 3Cs (cough, coryza, conjunctivitis) which lasts for 72 hours. Enanthem (mucosal rash) develops ~ 48 hours before the exanthem (rash). These are called **Koplik spots**, described as whitish spots on an erythematous base near the molars on the inner cheeks (Figure 4-46). Exanthem lasts for ~ 72 hours and evolves rapidly. It is characterized by numerous, generalized, blanching, fine, discrete, pinkish maculopapules that begin on the face and spread down the trunk, coalesce, then disappear, generally after 3 days. The rash evolves in the same way as having paint dumped on a person's head—it drips down from the top! Convalescence with immunity typically occurs after resolution of the rash. If fevers persist longer, then measles-related complications should be considered.

Figure 4-46: Measles; Koplik spots, small white spots that occur before the rash
Source: CDC

If rubella is suspected, place the patient in a room with airborne precautions and notify public health authorities. Viral encephalitis occurs in 1:1,000 of these patients. Autoimmune reaction (acute disseminated encephalomyelitis) rarely occurs, and if it does, it appears ~ 2 weeks after the rash and has ~ 20% mortality and considerable morbidity. **Subacute sclerosing panencephalitis** occurs in 1:100,000 about a decade later, and it is suspected to be from a variant virus; it is universally fatal.

RETROVIRUSES

Retroviruses are ssRNA viruses:

- HTLV-1 (human T-cell leukemia virus, Type 1) causes T-cell lymphoma and tropical spastic paraparesis, a neurologic syndrome seen in Japan and the Caribbean.
- HTLV-2 causes a rare T-cell variant of hairy cell leukemia.
- HIV-1 causes AIDS.
- HIV-2 causes AIDS (same as HIV-1); found in West Africa and parts of the U.S.

RESPIRATORY VIRUSES

Rhinoviruses

Rhinoviruses (all are ssRNA viruses) are a common cause of URI in adults.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV; an ssRNA virus) infections occur year-round, but more commonly during the autumn and winter. RSV infection has similar morbidity as influenza and especially affects the elderly and those with immunodeficiency. It is thought to be responsible for up to 25% of excess winter season mortality that was previously attributed solely to influenza.

RSV is also an important pathogen in hematopoietic stem cell transplant recipients and lung transplant recipients.

Diagnose by detecting RSV antigen or with PCR of nasal secretions. Use ribavirin, oral or inhaled, as an antiviral therapy in immunocompromised hosts, but the efficacy is limited.

Influenza

Influenza (an ssRNA virus) is a major cause of morbidity and mortality, especially in patients > 55 years of age with COPD. Annual vaccination decreases mortality.

There are 3 types of influenza viruses: influenzas A, B, and C. Subtypes of influenza A exist based on their specific neuraminidase and hemagglutinin antigens. Influenzas A and B cause the yearly epidemics of respiratory illnesses. Influenza C causes very mild symptoms, if any.

Influenza presents as an acute febrile respiratory illness with fever, cough, and myalgias. Serious complications include viral pneumonia, secondary bacterial pneumonia, rhabdomyolysis, encephalitis, and myocarditis.

A positive antigen test or PCR for influenza A and B from nasopharyngeal swab or respiratory secretions is diagnostic. Not every patient with influenza needs antiviral therapy.

Give treatment in 3 settings:

- 1) Those at high risk of complications (e.g., immunocompromised; pregnancy; underlying heart, lung, liver, or kidney disease; > 65 years of age; residents of chronic care facilities; active malignancy; diabetes; morbid obesity; hemoglobinopathies; neurologic conditions causing compromise of handling respiratory secretions; Native Americans; Alaska Natives)
- 2) Hospitalized patients
- 3) Severe, progressive, or complicated illness

In addition, anyone outside of these high-risk groups who presents with influenza within 48 hours of onset can be treated based on clinical judgment.

There are 3 classes of anti-flu drugs: neuraminidase inhibitors, cap snatch inhibitors, and adamantanes. Oseltamivir, a neuraminidase inhibitor, is the most commonly used. For a complete discussion of these medications, see [Antiviral Agents on page 4-85](#).

The prevalence of antiviral resistance to any specific agent is dependent on the circulating strains. Look to CDC guidance for up-to-date information on flu resistance to antiviral drugs.

All individuals > 6 months old should receive annual influenza vaccination with one exception: previous severe allergic reaction (i.e., anaphylaxis) to influenza vaccine. A history of Guillain-Barré syndrome is a precaution to vaccination, but not necessarily a contraindication. Egg allergy is **not** a contraindication to vaccination. If your patient reports hives only, give influenza vaccine. If your patient reports more

than urticaria (e.g., angioedema, swelling, recurrent vomiting, lightheadedness), give influenza vaccine in monitored healthcare setting with basic life support capability.

Influenza vaccines are targeted at the serotypes that are most likely to be present when the influenza season occurs. The better the antigenic match between this year's strains and next year's, the better the vaccine works. There are 3 types of influenza vaccines available in the U.S.: inactivated, recombinant, and intranasal live attenuated vaccine. Also, a high-dose influenza vaccine is available and is more effective than the standard dose vaccine in patients > 65 years of age, due to enhanced immunogenicity. Avoid the intranasal live attenuated vaccine in immunocompromised patients, pregnant patients, and healthcare workers who work with immunosuppressed populations. Regardless of which is used, administer vaccines when they become available each year, which is usually in September or October.

Adenoviruses

Adenoviruses (dsDNA) cause upper respiratory infections and conjunctivitis more often in children than adults. When they cause pharyngitis, they cause an exudative pharyngitis that is indistinguishable from streptococcal pharyngitis; however, there is a commonly associated bilateral conjunctivitis and coryza that are distinguishing clues. Diagnose by culture or PCR from secretions. In immunocompetent patients, the infection is self-limited.

Adenovirus is a feared virus in severely immunosuppressed populations. This includes patients who have undergone a bone marrow transplant, or who have severely depleted cell-mediated immunity. Pneumonia and disseminated disease carry a very high mortality. Cidofovir can be used—though nephrotoxicity is a major concern with this drug, and dialysis may be required frequently.

POLIOVIRUS

Poliovirus (an ssRNA virus) is asymptomatic in > 90% of infections. Symptomatic cases are characterized by aseptic meningitis and an asymmetric, flaccid paralysis due to infection and destruction of anterior horn cells. It has been eliminated in the Western hemisphere and in resource-rich countries worldwide secondary to vaccination, but it is still seen in resource-poor countries, especially India. In countries in which polio has been eradicated, enterovirus 68 and West Nile virus are mimics of the disease.

MUMPS VIRUS

Mumps (an ssRNA virus) occurs most commonly in winter and early spring. Although it commonly is asymptomatic, it can present with unilateral or bilateral parotitis, aseptic meningitis, and/or encephalitis.

Of postpubertal males with mumps, 15–20% get epididymo-orchitis, which is usually unilateral. Postinfection sterility is a rare occurrence. To differentiate mumps from bacterial parotitis, check a Gram stain of the parotid secretions. There are many WBCs and organisms in bacterial parotitis and **none** in mumps. Other causes of enlarged parotid glands are frequent vomiting or parotid duct stones. Always consider bulimia in an adolescent or adult with parotid gland enlargement.

PARVOVIRUS B19

Parvovirus B19 (an ssDNA virus) is spread by respiratory secretions and is usually acquired early in life, commonly manifesting as **erythema infectiosum** (fifth disease) with a high fever and a “slapped cheek” appearance. Adult-acquired illness typically consists of a self-limited fever, symmetric small joint arthritis, and a lacy rash on the trunk and/or extremities (Figure 4-47).

Figure 4-47: Parvovirus lacy rash
Source: CDC

The virus infects the red cell precursors, specifically the pronormoblasts, and causes arrest of red cell maturation. This causes a halt in RBC production for the ~ 1-week duration of the infection, resulting in pure red cell aplasia. In otherwise healthy adults, this causes a drop in Hgb of 5–10%, which is not symptomatic.

Only 3 groups of adults have any serious complications from the infection with this virus:

- 1) Immunocompromised hosts who cannot mount an antibody response have persistent red cell arrest and develop profound anemia.
- 2) Patients with chronic hemolytic anemias who rely on their reticulocytosis to maintain their Hgb levels (e.g., sickle cell disease) also become severely anemic.
- 3) In pregnant patients, if the virus is acquired during the 1st trimester, it can cause increased fetal loss due to hydrops fetalis.

Diagnosis is by assaying for IgM antibody in immunocompetent patients. In immunocompromised patients, who may not mount an antibody response, diagnosis can be made with a serum PCR assay for parvovirus DNA. Bone marrow exam, if done, shows giant pronormoblasts that are also diagnostic.

There is no specific antiviral therapy for parvovirus B19. Give immunocompromised patients passive immunity with IVIG to eradicate the virus. Maintain patients with hemolytic anemias with PRBC transfusions while they mount an antibody response to eradicate the virus.

ARBOVIRUSES

Arboviral Encephalitis

Arboviral encephalitis occurs throughout the U.S., typically in the late spring and summer. West Nile virus (WNV) is the most commonly identified arbovirus.

Arboviruses, like WNV, are named after the geographic area in which they were first found, so they carry names like La Crosse, St. Louis, Eastern equine, Western equine, Venezuelan equine, Powassan, and Colorado tick fever.

Almost all symptomatic arboviral infections have similar symptoms: fever, headache, chills, and varied severity of encephalitis or aseptic meningitis. WNV is asymptomatic in 80% of cases, but it can present as a nonspecific viral illness. Neuroinvasive disease (encephalitis, meningitis, or an asymmetric, flaccid paralysis similar to polio) occurs in only 1/150 patients. Since polio is no longer present in the U.S., test a person with a polio-like presentation for WNV. Less common presentations are tremor, myoclonus, parkinsonism, and cranial neuropathies.

Testing of patients with neurological disease should be done via sending the CSF for WNV IgM antibody. Virus concentration in the CSF is usually too low for PCR to be useful.

Treatment is supportive; no specific antiviral therapy is available.

Mosquito netting, repellents, and insect mitigation help to decrease the spread of these viruses.

Dengue Virus

The dengue virus (an ssRNA virus) causes a spectrum of disease ranging from asymptomatic infection to dengue fever to, most ominously, dengue hemorrhagic fever. It is the most common mosquito-borne viral disease and is seen throughout the tropics. The virus is transmitted to humans via the day-biting female *Aedes* mosquitoes, not the *Anopheles* mosquitoes that carry malaria.

Dengue fever symptoms are rapid onset of high fever (breakbone fever), markedly severe myalgias, arthralgias, and headache. This may be followed by a macular red rash that covers most of the body.

Dengue hemorrhagic fever is due to a diffuse capillary leak syndrome that results in hemoconcentration, anasarca, thrombocytopenia, and spontaneous bleeding. Death due to circulatory collapse may occur; it is seen in people who have had a prior infection with a different serotype of dengue.

Diagnose by a serum IgM antibody assay. Treatment is supportive with IV fluids. No specific antiviral therapy is available. There is a vaccine that causes a predictable immune response to all 4 dengue serotypes that is available in high prevalence areas, but not in the United States.

Chikungunya Virus

Chikungunya is an alphavirus endemic to West Africa and transmitted by the day-biting mosquitoes *Aedes aegypti* and *Aedes albopictus*. It has been present in the U.S. since 2014. It causes a syndrome very similar to dengue with high fever, polyarthralgia, headache, and maculopapular rash, except arthritis and arthralgias are much more prominent with chikungunya. Diagnosis is by detecting virus-specific IgM (which may not appear until 5–7 days of symptom onset) or by PCR. Treatment is supportive. Mortality is rare.

Zika Virus

Zika virus (an ssRNA virus) is a *Flavivirus* related to dengue and chikungunya viruses. It was first identified in the Zika forest of Uganda in 1947, found in a rhesus monkey in a program monitoring for yellow fever. Transmitted by the *Aedes* mosquito, Zika causes symptoms in only 20% of people infected. There is evidence of male-to-female sexual transmission.

Zika virus symptoms, if they occur, include fever, rash, muscle and joint pain, and conjunctivitis. The symptoms are usually mild and self-limited. Rarely, it can cause myelitis and/or encephalitis.

In 2015, an alarming increase in the number of infants born with microcephaly was seen in Brazil. Physicians found an association between Zika infection during pregnancy and infants born with microcephaly (see the [Women's and Men's Health](#) section). Subsequent studies have shown a 10–40% incidence of neurologic defects in babies born to women infected during pregnancy. Zika is also associated with Guillain-Barré syndrome. There was epidemic spread of the virus to South America, Central America, and the Caribbean in 2016, for which the WHO declared a public health emergency. As of 2019, there is no country worldwide with a Zika outbreak, but the virus is likely endemic in these new regions. Per the CDC, pregnant women and women of childbearing age should be cautioned against travel to Zika endemic regions, which include India, south-east Asia, Africa, the Caribbean, Central America, and South America. Zika has also been detected in Florida and Texas. Infected men can shed viral RNA in their semen for up to 6 months and place partners at risk.

The CDC has a reverse transcriptase polymerase chain reaction (RT-PCR) assay that can facilitate diagnosis in selected patients. There is no treatment for Zika virus. The CDC recommends prevention by avoiding insect bites.

Hantavirus

The primary reservoir for hantavirus (an ssRNA virus) in the U.S. is the deer mouse. The Four Corners area of the Southwest is the area of highest concern. On the East Coast and in the Southeast, the cotton rat is the reservoir. The infection occurs when the excreta or saliva of an infected rodent are inhaled (e.g., cleaning droppings, working in a barn). No human-to-human transmission is known.

Hantavirus pulmonary syndrome (HPS) starts as a non-descript viral syndrome, often with GI symptoms. Patients then develop muscle pain, fever, headache, and cough, which quickly progresses to hypoxia, hemorrhagic pneumonia, acute respiratory distress syndrome (ARDS), and death in > 50% of cases. Laboratory findings include hemoconcentration and thrombocytopenia. Diagnose by finding IgM antibodies in the blood or CSF. No specific antiviral therapy is available.

Ebola Virus

Ebola virus (an ssRNA virus)—first discovered in 1976 with an unknown reservoir, possibly fruit bats—causes episodic outbreaks of a hemorrhagic fever with severe vomiting, diarrhea, rash, and internal and external hemorrhage. Until 2014, no cases left the African continent. The 2014–2015 outbreak resulted in ~ 2 dozen cases that were exported to other continents, almost all of which were health care workers who were in the endemic areas caring for infected persons. Presentation is similar to that of dengue hemorrhagic fever, with a > 70% mortality rate. No specific treatment has been proven effective other than supportive care.

SLOW VIRUSES

There are 2 classes of slow viruses (long incubation time):

- 1) Normal viruses, such as papillomavirus (warts; [Human Papillomavirus \(HPV\)](#) on page 4-20) and polyomavirus (PML; [John Cunningham \(JC\) Polyomavirus](#) on page 4-37)
- 2) Defective viruses, such as the defective measles virus (subacute sclerosing panencephalitis; [Rubeola \(Measles\)](#) on page 4-72)

ANTIMICROBIAL AGENTS AND VACCINES

ANTIBACTERIAL AGENTS

PREVIEW | REVIEW

- Which antibiotics target deoxyribonucleic acid gyrase to interrupt protein synthesis?
- Which antibiotics antagonize folic acid?
- Which classes of antibiotics affect the developing bacterial cell wall?
- What are the definitions of minimal inhibitory concentration (MIC) and minimal bactericidal concentration?
- What is the difference between concentration-dependent and time-dependent killing?
- Which type of killing do aminoglycosides exhibit?
- What is the postantibiotic effect?
- What is the difference between concentration-dependent and time-dependent killing?
- In time-dependent killing, how long should a patient's serum concentration of a drug be higher than the infecting organism's MIC?
- What coverage does ampicillin add over penicillin?
- Which organisms do extended-spectrum penicillins cover?
- 3rd generation cephalosporins are known for their additional activity against which organisms?
- Which β -lactam drug can be given to patients with a penicillin allergy?
- Which carbapenem should be avoided in those with seizures?
- What are potential complications of linezolid use?
- Which drugs inhibit the absorption of quinolones?
- The use of which class of antibiotics increases the risk of tendon rupture?

HOW ANTIBIOTICS WORK

Most antibiotics work by disrupting bacterial protein synthesis, folate metabolism, or cell wall/membrane synthesis. First, let's review protein synthesis; then we'll tackle the mechanisms of action for specific antibiotics.

Quick Review — Protein Synthesis

Transcription: Protein synthesis requires the unwinding of DNA and having it cut and held open by DNA gyrase to be read by RNA polymerase.

RNA polymerase moves along a section of DNA to create a complementary strand of RNA, which is messenger RNA (mRNA).

Translation: The mRNA is translated into a sequence of amino acids to create the desired protein product by ribosomes. mRNA attaches to the 30S ribosomal subunit, after which a 50S ribosomal subunit binds to this complex to form a 70S ribosome.

Amino acid-specific transfer RNAs (tRNAs) bring in the corresponding amino acids to make the protein.

Antibiotics That Block Protein Synthesis

Rifampin binds to RNA polymerase and blocks transcription.

Quinolone antibiotics (e.g., ciprofloxacin, levofloxacin, moxifloxacin) block the ability of DNA gyrase to reconnect the cleaved DNA strands.

Metronidazole has a similar action to the quinolones. It also affects cell membrane function.

Aminoglycosides (e.g., gentamicin, tobramycin, amikacin) bind irreversibly to the 30S ribosomal subunit and prevent the 50S subunit from attaching.

Tetracyclines (e.g., doxycycline) and **glycylcyclines** (e.g., tigecycline) bind reversibly to the 30S subunit, distorting it so that the anticodons of the tRNAs cannot align properly with the codons on the mRNA.

Macrolides (e.g., erythromycin, clarithromycin, azithromycin) bind reversibly to the 50S subunit. They prevent peptide bond formation between the amino acids and, hence, keep the 70S ribosome from forming the desired protein.

Clindamycin works similarly to macrolides.

Oxazolidinones (e.g., linezolid, tedizolid) bind to the 50S ribosomal subunit, preventing attachment to the 30S unit.

Antibiotics That Affect DNA Replication

Trimethoprim and the **sulfonamides** block the production of folic acid from para-aminobenzoic acid (PABA). Folic acid is required to replicate DNA.

Quick Review — Cell Wall Synthesis

Peptidoglycan is a component of bacterial cell walls. It is composed of alternating polysaccharides: *N*-acetylglucosamine and *N*-acetylmuramic acid that are cross-linked to form alternating strands that make the wall solid. Gram-negative organisms have an outer membrane outside of the cell wall.

Antibiotics That Affect the Cell Wall

A variety of antibiotics act at 1 or 2 stages of peptidoglycan synthesis. In order for an antibiotic to affect the cell wall of gram-negative organisms, the drug must

pass through the outer membrane via channels called porins. Passage is affected by drug size and charge. Some gram-negative organisms have inherent resistance to certain cell wall agents because of the shape of their porins.

β -lactams are a class of antibiotics that interrupt formation of the bacterial cell wall. Because there is no analogous structure in human cells, people can tolerate relatively high doses.

Glycopeptide antibiotics (e.g., vancomycin, telavancin, dalbavancin, oritavancin) work by inhibiting cell wall synthesis of gram-positive organisms.

Antibiotics that Affect the Cell Membrane

Cyclic lipopeptides (e.g., daptomycin) insert into the plasma membrane of gram-positive bacteria, creating channels that allow the efflux of ions and disruption of membrane polarization. It also has a dual action on cell wall function.

Polymyxins (polymyxin B and colistin) bind to the cell membrane to create an efflux of ions and cell death.

Diagnostic Microbiology

When certain specimens are obtained (i.e., sputum, CSF, pleural, ascetic, urine), an attempt is made to directly visualize and identify the bacteria with a Gram stain before culturing it. For other samples, the specimen goes directly to culture (e.g., blood). The culture medium is incubated for 24 hours and observed for development of turbidity, which indicates bacterial growth.

Once bacterial growth is established, identification and sensitivity testing are done. Traditionally, the culture is then placed on various agar plates to identify the bacteria, and disk diffusion susceptibility is conducted to determine the minimum inhibitory concentration (MIC) and minimum bactericidal concentration (MBC) of the drug for those bacteria.

Most labs currently use an automated system that performs identification and sensitivity simultaneously, usually by a microtiter method.

Disk diffusion (Kirby-Bauer) testing is used for specific, difficult-to-treat bacteria that do not grow well in the automated media or for testing with antibiotics that are not included in the standard panels.

Minimal Inhibitory Concentration (MIC) and Minimal Bactericidal Concentration (MBC)

The **MIC** is the lowest concentration of antibiotic that **inhibits** visible growth (visible turbidity) in vitro after 24 hours of incubation. The **MBC** is the lowest concentration of antibiotic that **kills** 99.9% of the bacteria.

If the MIC of a drug vs. a specific isolate is achievable in tissue based on usual dosing of the antibiotic, the

organism is considered susceptible (sensitive) to the antibiotic and can be considered for treatment. All that needs to happen is for the drug to inhibit the growth of the organism, and the immune system does the rest to clear the infection.

In only a few circumstances, the goal is for the specified antibiotic to have an achievable MBC, not merely MIC. MBC is used to treat infections at sites that the immune system has trouble accessing (e.g., the center of an endocarditis vegetation, the CSF in meningitis) or when the patient is neutropenic.

General Rules of Antibiotic Use

Know these important points:

- Source control is key to treating serious infections. Examples of this are draining an abscess, removing dead tissue, and relieving a biliary or GU obstruction. Foreign bodies, lines, catheters, and devices may need to be removed.
- Pick the drug with the proper spectrum for the suspected or proven pathogen(s) and the site of infection.
- Adjust dosage for body size and clearance when appropriate.
- If the patient does not respond, consider 5 things:
 - 1) Is the patient getting/taking an effective drug?
 - 2) Is there resistance?
 - 3) Is there an undrained focus of infection?
 - 4) Is there a superinfection?
 - 5) Are the symptoms due to a noninfectious disease?

Concentration-Dependent Killing vs. Time-Dependent Killing

Concentration-Dependent Killing

Concentration-dependent killing means that killing increases as you increase the concentration of drug above the MIC for the bugs you are treating. This is sometimes referred to as dose-dependent killing because killing is based on concentration above MIC, not on time. Aminoglycosides and quinolones are drugs that exhibit concentration-dependent killing.

Quinolones and aminoglycosides also exhibit a **post-antibiotic effect (PAE)**. A PAE is persistent killing of bacteria even after the concentration of drug has fallen below the MIC at the site of infection. The dose-dependent killing and PAE allow these drugs to be dosed once daily, achieving a high peak concentration.

Time-Dependent Killing

In time-dependent killing, the concentration of drug above the MIC does not really matter. Instead, killing is related to how long the concentration of antibiotic remains greater than the organism's MIC at the site of

infection (a.k.a. time over MIC). β -lactams, macrolides, and glycopeptides (e.g., vancomycin) are such drugs. Aim for serum concentrations above the MIC for > 50% of the dosing interval.

Because β -lactams are time dependent, it is not important to aim for 8–10 $\times$ the MIC with each dose. Instead, patients need repeated, reliable dosing intervals so they do not have prolonged periods during the dosing interval when their serum levels fall below the MIC. The clinical relevance is that with time-dependent killing, patients who miss doses risk treatment failure.

β -LACTAM ANTIBIOTICS

Overview and Development of Penicillins

The 1st of the β -lactam antibiotics was penicillin. Its derivatives were created either to increase its spectrum of activity and/or to address developing bacterial resistance.

The development timeline of these drugs is as follows:

penicillin $\rightarrow$ semisynthetic penicillins $\rightarrow$ aminopenicillins $\rightarrow$ extended-spectrum penicillins $\rightarrow$ aminopenicillins/extended-spectrum penicillins + β -lactamase inhibitors

This topic area covers the penicillin-based antibiotics using the above developmental timeline.

Penicillin

Penicillin (PCN) is appropriate mainly for streptococci, sensitive enterococci, leptospirosis, *Listeria*, *Pasteurella*, and syphilis.

Staphylococci rapidly developed resistance by producing penicillinase, a β -lactamase enzyme that destroys the drug, so next came the...

Semisynthetic Penicillins

Methicillin (and later, **oxacillin**, **nafcillin**, and **dicloxacillin**): These are stable against staphylococcal penicillinase. These drugs are called semisynthetic penicillins or antistaphylococcal penicillins because they were synthesized from penicillin. They are the drugs of choice for methicillin-sensitive, penicillin-resistant staphylococci.

The semisynthetic penicillins lacked activity against gram-negatives, so next came the...

Aminopenicillins

The aminopenicillins are **ampicillin** and its oral formulation, **amoxicillin**. They retain the efficacy of prior penicillins but also kill many susceptible gram-negative organisms, such as *H. influenzae*, *E. coli*, *Proteus mirabilis*, and several strains of *Salmonella* and *Shigella*. Therefore, this new class added activity against urogenital and colonic bacteria. However, they are destroyed by staphylococcal penicillinase.

Unfortunately, resistance developed quickly; bacteria started producing other β -lactamases. Also, they had no activity against *Klebsiella* or *Pseudomonas*. So, the next major drug class to be developed was the...

Extended-Spectrum Penicillins

Piperacillin and **ticarcillin**: These drugs are called extended-spectrum PCNs because they take the spectrum of ampicillin and extend it to cover the more resistant GNRs, including *Pseudomonas*. Organisms created β -lactamases to this class, so the next addition to come along was the...

β -Lactamase Inhibitors

Addition of a β -lactamase inhibitor (BLI)—**sulbactam**, **tazobactam**, **avibactam**, or **clavulanic acid**—in combination with an aminopenicillin or an extended-spectrum penicillin protects the penicillin from β -lactamase hydrolysis.

Combinations include:

- IV ampicillin + sulbactam
- PO amoxicillin + clavulanic acid
- IV piperacillin + tazobactam (active against *Pseudomonas*)

The drugs retain the activity of the parent penicillin, but they are also effective against bacteria that make β -lactamase, including most anaerobes.

Evolution of Methicillin-Resistant *Staphylococcus aureus*

Staphylococci eventually acquired the *mecA* gene, which encodes a change in the penicillin-binding proteins that the β -lactams use to bind the bacteria. *MecA* transcription results in reduced affinity of all β -lactams for the organisms' cell walls—except for the newest 5th generation cephalosporin, ceftaroline. The staphylococci that express this gene are called methicillin-resistant staphylococci (methicillin-resistant *S. aureus* [MRSA], methicillin-resistant *S. epidermidis* [MRSE], and other methicillin-resistant coagulase-negative staphylococci).

Vancomycin, daptomycin, and linezolid effectively treat serious MRSA infections. Newer drugs with anti-MRSA activity include ceftaroline, oritavancin, dalbavancin, telavancin, and tigecycline; these are not for MRSA bacteremia. MRSA in skin and soft tissue infections often retains susceptibility to clindamycin, TMP/SMX, or doxycycline.

Penicillin Allergy

Most reported penicillin allergies are not true allergic responses. Penicillin allergy is often incorrectly reported by patients due to recollection of nonallergic symptoms while treated in the past (e.g., diarrhea, nausea). The American Academy of Allergy, Asthma, and Immunology recommends increased use of

penicillin skin testing, which is safe and effective. In patients in which a penicillin is the drug of choice or essential (e.g., neurosyphilis), skin testing can be performed. A negative skin test has a negative predictive value of > 95%, making an anaphylactic reaction to penicillin very unlikely. If truly allergic, patients can also be desensitized. See the [Allergy & Immunology](#) section for more on drug desensitization.

Cephalosporins

Cephalosporins also contain the β -lactam ring, but are inherently penicillinase-resistant because of their structure. Cephalosporins have no activity against enterococci or *Listeria*. With the exception of ceftaroline, all methicillin-resistant staphylococci are resistant to all cephalosporins.

1st Generation Cephalosporins

1st generation cephalosporins are active against MSSA and streptococci. There is 1 parenteral form available, IV **cefazolin**, and 2 oral forms, **cephalexin** and **cefadroxil**. They are unlike penicillin in that they have some coverage against community-acquired GNRs, such as *E. coli*, *Klebsiella*, and *Proteus*. 1st generation cephalosporins are commonly given for:

- Skin and soft tissue infections from sensitive organisms
- Surgical prophylaxis
- UTIs from sensitive organisms

2nd Generation Cephalosporins

Gram-negative coverage increases with coverage of *H. influenzae* (cefuroxime), *Moraxella*, *Enterobacter*, and *N. gonorrhoeae*. Pneumococcal coverage is retained. In this group, 2 drugs, **cefoxitin** and **cefotetan**, also have anaerobic coverage. These 2 drugs are used to treat:

- Pelvic inflammatory disease (PID)
- Postoperative abdominal infections

The 3rd generation cephalosporins have largely replaced the 2nd generation except for anaerobic infections, usually due to gut flora.

3rd Generation Cephalosporins

3rd generation cephalosporins are stable against most β -lactamases and have enhanced activity against pneumococci, *H. influenzae*, and *N. gonorrhoeae*. The GNR coverage is also enhanced over previous generations, so these drugs are better for the Enterobacteriaceae (*E. coli*, *Klebsiella*, *Proteus*, *Enterobacter*, and *Serratia*).

Remember the following facts about 3rd generation cephalosporins:

- They are great pneumococcus drugs, so they are recommended as 1st line agents for community-acquired pneumonia and meningitis in combination with vancomycin for empiric treatment.

- None of the drugs are 1st line agents for MSSA; 1st generation cephalosporins or nafcillin/oxacillin are preferred.
- None of the drugs cover anaerobes. 2nd generation cephalosporins or PCNs are better.
- **Ceftazidime** is the only 3rd generation drug that has antipseudomonal activity.
- **Ceftazidime**, **ceftriaxone**, and **cefotaxime** cross an inflamed blood-brain barrier. Any of these can be used as primary therapy for meningitis caused by *Enterobacteriaceae*.
- **Ceftolozane** was FDA approved in 2014 to treat complicated intraabdominal infections and UTIs. It is only available in combination with tazobactam.
- Cefdinir (Omnicef), cefditoren (Spectracef), cefixime (Suprax), cefpodoxime-proxetil (Vantin), and ceftibuten (Cedax) are 3rd generation cephalosporins.

4th Generation Cephalosporins

Cefepime is the only 4th generation cephalosporin. Think of it as the gram-positive activity of a 1st generation cephalosporin combined with the gram-negative activity of ceftazidime (including *Pseudomonas aeruginosa*), with enhanced stability against cephalosporinases. It has limited anaerobic coverage and is commonly used for neutropenic fever.

5th Generation Cephalosporins

Ceftaroline is the only cephalosporin that treats MRSA. Think of it like vancomycin combined with ceftriaxone. It does **not** treat *Pseudomonas* infections.

Advanced Generation Cephalosporins

Cefiderocol is a novel cephalosporin that binds with iron. It is recognized by bacteria as a siderophore-iron complex and is actively transported through the outer membrane (think Trojan horse), where it can bind to penicillin-binding proteins and halt cell wall synthesis in the same way as other cephalosporins. Gram-negative spectrum is extensive, including multidrug-resistant *Pseudomonas aeruginosa* and carbapenem-resistant *Enterobacteriaceae*. Gram-positive and anaerobic spectrum is limited. Cefiderocol is approved by the FDA for complicated urinary tract infections. Its therapeutic niche is treatment of infections caused by highly resistant gram-negative rods.

Addition of β -Lactamase Inhibitors

There are 4 newly approved β -lactam + β -lactamase inhibitor combinations available for extremely drug-resistant, gram-negative infections. These include the following:

- 1) IV ceftolozane + tazobactam
- 2) IV ceftazidime + avibactam

3) IV meropenem + vaborbactam

4) IV imipenem-cilastatin + relebactam

The specifics of when to use these agents should generally be discussed with an infectious disease specialist and/or antimicrobial stewardship department.

Monobactams

Aztreonam is the only monobactam with a β -lactam ring. It covers **only** GNBs, including *Pseudomonas*. Its spectrum is similar to aminoglycosides and 3rd generation cephalosporins. It is not active against gram-positive cocci or anaerobes. This drug can be used in patients with both a β -lactam allergy and penicillin allergy, which is its niche. It is available for intravenous or inhaled use only.

Carbapenems

Imipenem, **meropenem**, **doripenem**, and **ertapenem** are broad-spectrum β -lactams recommended **only** for use in **complicated** infections involving **multiple** organisms (such as in the abdomen or the diabetic extremity with possible bacteremia), against multidrug-resistant organisms, and for empiric treatment of the critically ill.

Carbapenem Resistance

Carbapenemases are carbapenem-hydrolyzing β -lactamases that confer carbapenem resistance. Various forms of these have been identified over the last several years.

Individual Carbapenems

Imipenem covers **most** bacterial classes: gram-positive cocci (GPC; excluding MRSA), gram-negative rods (GNRs; including *Pseudomonas* and other resistant GNRs), and mouth and gut anaerobes (particularly *Bacteroides fragilis*). It also is effective against extended-spectrum β -lactamase (ESBL)-producing organisms.

The few organisms resistant to imipenem:

- *Enterococcus faecium*
- *Burkholderia cepacia*
- *Corynebacterium jeikeium* (JK)
- *Stenotrophomonas maltophilia*
- *Acinetobacter* species
- MRSA

Also, remember that although *E. coli* and *K. pneumoniae* are typically sensitive to imipenem, the carbapenemase-producing variety can spread easily and cause major problems.

Resistance is increasingly common in *Pseudomonas* isolates, especially in those patients with recurrent infections—such as patients with cystic fibrosis.

Imipenem can lower the seizure threshold, so do not use it in patients with seizures and/or advanced-stage chronic kidney disease.

Imipenem is always formulated with equal amounts of cilastatin. Cilastatin is an enzyme inhibitor that impairs the metabolism of imipenem in the renal tubule, thereby increasing its half-life.

Meropenem is a similar carbapenem with a longer half-life, so there is no need for an enzyme inhibitor.

Doripenem is a carbapenem with similar activity and pharmacokinetics to meropenem.

Ertapenem is a carbapenem with convenient 1×/day dosing but **no** activity against *Pseudomonas*. Otherwise, its spectrum is similar to the other carbapenems. It is useful for outpatient parenteral treatment, especially of diabetic foot wounds, and for abdominal, pelvic, skin, and soft tissue infections.

GLYCOPEPTIDES

Vancomycin

Vancomycin is a glycopeptide antibiotic that is effective against most gram-positive organisms, including MRSA, MRSE, *Clostridium*, and *Corynebacterium*. It is a large molecule that diffuses poorly into most tissues, with only ~ 1/8 of the blood concentration reaching the site of infection. It exhibits time-dependent killing, so predose (**trough**) levels are measured to assure that they are ~ 8× the usual cutoff for susceptibility (2 mcg/mL), as well as to limit toxicity. For most serious infections, predose levels between 15 and 20 mcg/mL are recommended.

Clearance of vancomycin in patients undergoing hemodialysis can vary widely depending on the membranes used, so levels are needed to guide dosing.

Some strains of enterococci are vancomycin resistant. MICs are increasing in staphylococci, but vancomycin-resistant staphylococci (MIC ≥ 16 mcg/mL) are exceedingly rare. However, increases in the MIC that are still within the susceptible range (1–2 mcg/mL) can result in vancomycin treatment failure. Some experts suggest using an alternative drug to treat the infection (e.g., linezolid, telavancin, daptomycin). (Remember that daptomycin is inactive in the lungs, so use linezolid for vancomycin-resistant staphylococcal pneumonia.) It remains controversial whether to start an alternative agent as soon as the MIC is available or to wait for clinical outcome. Staphylococci with a MIC between 2 and 8 mcg/mL for vancomycin are considered to have intermediate susceptibility; use alternative drugs if possible.

Vancomycin, when it is rapidly infused, sometimes causes so-called **red man syndrome**, consisting of tachycardia, flushing, occasional angioedema, and generalized pruritus. It is an infusion rate-related phenomenon that is usually the result of mast cell degranulation and release of histamine. Red man syndrome is not a

true allergy. Patients who experience this reaction can be retreated with the drug if it is infused more slowly. Pretreat these patients with H1 blockers. Renal and ototoxicity are rare at normal doses (< 4 g/day).

The sole indication for **PO** vancomycin is *C. difficile* infection. IV vancomycin is **not** effective for *C. difficile* because it does not achieve therapeutic levels in the bowel.

Newer Glycopeptides

The FDA approved 3 glycopeptides in 2013 and 2014: **telavancin**, **oritavancin**, and **dalbavancin**. They have the same spectrum as vancomycin but have longer half-lives of 7–10 hours, 10 days, and 14 days, respectively, thus allowing for less frequent IV dosing of once daily, once weekly, or biweekly, respectively. These drugs lend themselves nicely to ambulatory treatment of infections and are FDA approved for the treatment of acute bacterial skin and skin structure infections. Telavancin is also approved for ventilator-associated and hospital-acquired pneumonia when alternatives are not appropriate. It has some cross sensitivity with vancomycin, so use caution if a known allergy exists.

OXAZOLIDINONES

Linezolid and **tedizolid** are the only oxazolidinones on the U.S. market.

They are bacteriostatic agents active against gram-positive organisms, including MRSA, MRSE, and vancomycin-resistant enterococci (VRE). Neither has an indication for bacteremia. They are highly bioavailable orally and come in IV and PO preparations. Linezolid is dosed twice daily, and tedizolid is dosed once daily.

These drugs are useful alternatives to vancomycin for MRSA. Tedizolid is only approved for skin and soft tissue infections.

Linezolid can cause reversible thrombocytopenia, anemia, and leukopenia especially if the patient has been taking it > 2 weeks. Tedizolid may cause this less frequently but has only been studied for short courses of therapy. Both drugs may cause a peripheral neuropathy. Both drugs can cause serotonin syndrome when used concurrently with selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs).

STREPTOGRAMINS

Quinupristin and **dalfopristin** are streptogramins, which are administered as a combination IV antibiotic. This compound has a narrow spectrum against certain aerobic, gram-positive organisms—specifically vancomycin-resistant *E. faecium* and MSSA—and is used when these organisms are resistant to, or patients are intolerant to, other agents. It is rarely used, given the availability of newer agents.

CYCLIC LIPOPEPTIDES

Daptomycin is a cyclic lipopeptide active against gram-positive organisms. It is a parenteral drug with a long half-life that allows once-daily dosing. It is used to treat skin and soft tissue infections, bacteremia, and right-sided endocarditis caused by MSSA or MRSA. It is reserved for resistant organisms, such as MRSA and VRE, or for patients intolerant to other drugs used for these organisms. It is also a useful drug to treat MRSA that have relatively high MICs to vancomycin.

It is inactivated by pulmonary surfactant and thus is not effective in treating pneumonia. Myopathy is a potential side effect, so monitor CK levels at least weekly during long-term use, especially in patients who are also taking a statin.

GLYCYLCYCLINES

Tigecycline is a parenteral glycylicycline that is a derivative of tetracycline. It is very broad-spectrum with activity against gram-positive organisms (e.g., VRE, MRSA), anaerobes, and GNRs. It has coverage against ESBL-producing GNRs. However, it is **not** active against *Pseudomonas* and has reduced activity against *Proteus* and *Providencia*.

Tigecycline is indicated for complicated skin and soft tissue infections and intraabdominal infections. Nausea and vomiting are its main side effects, occurring in > 20% of patients. There is a black box warning of increased mortality for tigecycline because certain patients, particularly those with pneumonia, did worse on tigecycline compared with other antibiotics. There is still a role for this antibiotic in multidrug-resistant infections, but it should generally be given in collaboration with infectious disease colleagues.

POLYMYXINS

Colistin is a nephrotoxic agent that was essentially replaced by the less (but definitely) nephrotoxic aminoglycosides, only to have a new niche with the advent of multidrug-resistant *P. aeruginosa* and *Acinetobacter*. Because nephrotoxicity occurs in 20–50% of patients, its use is limited to treatment of those multidrug-resistant organisms for which no other antibiotics are available and/or tolerable.

Polymyxin B is also available in parenteral and topical forms and is used for resistant gram-negatives. It is also toxic, and its use is limited as above.

AMINOGLYCOSIDES

Aminoglycosides (e.g., **gentamicin**, **tobramycin**, **amikacin**, **streptomycin**) are active against the following:

- Enteric GNRs (but not anaerobic GNRs, such as *Bacteroides fragilis*)
- *Yersinia pestis* (plague)
- *Francisella tularensis* (tularemia)

- *Pseudomonas aeruginosa*
- *Brucella* species (brucellosis)
- *Mycobacterium tuberculosis*
- *M. avium-intracellulare*

Aminoglycosides are also used to treat patients with febrile neutropenia, in combination with a 3rd generation cephalosporin or an extended-spectrum penicillin + β -lactamase inhibitor if local β -lactam resistance rates are too high to trust β -lactam monotherapy.

These drugs exhibit concentration-dependent killing and a considerable postantibiotic effect. Hence, they are best dosed once daily after a loading dose. Potential complications include ototoxicity and nephrotoxicity.

FLUOROQUINOLONES

Ciprofloxacin, **levofloxacin**, **moxifloxacin**, and **delafloxacin** are available in IV and oral form. **Gemifloxacin** is available only in oral form. Their oral bioavailability is ~ 100% but is reduced by chelation with divalent cations (Mg^{2+} , Ca^{2+}) that may be components of vitamins and laxatives. Other drugs can decrease absorption (e.g., aluminum/magnesium antacids, sucralfate, ferrous sulfate). They can also prolong the QT interval, so you must avoid concomitant use with other QT-prolonging agents (e.g., amiodarone).

They all have aerobic GNR coverage, and ciprofloxacin and levofloxacin have *Pseudomonas* activity. Ciprofloxacin should **not** be used for empiric *S. pneumoniae* coverage. On the other hand, levofloxacin and moxifloxacin are approved for *S. pneumoniae*, which is why some refer to them as “respiratory fluoroquinolones.” Although *S. aureus* may be susceptible in micro reports, resistance commonly develops during treatment, and fluoroquinolones should not be used, with the exception of delafloxacin.

Delafloxacin was FDA approved in 2017 for skin and soft tissue infections only, and the indication includes MRSA.

Moxifloxacin is less active than the others against GNRs, but it is the most active quinolone for *M. tuberculosis* and is active against most anaerobes.

There are many caveats with this class:

- Do not give to pregnant/lactating patients.
- Due to inhibition of tendon and bone formation, their use in persons < 18 years of age is not recommended by the FDA, with the exception of ciprofloxacin, which is approved for 2nd line therapy in children with UTIs and patients with cystic fibrosis.
- In adults, injury to tendons (specifically the Achilles tendon), muscle, joints, and peripheral nerves can occur, especially in the elderly. Thus, the FDA recommends against their use as 1st line drugs for acute bacterial sinusitis, exacerbations of COPD, and uncomplicated UTIs.

MACROLIDES

There are 4 macrolides currently available: erythromycin, clarithromycin, azithromycin, and telithromycin.

The parent drug **erythromycin** is effective against:

- *Mycoplasma pneumoniae*
- *Chlamydomphila pneumoniae*
- *Campylobacter*
- Diphtheria
- Pertussis

Erythromycin has a short half-life of 2 hours and thus must be dosed several times a day. It increases intestinal motility and may cause nausea, vomiting, and/or diarrhea. It increases the concentrations of many drugs, including theophylline, cyclosporine, and warfarin.

Clarithromycin, **azithromycin**, and **telithromycin** have better *S. pneumoniae* and *H. influenzae* coverage than erythromycin, and have better GI tolerance. Clarithromycin and telithromycin are available only orally, but azithromycin comes in both IV and PO formulations. These 3 agents have longer half-lives that permit more convenient dosing—either bid or daily for clarithromycin ($T_{1/2}$ = 3–7 hours), daily for azithromycin ($T_{1/2}$ = ~ 3 days), and daily for telithromycin ($T_{1/2}$ = 10 hours). The use of telithromycin is severely restricted due to increased toxicity in comparison to the other agents.

URINARY TRACT AGENTS

3 agents—nitrofurantoin, fosfomycin, and methenamine—are often considered together because their only indication is for the treatment of UTIs.

Nitrofurantoin has multiple mechanisms of action that disrupt protein, DNA, RNA, and cell wall synthesis; this explains why resistance is rare among species that are intrinsically susceptible, which includes most *E. coli*. All *Proteus* and most *Klebsiella* are resistant. Blood levels are not sufficient to treat pyelonephritis or systemic infections, so its use is limited to uncomplicated cystitis from susceptible strains. Toxicity is rare if renal function is normal. It is not recommended if creatinine clearance is < 60 mL/minutes/1.73m² (1.00 mL/seconds/m²). It is a 1st line drug for uncomplicated cystitis and is safe in pregnancy, except at term. It can also be used as low-dose prophylaxis of recurrent UTIs related to sexual activity in women.

Fosfomycin is a phosphonic antibiotic that has activity against most enterococci and *E. coli*, *Klebsiella*, and *Enterobacter*. For the same reasons as nitrofurantoin, it should not be used for pyelonephritis or systemic infections. It is a 2nd line agent for uncomplicated cystitis and has the advantage of only requiring a single dose.

Methenamine is a heterocyclic antibiotic made from combining ammonia and formaldehyde. In acidic urine, formaldehyde is released, which is bactericidal

to organisms. No formaldehyde is created in the alkaline environment of the blood or renal parenchyma, so toxicity is minimal. It is relegated to use in suppressing recurrent UTIs.

ANTIFUNGAL AGENTS

PREVIEW | REVIEW

- Liposomal amphotericin B preparations are used in which circumstances? Against which fungi?
- Which candidal species are usually resistant to fluconazole?
- What are the indications for voriconazole?
- What are the indications for echinocandins?

POLYENES (AMPHOTERICIN AND NYSTATIN)

Polyenes bind to ergosterol on fungal cell walls, altering their permeability and producing cell death.

The original formulation of **amphotericin B deoxycholate** has been mostly replaced by lipid polyene formulations, echinocandins, and azoles. When given intravenously, it has many side effects: acute kidney injury, anemia, phlebitis, renal tubular acidosis, hypokalemia, and hypomagnesemia. Infusion-related chills and fevers can be severe, and hypotension can occur.

Liposomal amphotericin B preparations are less nephrotoxic and have fewer infusion-related side effects but are more expensive. Lipid preparations are better for some fungal infections, especially those that enter the reticuloendothelial system, such as cryptococcal meningitis and disseminated histoplasmosis. Lipid amphotericin B is also used to treat mucormycosis (*Mucor* and *Rhizopus*) because higher doses of the preparation can be given without nephrotoxicity. They are also used when toxicity has occurred with the amphotericin deoxycholate preparation. The very low level excreted in the urine is the reason they are not indicated in treating fungal UTIs. The original version can be used to treat fluconazole-resistant UTIs.

Topical polyene macrolides are **nystatin** and **amphotericin B**. These are effective only against mucocutaneous candidiasis. Both are also available in liquid form for oral and esophageal candidiasis.

AZOLES

Azoles work by inhibiting the synthesis of ergosterol, a necessary component of the fungal cell wall.

Ketoconazole is an oral and topical preparation that is rarely used systemically because of increasing resistance and more toxicity than other azoles. It can be

used to treat refractory tinea infections. Ketoconazole is a potent P450 inhibitor and therefore has many drug-drug interactions.

Clotrimazole and **miconazole** are available in both cutaneous and vaginal (for vaginal candidiasis) preparations. Many other preparations are also available. They are also used to treat cutaneous candidiasis, tinea versicolor, and ringworm.

Fluconazole is indicated for oral and esophageal candidiasis, candidemia (for susceptible isolates), disseminated candidiasis from *C. albicans*, coccidioidomycosis, cryptococcosis, and vulvovaginal candidiasis. It has excellent penetration into the CSF. **Never** use fluconazole as empiric antifungal treatment in febrile neutropenic patients. *Candida krusei* is entirely resistant, and many *Candida glabrata* are resistant.

Fluconazole is a moderate P450 inhibitor and therefore has many drug-drug interactions.

Itraconazole is a triazole analog of ketoconazole that is more effective and safer. Capsules should be taken with food; a carbonated drink (acidity) helps with absorption. Always check levels when using itraconazole. Consider itraconazole for patients with non-life-threatening endemic fungal infections (e.g., histoplasmosis, blastomycosis) and sporotrichosis.

Itraconazole also is a potent P450 inhibitor and therefore has many drug-drug interactions.

Voriconazole is a triazole with an extended antifungal spectrum compared to fluconazole. Voriconazole is 1st line therapy for invasive aspergillosis—this is the most important indication to remember. It can also be used for certain resistant, invasive candidal infections with ocular involvement (azoles generally penetrate the blood-brain/blood-eye barrier), as well as other hyaline and dematiaceous mold infections. The drug can be given orally or by IV.

Major toxicity is transient, with reversible alterations in visual acuity and color vision. It happens in ~ 30% of patients 30 minutes after administration and lasts 30 minutes (30-30-30 rule). Check voriconazole serum levels whenever you are treating a serious infection because significant variations in levels occur from person to person.

Voriconazole is a potent P450 inhibitor and therefore has many drug-drug interactions.

Posaconazole is a triazole with the extended antifungal spectrum of voriconazole, with additional activity against the Zygomycetes (e.g., *Rhizopus*, *Mucor*). It is FDA approved for prophylaxis of *Aspergillus* and *Candida* infections in those with severe immunocompromised states, including prolonged neutropenia or stem cell transplant recipients with graft-versus-host disease. It is also used for treatment of oropharyngeal candidiasis (particularly infections refractory to itraconazole or fluconazole), invasive *Aspergillus*, and Zygomycetes.

Posaconazole is a potent P450 inhibitor and therefore has many drug-drug interactions.

Isavuconazole was FDA approved in 2015 for the treatment of invasive aspergillosis and mucormycosis. It is at least as good as voriconazole for the former and was found reasonably effective for the latter in an open-label study published in 2015. Drug levels do not need to be monitored. It is also a potent P450 inhibitor.

ECHINOCANDINS

Echinocandins inhibit β -1,3-glucan, an essential component of the cell walls of several fungi, including *Aspergillus*. They act very similarly and are used interchangeably. Think of echinocandins primarily for severe *Candida* infections in sick patients, such as candidemia. It is the 1st choice for empiric antifungal therapy in prolonged febrile neutropenia.

Caspofungin has a half-life of 30–50 hours and is dosed once daily after an initial loading dose. Caspofungin is approved for:

- Candidemia and *Candida* infections of the abdomen, peritoneum, and pleural space and fluconazole-resistant esophagitis
- Invasive aspergillosis in severely immunocompromised patients who are intolerant of lipid amphotericin B or voriconazole

Caspofungin is the only echinocandin additionally approved for invasive aspergillosis as salvage therapy. Caspofungin also has the most drug interactions. No dose adjustment is needed for renal failure.

Several drugs interfere with its metabolism: phenytoin, dexamethasone, carbamazepine, efavirenz, nevirapine, and rifampin.

Micafungin has a half-life of 11–21 hours and does not require a loading dose. It has fewer drug interactions.

Anidulafungin has a half-life of 40–50 hours and is dosed once daily after an initial loading dose. It has very few drug interactions.

OTHER ANTIFUNGALS

Flucytosine (a.k.a. 5-fluorocytosine; 5-FC) is metabolized to the antimetabolite 5-fluorouracil which competes with uracil and inhibits RNA synthesis. It is highly soluble and penetrates well into the CSF. Most *Candida* and endemic fungi are susceptible, but if used alone, drug resistance develops quickly. When combined with amphotericin B, resistance does not develop and there is a synergistic antifungal effect. This combination is used in the induction treatment of severe cryptococcosis. 5-FC can cause serious GI, hepatic, renal, and bone marrow toxicities—the latter usually presents as neutropenia and thrombocytopenia. It is renally excreted, so a decrease in renal function predisposes to toxic effects.

ANTIPARASITIC AGENTS

Praziquantel is the **only** drug effective against **all** species of *Schistosoma*. It is effective against flukes and tapeworms. It is a 2nd line drug to treat neurocysticercosis (brain cysts) caused by the pork tapeworm, *Taenia solium*.

Albendazole is a 1st line drug for all nematodes (except filariasis) and cysticercosis. It is 2nd line for strongyloidiasis and schistosomiasis. Use only in nonpregnant patients.

Niclosamide is used for the treatment of tapeworm.

Pentamidine is effective against trypanosomiasis (African sleeping sickness). For *Pneumocystis*, which is a fungus and not a parasite, treat with IV or via inhalation for prophylaxis. It is not used as a 1st line drug for treatment because of the many side effects, including azotemia, leukopenia, pancreatitis, and hypo- or hyperglycemia.

Nitazoxanide is approved for treatment of *Giardia lamblia* and *Cryptosporidium parvum*.

Miltefosine is used to treat *Naegleria* and *Leishmania*. It is only available through the CDC.

Eflornithine is used to treat *Trypanosoma brucei gambiense* meningoencephalitis (sleeping sickness).

Atovaquone is used to treat babesiosis and as a 2nd line drug for *Pneumocystis*.

Nifurtimox is used to treat *Trypanosoma cruzi* and *T. b. gambiense*.

Benznidazole, an orphan drug, is used to treat *Trypanosoma cruzi*.

Ivermectin is the drug of choice for *Strongyloides* infections.

Diethylcarbamazine is the drug of choice for all forms of filariasis. It is only available through the CDC.

Triclabendazole is used to treat *Fasciola hepatica* but is not available in the U.S.

Antimalarial drugs: See *Plasmodium* (Malaria) on page 4-60.

Valacyclovir and **famciclovir** are oral antivirals that also treat herpes simplex and varicella-zoster infections. Only acyclovir is available intravenously to treat severe infections. Valacyclovir and famciclovir drugs are used primarily for less-frequent dosing of outpatients. They are more expensive than acyclovir.

Ganciclovir is used to treat cytomegalovirus (CMV) infections, which are seen most often in posttransplant patients and those with HIV/AIDS. Typical CMV infections are retinitis, encephalitis, pneumonitis, colitis, and, occasionally, severe bone marrow suppression (neutropenia and thrombocytopenia).

Valganciclovir is an oral preparation similar to ganciclovir but with better absorption, leading to blood levels comparable to IV ganciclovir.

Foscarnet is used in patients with ganciclovir-resistant herpes infection or as an alternative to ganciclovir for CMV. Foscarnet toxicity includes decreases in serum K⁺, Ca²⁺, Mg²⁺, and phosphorus along with acute kidney injury.

Cidofovir is a 2nd line drug to treat CMV infections in immunocompromised hosts.

Ribavirin is used as part of combination therapy for hepatitis C. It can cause significant hemolytic anemias, requiring downward dose adjustments.

Neuraminidase inhibitors are the primary drugs used to treat influenza A and B. They prevent virion release from cells by inhibiting the enzyme neuraminidase. The three FDA approved drugs in this class are oseltamivir (Tamiflu), zanamivir (Relenza), and peramivir (Rapivab).

Cap snatch inhibitors interfere with viral RNA transcription and viral replication. These are active against influenza A and B. The one drug in this class that is FDA approved is baloxavir marboxil (Xofluza).

Adamantanes target the M2 ion channel protein of influenza A viruses. They are not active against influenza B. Presently, nearly all influenza A is resistant to these drugs, so they are not recommended for treatment. The two drugs in this class are amantadine and rimantadine.

See **Antiretroviral Drugs** on page 4-31.

ANTIVIRAL AGENTS

PREVIEW | REVIEW

- What are the indications for ganciclovir?

Acyclovir is a nucleoside analog used for the treatment of herpes simplex and varicella-zoster viruses. Treatment of zoster infections requires higher doses. High intravenous doses to treat herpes simplex encephalitis can crystalize in the urine, causing a microobstructive acute kidney injury that resolves with hydration.

VACCINES

PREVIEW | REVIEW

- Which vaccines contain live virus? Which patients should not receive them?
- Which vaccines are safe to administer to immunocompromised or pregnant patients?
- Which vaccines are recommended to adults and in which age groups?

- How many doses of measles, mumps, and rubella vaccine are considered most desirable and protective?
- Which patient groups should receive the pneumococcal polysaccharide vaccines and in what order?
- How do you decide how to prevent tetanus in a patient presenting with a wound?

VACCINE TYPES

Vaccines used solely in childhood are not discussed here.

Do **not** give live attenuated vaccines to the immunocompromised or pregnant patients (see the [Women's and Men's Health](#) section). **Live attenuated vaccines** include:

- MMR (measles-mumps-rubella)
- Varicella
- Zoster
- Smallpox
- Typhoid oral
- Cholera oral
- BCG (bacillus Calmette-Guérin)
- Yellow fever
- Intranasal influenza

Killed (inactivated) vaccines are safe for the immunocompromised and pregnant, and include:

- Td (tetanus-diphtheria toxoid)
- Tdap (tetanus toxoid, reduced diphtheria toxoid, acellular pertussis)
- Hepatitis A
- Hepatitis B
- Polio
- Cholera (not available in the U.S.)
- Rabies
- Japanese encephalitis
- Typhoid polysaccharide
- HPV
- Pneumococcal vaccines (PPSV23 and PCV13)
- Meningococcal
- Influenza

VACCINE SCHEDULES

Vaccine schedules are noted here with vaccine-specific discussions to follow later in this section. The specific schedule for vaccinations changes frequently. The current schedule can be found on the web page for the Advisory Committee on Immunization Practices (cdc.gov/vaccines/schedules).

Vaccinations that are recommended for adults, according to age groups:

- **Td or Tdap:** 1 dose q 10 years. Tdap is approved for **all** > 7 years of age. Tdap should be given only once as an adult if the 3-dose primary childhood series has been given; after that, Td can be given.

- **HPV:** 2 or 3 doses (depending on age at which the 1st dose is administered) for 9–26 years of age for both males and females
- **Varicella (chickenpox vaccine):** 2 doses, if no history of immunity or vaccination
- **Zoster (booster to prevent shingles):** adults > 50 years of age
- **MMR:** For patients born after 1956 or those who have not had naturally occurring infection or laboratory evidence of immunity, give 2 doses if not vaccinated or 1 more if received only 1 vaccine as a child.
- **Influenza:** given annually to **all** persons > 6 months of age
- **Pneumococcal vaccination:** > 65 years of age and those at risk. There are 2 vaccines that should be given to most individuals.
- **Hep A:** at-risk adults (chronic liver disease, men having sex with men [MSM], travelers to endemic countries, and intravenous drug abuse [IVDA])
- **Hep B:** at-risk adults (health care/safety workers, chronic liver disease, end-stage renal disease, HIV, IVDA, and MSM) without evidence of immunity and no history of childhood vaccination
- **Meningococcal polysaccharide or conjugate:** everyone 11–18 years of age and at-risk adults 19–55 years of age

Zoster vaccines: There are two zoster vaccines currently available. The Advisory Committee on Immunization Practices (ACIP) and the CDC recommend the recombinant vaccine for all healthy adults > 50 years of age. The ACIP also recommends that those who received the earlier zoster vaccine (live attenuated) be revaccinated with the newer version (recombinant).

Recombinant zoster vaccine (RZV; Shingrix): In those 50–69 years of age, recombinant zoster vaccine has an effectiveness of 97%; it is 91% effective in preventing herpes zoster and postherpetic neuralgia, respectively. At > 70 years of age, this falls a bit to 91% and 89%, respectively. Two total doses are required, 2–6 months apart.

Attenuated live vaccine (Zostavax): The attenuated live vaccine has an overall effectiveness of 50% and 75% to prevent herpes zoster. Because it is a live virus, this vaccine is contraindicated in immunodeficient and pregnant patients. Both the varicella and the zoster vaccine have the same virus, but the latter has a much higher dose. One total dose required.

MMR: It is recommended that persons born after 1956 receive 2 doses of live measles vaccine. These should be given at least 1 month apart, but they can be given years apart. Any adults born after 1956 who have had only 1 live measles vaccine should receive another.

Pneumococcal vaccine: The 2 pneumococcal vaccines include the 23-valent polysaccharide vaccine (PPSV23), which was approved in 1983 and contains 60–70% of prevalent serotypes, and the 13-valent conjugate vaccine (PCV13), which was approved in 2010 and contains the 13 most common serotypes. The approach to giving

these vaccines is a little complicated. First, decide whether PCV13 is indicated; if so, give it before the PPSV23. If PCV13 is **not** indicated, decide whether PPSV23 is indicated. There is no circumstance in which PPV13 is given alone.

PPSV23 should be given:

- Alone to adults < 65 years of age if at risk because of:
 - Smoking
 - HF
 - COPD
 - Cirrhosis
 - Diabetes mellitus
 - Ethanol abuse
- In combination with and after PCV13 in persons ≥ 65 years of age, or if very high risk, defined as:
 - CSF leak or cochlear implant
 - Asplenic
 - Chronic kidney disease or nephrotic syndrome
 - Immunocompromised
 - Leukemia, lymphoma, or myeloma
 - Disseminated cancer
- With an interval between doses:
 - If given because of high risk (≥ 8 weeks)
 - If given because ≥ 65 years of age (≥ 6 months)
 - In patients who have already received PPSV23 and now have an indication for PCV13, the latter should be given ≥ 1 year after the former.

Hepatitis A vaccine: Unless otherwise contraindicated, inactivated HepA vaccine is universally recommended at or after 1 year of age. It is also recommended for men who have sex with men; patients with chronic liver disease, including hepatitis B and/or C; patients with clotting disorders; and travelers to countries with high rates of hepatitis A.

Hepatitis B vaccine: This vaccine is universally recommended at birth and for all adolescents who were not immunized in childhood. Chronic hepatitis B is a risk factor for hepatocellular cancer. Vaccination is recommended in high-risk adults.

According to the CDC's Advisory Committee on Immunization Practices (ACIP):

- All unvaccinated adults at risk for hepatitis B infection should be vaccinated. This includes:
 - Sex partners of people infected with hepatitis B
 - Men who have sex with men
 - People who inject street drugs
 - People with > 1 sex partner
 - People with chronic liver or kidney disease
 - People < 60 years of age with diabetes
 - People with jobs that expose them to human blood or other body fluids
 - Household contacts of people infected with hepatitis B

- Residents and staff in institutions for the developmentally disabled
- Kidney dialysis patients
- People who travel to countries where hepatitis B is common
- People with HIV infection
- Other people may be encouraged by their doctor to get the HepB vaccine; for example, adults ≥ 60 years of age with diabetes.
- Anyone else who wants to be protected from hepatitis B infection may get the vaccine.
- Pregnant women who are at risk for 1 of the reasons stated above should be vaccinated (see the [Women's and Men's Health](#) section). Other pregnant women who want protection may be vaccinated.

Serologic testing for immunity is recommended only for specific groups:

- Health care and public safety workers
- Chronic hemodialysis patients
- HIV-infected persons
- Immunocompromised persons
- Sexual partners of HBsAg-positive persons

Give persons who do not develop a protective response (anti-HBs concentration of < 10 mU/mL) another full vaccine series.

Meningococcal vaccines: Meningococcal disease is devastating; therefore, preventing disease is of paramount importance. Remember the risk factors for severe disease to help remember the vaccination recommendations. They include:

- Asplenia
- Complement deficiencies (See more on complement deficiencies in the [Allergy & Immunology](#) section.)
- 1st year college students who live in dorms
- Military recruits
- People who are traveling to the meningitis belt of sub-Saharan Africa, Saudi Arabia (e.g., for the Hajj), or Nepal
- Lab workers who work with *Neisseria*

There are two broad groups of meningococcal vaccines; only those available in the U.S. will be reviewed.

Quadrivalent polysaccharide conjugate vaccine: Serogroups A, C, W, and Y are covered by the quadrivalent conjugate. Two quadrivalent vaccines are approved for use in the U.S.:

- MenACWY-DT (Menactra)
- MenACWY-CRM (Menveo)

Indications for quadrivalent vaccination are all individuals 11–18 years of age and individuals ≤ 10 or ≥ 19 years of age who are at risk for invasive meningococcal disease.

Monovalent vaccine: Serogroup B in the U.S., other serotypes (C and A) are used outside of the U.S. Two serogroup B vaccines are approved for use in the U.S.:

- MenB-FHbp (Trumenba)
- MenB-4C (Bexsero)

Indications for MenB vaccination:

- Individuals ≥ 10 years of age who are at increased risk for invasive meningococcal disease
- During outbreak scenarios
- Individuals 16–23 years of age who are at average risk for invasive meningococcal disease for short-term protection (e.g., new college students in dorms or new military recruits in barracks)

Pertussis: Adults are the major reservoir for pertussis. Although it is usually self-limited in adults, it can be deadly for infants.

To help protect children, it is recommended that all adults receive 1 booster with Tdap sometime in adulthood. In addition, give pregnant women Tdap with each pregnancy.

APPROACH TO TETANUS PREVENTION

Tetanus can be prevented with the appropriate use of tetanus toxoid (Td) and tetanus immunoglobulin (TIG). The use of these depends on the type of wound and the vaccination status of the patient.

Tetanus-prone wound: Tetanus-prone wounds include crush injuries, bite injuries, dirt- or fecally contaminated wounds, puncture or missile wounds, deep penetration wounds, wounds containing foreign bodies (e.g., wood splinters), and reimplantation of an avulsed tooth. Tetanus can be prevented based on how certain it is that patients have had the primary series of 3 injections of Td or not.

Give a booster dose of Td to those who have had a primary series if they have not received Td in the last 5 years. This stimulates sufficient production of antitoxin antibodies before the tetanus toxin can travel from the wound site to the CNS.

Patients with a tetanus-prone wound who have **not** received the primary series or have uncertain immunization history are considered at high risk for tetanus. Give these patients Td to begin the primary series. However, since they have not had adequate prior immunization, boosting of their immune response cannot be relied upon. Therefore, these are the patients for whom tetanus immune globulin (TIG) is indicated.

Non-tetanus-prone wound: Persons who do not have tetanus-prone wounds (often called “clean wounds”) are not at risk for tetanus from the wound. However, the patient encounter provides an opportunity to begin immunization in the previously unvaccinated or to boost immunity in people who haven’t received a booster in the last 10 years. Thus, give those who have not received

all 3 primary series injections of Td (or are uncertain) as many Td injections as needed to complete the 3-shot primary immunization sequence. Give a Td booster to those who have completed the primary series but have not been boosted in the last 10 years. TIG is **never** indicated in the management of non-tetanus-prone wounds.

UNCOMMON VACCINES FOR SPECIAL SITUATIONS

Japanese encephalitis vaccine is recommended for travelers who plan to stay a long time in rural Asia.

Rabies vaccine is discussed under [Rabies on page 4-24](#).

Typhoid vaccine is recommended for travelers > 2 years of age who go outside of the usual tourist areas within Latin America, Asia, and Africa. An oral live attenuated vaccine is recommended for those > 2 years of age. It has a protection rate of only 35–60% and can be repeated every 5 years. A parenteral polysaccharide vaccine has an efficacy of 60–70% and can be repeated every 2 years.

Polio vaccine is not routinely recommended to persons > 18 years of age. Polio vaccine is recommended for previously unimmunized travelers to endemic areas. A booster is indicated for travelers who have had only the primary vaccination and who travel to areas where exposure to the wild-type virus is likely. Only the inactivated vaccine is recommended in the U.S.

Yellow fever vaccine is recommended for travel in equatorial Africa and much of tropical South America. It is a live vaccine; therefore, do not give to immunosuppressed patients. As of early 2020, supply of yellow fever vaccine was totally depleted, and the manufacturer is expected to have an update by the end of 2020.

Cholera vaccine was approved in the U.S. in 2016 and is a live attenuated oral vaccine that can be given to adults traveling to regions with active cholera cases within the last year.

DEMOGRAPHICS

Life expectancy correlates with race and gender. Caucasian women live the longest. African American women and Caucasian men tie for 2nd place. African American men have the shortest lifespans. Generally, women live longer than men, are less likely to remarry, lack money to take care of all their needs, and are more often disabled as they age.

61–79% of patients > 65 years of age have hypertension, and roughly 27% have diabetes. Mortality data from the Centers for Disease Control and Prevention (CDC) for 2017 shows that heart disease is the leading cause of death, followed by cancer, in older adults (a.k.a. the elderly). Many studies show that elderly patients are **not** offered the same life-saving procedures as younger patients with the same disease states, even though age alone has no adverse effect on outcomes of the interventions. **Age alone is not enough of a reason to withhold an intervention.**

THE PHYSIOLOGY OF AGING

PREVIEW | REVIEW

- Know the meaning of these terms: senescence, normal aging, usual aging, life expectancy, and maximum life-span potential.
- Explain the various theories for the causes of aging.
- What are the cellular processes involved in aging?
- What is sarcopenia?
- What are the physiologic changes that occur in the various sense organs of the body with aging?

OVERVIEW

In 2016, 49.2 million people in the U.S. were ≥ 65 years of age (15% of the total population), with projections to be 98.2 million in the year 2060. The fastest-growing segment of the population is those > 85 years of age. If the present growth rates continue, there will be about 834,000 centenarians by 2050, and 82% will be women. It is very important to understand the physiology of aging, as this helps differentiate between normal age-related physiologic changes from pathologic processes and aging.

Aging is a progressive process that is associated with declines in structure and function, impaired ability to maintain and repair tissues, and increased susceptibility to disease and death. The aging process is the most significant risk factor for disease and disability.

While recognizing aging is easy, defining aging is a little more difficult. There are certain phenotypic components of aging that can be subclassified into the following:

- Primary aging changes: e.g., gray hair, decreased muscle mass (sarcopenia)
- Age-related diseases: e.g., dementia, osteoporosis, osteoarthritis, increased insulin resistance

Additionally, in contrast to the younger cohort, older people have multiple comorbidities and chronic diseases and are more vulnerable to malnutrition. Microvascular dysfunction, mitochondrial impairment, and oxidative injury are typical changes associated with aging and underlie many of the pathologic changes.

Some terms:

- **Senescence** refers to postmaturational processes that lead to diminished homeostasis and increased vulnerability of the living person.
- **Normal aging** refers to physiologic processes that occur at certain points during the aging process. A good example of this is menopause in females.
- **Usual aging** refers to age-related disease processes that occur in older individuals. Examples of these processes include hypertension and coronary artery disease, which occur more frequently as one grows older.
- **Life expectancy** refers to the average age expected to live based on current age, race, gender, and other demographic factors (e.g., financial, marital, health status).
- **Maximum life-span potential** is the age obtained by the longest living member of the given population.

In human beings, the maximum life-span potential for a male is approximately 120 years and for a female is approximately 122 years. The approximate life expectancy is 76 years for males and 81 years for females. In general, females outlive males in most species in the animal kingdom.

THEORIES OF AGING

There is no single, definitive theory that gives a satisfactory explanation for the aging process.

The **stochastic theory of aging** hypothesizes that random damage to cellular structures accumulates and results in progressive decline in cellular function and eventual death. The various processes under this theory include mutations and free radical-induced injuries. Free radicals are highly reactive byproducts of metabolism, and they can affect the cells and their various components. Accumulation of free radicals results in dysfunctional cells and subsequent cell death.

Genetic theories of aging state that genes are programmed for a person's growth from birth to death. About a quarter of human lifespan variation is believed to be genetic. For example, longevity appears to correlate with the presence of the apolipoprotein E (*APOE*) e2 allele and/or the absence of *APOE* e4.

According to the **neuroendocrine theory of aging**, the hypothalamic-pituitary-adrenal axis plays a significant role in the various stages of development, and as its function declines, aging occurs.

The **vascular aging** theorists believe that changes in the endothelial structure of the blood vessels correlate with significant changes in all body parts. They conclude that

age-related changes in the arteries (such as vascular stiffening and abnormal vasomotor regulation with alterations in arteries [e.g., coronary arteries]) adversely affect cell function.

The **immunologic theory of aging** proposes that alterations in the immune system increase susceptibility to disease and, therefore, affect longevity.

AGING AT THE CELLULAR LEVEL

At the cellular level, the following processes seem to cause aging:

- Oxidative stress and increase in free radical formation
- Mitochondrial dysfunction causing altered mitochondrial adenosine triphosphate (ATP) formation, again leading to increased free radical formation
- Progressively shortening telomere length and replicative senescence (Hayflick limit refers to the limit at which the cell stops dividing when the telomere length reaches below a critical limit.)
- Altered gene expression due to epigenetic changes (e.g., DNA methylation, chromatin remodeling, histone acetylation)
- Impaired autophagy causing defective cell repair

AGE-RELATED CHANGES

Height

Bone is built until the 3rd decade of life and then loss of bone starts to occur. Height loss averages 1/2 inch every 10 years and is even more rapid after 70 years of age. This is caused by decrease in vertebral body height, thinning of the intervertebral discs, slight flexion at the hips and knees, and flattening of the arches of the feet.

Weight and Body Composition

Weight is not directly related to aging and is influenced by multiple factors, including diet, activity level, and socioeconomic status. However, **body composition** does change with age. Total body water decreases with age. Lean body mass decreases by 1% per year from approximately 55 years of age. The fat component doubles from 15% to 30% of the body weight by the 7th decade of life in men. Across the board, the fat component is slightly higher in women across all ages. As aging occurs, fat becomes more centrally distributed—mainly in the abdomen.

Musculoskeletal System

Sarcopenia is decreased muscle mass with decrease in strength caused by aging. This occurs due to a decrease in lean body mass, alterations in neuronal and neuromuscular transmission, and muscular changes that occur with aging. This muscle loss mainly involves the Type II fibers. Lipofuscin accumulation is a pathologic feature observed in sarcopenia. One muscle that is notably spared in aging is the diaphragm.

Joints and cartilage become concomitantly stiffer with aging. In postmenopausal females, estrogen loss causes a significant increase in bone loss, leading to osteoporosis.

Gait and Balance

Gait velocity correlates with functional status. The slower the gait, the higher risk for health decline and mortality. Decreased gait correlates with decrease in arm swing. Sarcopenia, slower gait, and decreased arm swing contribute to imbalance and cause a slightly increased propensity to fall. In addition to these, concomitant disease processes, impaired vision, and medications also independently increase the risk of falling. See more under [Mobility and Gait on page 5-5](#).

Skin

Skin turnover time is increased in aging. Blood supply to the skin is also decreased, resulting in dry skin (xerosis) with decreased functioning of both sweat and sebaceous glands. All of these not only cause the skin to become more prone to injury but also prolong the healing time with even minor injuries. Wrinkling of the skin occurs due to loss of elastin and collagenous and subcutaneous fat. Hair loss is increased. Graying of hair occurs because of progressive loss of melanocytes. Synthesis of vitamin D is less efficient in sunlight-exposed aging skin, which contributes to this vitamin deficiency.

Sensory Changes

Vision

Several changes occur across various parts of the eye with aging. **Important changes:** the iris responds more sluggishly to light stimulation due to increased rigidity, and the lens becomes yellowed due to photo oxidation of tryptophan, which affects blue color perception. Significant glare can occur when light is scattered into the eyes, and this adversely affects driving, among other things. Presbyopia refers to the process of decreasing lens elasticity and ciliary muscle atrophy. Both light and dark adaptation are impaired, and contrast sensitivity is diminished. Because of these, the use of night lamps and glare-free lights are important to decrease the risk of injury from falls.

Hearing

As we age, the auditory canals become narrowed, predisposing older individuals to cerumen impaction. Cerumen impaction also occurs because the cerumen is drier and the hair in the canal gets coarser. These independently can cause conductive hearing loss in older patients in addition to the sensorineural hearing loss that occurs with aging. Presbycusis describes the bilateral, symmetric hearing loss involving higher frequencies in older patients. Hearing aids can be beneficial. Be sure to check for cerumen impaction.

Taste and Smell

Taste perception and smell perception both decrease significantly with normal aging. Smell acuity declines to about 50% of its peak by 80 years of age. The number of taste buds declines after 60 years of age, and the remaining buds shrink in size, resulting in reduced taste. Common medications such as antihypertensives, antibiotics, and cholesterol-lowering drugs can also decrease smell and taste. These sensory alterations can contribute to anorexia and decreased appetite. However, profound anorexia is almost always pathological. Flavor enhancers, such as pepper, cinnamon, vinegar, and ginger, may be helpful in increasing appetite. While sugar and salt addition may achieve the same thing, excessive use of sugar and salt are associated with adverse health consequences and, therefore, preferably avoided.

Immunity

There is an age-related decrease in immunity. The total number of T cells declines, and there is a change in T-cell subsets. CD4 T cells decrease with age, and the number of CD8 T cells increases with age. CD4 decline causes less stimulation of B cells; also, the bone marrow makes fewer B cells with a net result: less antibody production. Also, only half of the T cells remain competent, which is why herpes zoster and reactivation tuberculosis are often seen in older adults.

CLINICAL PEARL

As aging occurs, smaller doses of water-soluble drugs (e.g., aminoglycosides) achieved therapeutic levels as compared to their use in younger people. In contrast, lipid-soluble drugs like benzodiazepines (BDZs) accumulate in the fat in elderly people. This causes the effect of these fat-soluble medications to be present long after withdrawal of the medications.

EPIDEMIOLOGY OF AGING

PREVIEW | REVIEW

- What are the 3 Ds in aging?
- What factors influence disease and disability in older adults?
- Do gender and race affect morbidity and mortality?
- What are the major causes of mortality in older adults?
- What are ADLs and IADLs?

OVERVIEW

The main health concerns of older patients can be summarized as 3 Ds: disease, disability, and dependency. Various factors influence the 3 Ds: age, gender, race,

education, and income level. Epidemiology of aging refers to the disability, morbidity, and mortality caused by various diseases, including their effect on independent living in older adults.

The simplest and often the best way for you to assess your patient's health is to ask them to rate their health on a scale of 1–5:

- 1—Poor
- 2—Fair
- 3—Good
- 4—Very Good
- 5—Excellent

A patient's self-assessed health correlates significantly with their clinical condition and is a good predictor of their health outcomes, including hospitalizations, health care expenditure, nursing home placements, morbidity, and mortality.

AGE

As people age, the incidence and prevalence of chronic diseases, such as arthritis, cancer, hypertension, and heart disease, increase. Mortality and morbidity rates also increase with age.

GENDER

Females have a longer life expectancy than males—although the exact cause of this is unclear. Premenopausal women suffer less from heart disease due to the protective effect of estrogen. Additionally, in general, women notice problems sooner and seek attention faster than men. In contrast, a higher percentage of men indulge in high-risk behaviors like smoking or alcohol or drug use and are likely to work in occupations that involve higher risk and higher occupational exposure to toxins. These reasons may explain why men have a shorter life expectancy than women.

Paradoxically, women have higher disability and morbidity rates compared to men, but again, the exact causes are unclear.

RACE

African American, Hispanic, and Native American populations have higher mortality rates when compared to Caucasian Americans of the same age. Overall, rates of chronic diseases (including arthritis, diabetes, hypertension, coronary artery disease, and strokes) are significantly higher in minority populations. Asian Americans are a notable exception to the rule—although even they have slightly poorer health care outcomes.

EDUCATION AND INCOME LEVEL

Higher levels of education are associated with better health; similarly, lower levels of education are associated

with poor health outcomes. Higher education is associated with better physical health behaviors (e.g., more time spent on exercise, lower smoking rates, lower BMIs). Higher subjective levels of happiness are also reported in people who have attained higher education. Similarly, higher income levels are also consistently associated with better health outcomes.

MAJOR CAUSES OF MORTALITY IN OLDER ADULTS

The majority of deaths in the early 1900s were due to infectious disease. In contrast, in 2017, nearly half of all older Americans died from heart disease (25%) and cancer (21%), followed by chronic lower respiratory diseases, stroke, Alzheimer disease, and other diseases. Currently, infections such as influenza and pneumonia account for only about 2% of all deaths in older Americans. Although women have a lower mortality rate at a given age than men, the causes of death in older women are the same as older men.

MORBIDITY

Morbidity refers to the burden of disease. Chronic diseases form the bulk of these problems. Nearly 2/3 of older adults have hypertension, 1/2 have elevated blood lipids, and arthritis, diabetes, and heart disease each affect 1/3.

Comorbidity refers to the presence of > 1 disease. About 85% of older Americans have 1 chronic disease and 60% have ≥ 2 chronic diseases. Even at 60 years of age, 25% of Americans have a chronic disease that significantly impacts their ability to perform at least 1 of the activities of daily living (ADLs; see [Disability](#)). Comorbid diseases are a significant cause of loss of independence. Chronic diseases and mental health account for 90% of American health care expenditures. When hospitalized, older adults have a longer length of stay compared to younger adults, primarily due to the comorbidities.

DISABILITY

As previously mentioned, women have a higher rate of disability than men. Age is a major risk factor for loss of independence; 20% of women are dependent at 70 years of age, and this number increases to 60% by 90 years of age.

Disability is assessed through activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs are the basic self-care activities necessary for independent living, while IADLs are higher-level activities required to function independently in society.

ADLs can be remembered by the mnemonic **DEATH**:

- Dressing
- Eating
- Ambulating
- Toileting
- Hygiene

IADLs can be remembered by the mnemonic **SHAFT**:

- Shopping
- Household work
- Account management (managing finances)
- Food-making (cooking)
- Transport (ability to move around from place to place)

Most people with ADL limitations have limitations in IADLs, whereas the converse is not true: people with IADL limitations need not have any ADL limitations. This is because ADLs assess more basic functions as compared to IADLs.

RECENT TRENDS IN LIFE EXPECTANCY

The encouraging news is that with medical advancement and understanding of disease processes, total life expectancy and disease-free life expectancy have mostly increased. Declines in life expectancy largely related to drug overdoses and unintentional injuries began to reverse in 2018, aided by lower death rates due to cancer. Threats to continued improvement include rising rates of liver disease, diabetes, and obesity. Other potential threats to human longevity are pandemics (such as the one caused by the novel coronavirus SARS-CoV-2 in 2020), epidemics, and nuclear warfare. Despite these unknowns, medical science strives to usher in a golden period in human history in terms of improvements in life expectancy.

GERIATRIC ASSESSMENT

PREVIEW | REVIEW

- How do you diagnose frailty?
- What assessments should be done periodically in older patients?
- What are the major features of delirium, using the Confusion Assessment Method?

Frailty affects a large number of older adults. It can be caused by comorbid illness and/or disability, but not necessarily so. Frail patients are more likely to fall, become disabled, or die. Make a diagnosis of frailty if ≥ 3 of the following are present:

- 1) Unintentional loss of ≥ 10 lb/1 year
- 2) Exhaustion due to lack of endurance
- 3) Decreased hand strength
- 4) Walking slowly
- 5) Reduced activity

All geriatric patients should have a specific interval assessment of **function** because functionality is related to longevity. Functional assessment evaluates several components:

- ADLs
- IADLs

- Cognition
- Hearing
- Vision
- Nutrition (See [Nutrition and Gastroenterology on page 5-10.](#))
- Gait and balance (See [Mobility and Gait.](#))
- Driving ability (See [Older Adults and Driving on page 5-23.](#))

Start by assessing **ADLs**: Can the patient dress, bathe, feed, use the bathroom, and move around without help? IADLs are those activities that connect the patient with the community: Can the patient manage their money, take their own medication, manage transportation, make phone calls, do the shopping and housework, and make their own meals? To perform IADLs requires effective executive functioning, an umbrella term that refers to a set of mental skills that allow us to plan, juggle tasks, call up from memory, and focus attention.

To assess **cognition**, look for evidence of dementia and delirium:

- Assessing **dementia**: A quick way is to use the Mini-Mental State Exam (MMSE) or the Mini-Cog (easier to remember) to assess dementia. To perform the Mini-Cog, ask the patient to remember 3 words, and then ask them to draw a clock showing a specific time. After drawing the clock, ask the patient to recite the 3 words. Score by giving 1 point for each word remembered correctly and 2 points for an accurate clock (0–2 points = dementia). The Montreal Cognitive Assessment (MoCA) test is more sensitive for mild cognitive impairment than the MMSE or Mini-Cog.
- Assessing **delirium**: The best tool to assess delirium is the Confusion Assessment Method (CAM; 94–100% sensitive; 90–95% specific). See [Table 5-1](#). Delirium is present when the patient has features 1 and 2 along with either 3 or 4.

Table 5-1: Confusion Assessment Method (CAM)

Feature	Description
1	Acute onset and fluctuating course: Is mental status acutely changed from baseline, and does the change fluctuate throughout the day?
2	Inattention: Is there a problem focusing attention (e.g., easily distracted)?
3	Disorganized thinking: Is conversation rambling or irrelevant? Are ideas illogical in flow?
4	Altered level of consciousness: Is the patient alert (normal state), hyper-alert, drowsy but easily aroused, difficult to arouse, or unarousable?

Read more under [Delirium on page 5-13](#) and [Dementia on page 5-14](#).

Assess **hearing** and **vision** using traditional instruments such as the whisper test and the Snellen eye chart. The whisper test is performed by covering the ear that is

not being tested, then whispering a question while standing about 2 feet away. If the patient responds correctly, then no more testing is required. Give the patient 6 tries. Refer for further audiometric testing if the patient answers ≥ 3 questions (out of 6) incorrectly.

Gait and balance are assessed by observing gait and by watching the patient get up from a chair, walk across the room, turn around, walk back, and sit down (the **Get Up and Go** test).

Older adults (and teens) have more driving violations compared to the general population. Usually, patient performance on the vision, hearing, and gait assessment gives you an adequate estimate of a patient's physical ability to operate a vehicle. Formal assessment is offered for older adults through departments of motor vehicles.

Assess for safety annually and potential abuse at each visit. Patients often do not voice these types of concerns unless asked directly. See more under [Elder Mistreatment on page 5-21](#).

MOBILITY AND GAIT

PREVIEW | REVIEW

- What are risk factors for falls in older adults?
- What is the most common foot deformity among older adults?
- What factors can contribute to the development of decubitus ulcers?
- What is the role of wet-to-dry dressings in decubitus ulcer treatment?

FALLING

Aging contributes to **increased instability and falls**. 50% of patients ≥ 80 years of age fall each year! Older adults have a stiffer, less agile gait with decreased position reflexes. 5% of falls result in fractures, and, if the patient cannot get up, there is an increased possibility of hypothermia, dehydration, pressure injuries, and rhabdomyolysis.

Aging is also associated with decreased proprioception and baroreceptor reflexes, so orthostatic hypotension and swaying are common. Carotid sinus hypersensitivity increases with aging and can increase the risk of falls and fractures. Postprandial hypotension occurs frequently in older adults—risk can be decreased by eating smaller meals and fewer carbs per meal.

Risk factors for falls:

- Age
- Female gender
- History of falls
- Rugs, untidiness, and dim lighting
- Poor vision

- Orthostatic hypotension
- Unsteady gait
- Cognitive impairment
- Musculoskeletal disease
- Cardiovascular disease (e.g., syncope)
- Psychotropic drug use
- Peripheral neuropathy

Use of physical restraints (e.g., arm or leg restraints, hand mitts, vests) increases the risk of injuries, so avoid physical restraints when possible.

Fall risk assessment in older adults includes 5 quick office tests:

- 1) Get Up and Go test
- 2) Gait speed (slower = ↑ risk)
- 3) Tandem (heel-to-toe) walk
- 4) Visual acuity
- 5) Calf circumference (smaller = ↑ risk)

Workup for the patient with falls includes a good history and physical exam with emphasis on a multidisciplinary assessment and evaluation for a cardiovascular cause. Do a syncope workup if the patient does not remember the fall or if the history is suggestive. Also think about weakness caused by osteomalacia—especially in nursing home patients who are bedridden and never exposed to sunlight. Check 1,25-(OH)₂-D if you suspect osteomalacia and treat any deficiency, because treatment decreases fall risk. Bone mineralization is impaired without adequate vitamin D. Look for other laboratory clues to osteomalacia such as low serum levels of calcium (leading to increased parathyroid hormone levels) and decreased serum phosphate. Another finding is increased alkaline phosphatase, a result of increased osteoblast activity.

Anticipatory guidance for fall reduction includes restriction of certain activities, improving the lighting at home (e.g., use night-lights), decreasing hazards (e.g., remove rugs and loose carpets), and placing extra supports (e.g., bars in the shower). If possible, discontinue medications known to increase fall risk (e.g., diuretics, anticholinergics, BDZs, muscle relaxants, antidepressants, neuroleptic agents, antihypertensive medications). Exercise, especially focused on balance and resistance training, is **very important** in reducing fall risk.

Falls and osteoporosis are major risk factors for hip fractures in older adults. 90% of hip fractures occur from a simple fall. Women are at higher risk compared to men due to higher rates of osteoporosis. See the [General Internal Medicine](#) section for more on osteoporosis and falling.

COMMON FOOT PROBLEMS

After 75 years of age, < 30% of patients are able to care for their feet due to physical and cognitive limitations.

Lack of preventive care can lead to common foot problems in older adults. The ankles, subtalar joints, and first metatarsophalangeal (MTP) joints frequently develop arthritis. Bunions account for 75% of foot deformities. Their etiology is unknown and likely contributing factors are altered foot mechanics or anatomy and genetics. Hammer toes are deformities due to high tension in muscles and tendons in toe joints. Toenails usually become thicker and brittle with aging and onychomycosis, poor circulation, or hypothyroidism. Ingrown toenails can lead to pain and infection. Other foot health issues include foot ulcers from diabetes and lower extremity edema from cardiovascular diseases, a medication side effect, and poor nutrition. Properly fitting shoes, routine foot care, and treatment of underlying conditions prevent long-term complications.

IMMOBILITY

Immobilization causes muscle atrophy. Patients adapt to bed rest, and the longer a patient is immobilized, the harder it is to ambulate again. Immobilization causes decreased ADH secretion → diuresis → decreased blood volume → orthostatic symptoms. The heart continually deconditions after 2 days of bed rest. Treat with rehabilitation.

The goal of rehabilitation is to get the patient to function at the highest level possible given the physical impairment. Enhance functional abilities and limit demands. This can be achieved by limiting medications, enhancing nutrition, providing assistive devices and human help, modifying living arrangements, and providing adaptive training. The greatest rehabilitation potential is achieved with coordinated care with the patient, family, and caregivers. This is often achieved across multiple settings, including the hospital, nursing home, and home health services.

Geriatric patients struggle with the decision to stay in their home vs. an alternative location such as a nursing home or assisted living facility. Most studies show no differences in health outcomes between rehabilitation at home vs. nursing homes. The best results involve decisions made between the patient, family, and caregivers regarding where the best care can be delivered. Often, home care can be cost prohibitive, and the level of care needed by the patient is best delivered in a nursing home.

PRESSURE INJURIES

Pressure injuries (a.k.a. decubitus ulcers) occur most commonly on the heels, greater trochanter, sacrum, and iliac crest. The main etiology is sustained pressure over a prominent bone. Shearing and friction tear the skin and cause necrosis with ulceration. **Moist** environments (notably, in urinary incontinence), neurologic impairment (e.g., dementia), and **malnutrition** (i.e., ≥ 10-lb weight loss in the past 6 months) also increase the risk for developing pressure injuries.

Pressure injuries in **nursing home patients** increase mortality (usually from osteomyelitis and bacteremia/sepsis).

There are 4 stages of pressure injury:

- Stage 1 is nonblanching erythema (reddish macules).
- Stage 2 is partial-thickness skin loss (small, superficial ulcer).
- Stage 3 is full-thickness skin loss (fat visible).
- Stage 4 is loss of tissue down to the muscle, tendon, or bone.

Bed-bound patients should be rotated from side to side (30° angle) every 2 hours. This prevents continued contact against bony prominences. Special mattresses and heel/elbow pads also help.

In **established ulcers**, keep pressure off the area, and if an eschar exists, remove it for proper staging. Then determine whether any arterial or venous insufficiency exists, treat infection if present, and maintain a “clean” ulcer.

Effective healing requires **debridement** of necrotic tissue back to healthy granulation tissue, using either chemical topical treatments or a scalpel.

Next, the wound must be cleaned and dressed. **Saline cleansing** is best because it is gentle on growing tissue, and iodine or peroxide hinder wound healing if used repeatedly. The choices for wound dressings are wide and variable. Follow the advice given by the wound care therapist. As a means for debriding wounds, wet-to-dry dressings have fallen out of favor, because too often they damage friable new tissue.

Give antibiotics, in addition to local wound care, if the patient is systemically ill. Use deep wound cultures to guide your choice.

Wounds do **not** heal in malnourished patients, so follow the recommendations of the registered dieticians to provide adequate increased nutrition.

Know: Wounds that develop in the setting of arterial or venous insufficiency do not heal unless the local blood flow is corrected—most often via surgical intervention. Sometimes this is feasible, sometimes not, depending on the patient’s comorbidities.

Stage 1 and 2 ulcers typically heal quicker than Stage 3 and 4 ulcers, which can take months or longer.

A chronic wound is defined as a wound that does not heal within 1 month. Chronic venous insufficiency can lead to progressive edema and ulceration. Management of chronic wound and venous ulcers is similar to that of an acute wound, requiring debridement and proper wound dressing. For venous ulcers, reducing the edema via leg elevation and compression therapy is paramount to wound healing.

HIP FRACTURE

PREVIEW | REVIEW

- What are the risk factors for hip fracture in older adults?
- What are the different classifications of hip fractures?
- Which type of hip fracture is subject to avascular necrosis?
- Which type of hip fracture has the greatest risk for hemodynamic compromise?
- What is the primary management for hip fracture?
- Which anticoagulants are used for venous thromboembolism prophylaxis and for how long after hip fracture?

OVERVIEW

In the United States, hip fractures represent the 2nd leading cause of hospitalizations among older adults. Every year more than 300,000 people > 65 years of age are hospitalized for hip fractures. It is imperative that you recognize, prevent, and correctly manage hip fractures in older patients.

> 95% of hip fractures are caused by falling, most commonly from a standing position, with osteoporosis as the major comorbid factor. Other risk factors include cardiovascular disease, diabetes, low BMI, sedating medications, and low socioeconomic status.

PRESENTATION

Hip fractures are classified by anatomic location (Figure 5-1):

- Intracapsular (femoral neck and head)
- Extracapsular (intertrochanteric and subtrochanteric)

Figure 5-1: Types of hip fractures

Intracapsular fractures have a higher rate of malunion and avascular necrosis compared to extracapsular fractures; this is because the collateral blood circulation to the head of the femur is limited. Intracapsular fractures can be subdivided by anatomic location into subcapital, transcervical, and basicervical. They can also be subclassified by the degree of displacement (Garden classification from anteroposterior radiograph). Symptomatically, some patients can bear weight (e.g., nondisplaced fractures) but will be non-weight-bearing if the fracture is displaced and the limb is externally rotated and shortened on the physical exam.

Extracapsular fractures have a decreased risk of avascular necrosis due to rich dual irrigation by the medial and lateral femoral circumflex arteries (branches of the deep femoral artery). Both arteries encircle the base of the femoral neck around the trochanter. Due to their rich vascularization, extracapsular fractures present with ecchymosis and can have significant hemodynamic compromise due to blood loss. They also have an increased need for implant devices and have higher rates of implant failure due to the high stresses placed upon the femur. Extracapsular fractures are subdivided into intertrochanteric and subtrochanteric fractures, with subtrochanteric fractures presenting with groin pain.

DIAGNOSTIC IMAGES

Order a 2-view hip x-ray with comparison with the uninjured hip as the 1st diagnostic test. If x-ray is negative but clinical suspicion is high, MRI can be diagnostic. If MRI is contraindicated, bone scan is another acceptable option.

MANAGEMENT

The goal of managing hip fractures is to restore the patient's functional status to their preinjury level. Surgical management is best if the patient is medically fit for surgery. Do not delay surgery > 24 hours because delay slows recovery and increases mortality and postsurgical complication risks. Assess the preinjury functional level and risk of surgery before deciding if the patient would benefit from surgical management. In a bed-bound patient with multiple comorbidities, nonoperative management can be undertaken. On admission, all patients require orthopedic consultation and appropriate pain management.

Intracapsular Fractures

There are 4 types of intracapsular fractures, as described in the Garden classification of hip fractures:

- Type 1—incomplete or impacted bone injury with valgus angulation of the distal component
- Type 2—complete (i.e., across whole femoral neck); nondisplaced

- Type 3—complete; partially displaced
- Type 4—complete; totally displaced

Femoral neck Type 1 and 2 fractures are managed with internal fixation and a screw-type device. For Type 3 and 4 fractures, arthroplasty is preferred. Total hip arthroplasty has increased risk of postoperative dislocation and blood loss compared to hip hemiarthroplasty (prosthetic replacement of only femoral head and neck).

Extracapsular Fractures

As mentioned, there are 2 types of extracapsular fractures.

Intertrochanteric fractures have increased risk of displacement; therefore, treatment is open reduction with internal fixation. Severely comminuted fractures are often treated with long-stemmed implants and can require calcar bone graft. An alternative used with unstable fractures, especially in frail patients at increased risk for another fall, is hemiarthroplasty with a calcar-replacing prosthesis.

Subtrochanteric fractures are treated with open reduction and internal fixation.

CLINICAL PEARL

For all extracapsular fractures (both intertrochanteric and subtrochanteric), open reduction and internal fixation is the treatment of choice. If surgery is an option, it should be performed no less than 3 days from injury with early mobilization after surgery.

VENOUS THROMBOEMBOLISM PROPHYLAXIS

Deep venous thrombosis occurs in 27% of patients after hip fracture who are not prophylaxed, while pulmonary embolism occurs in about 5% in the first 3 months following hip fracture surgery. The greatest risk for venous thromboembolism (VTE) is during the first 7–14 days following hip surgery.

The 2016 American College of Chest Physicians (ACCP) guidelines recommend the use of low molecular weight heparin (LMWH), fondaparinux, direct anticoagulant (DOAC, e.g., rivaroxiban, apixaban), low-dose unfractionated heparin, vitamin K antagonist, aspirin, or intermittent pneumatic leg compression for at least 10 days after surgery. If surgery is initially delayed, VTE prophylaxis is recommended until surgery is scheduled.

Of these, fondaparinux is recommended as 1st line by the ACCP. Aspirin is significantly less effective than the above-mentioned anticoagulant agents, but it reduces the rate of VTE when compared to a placebo. Its use is only recommended in patients with high risk for hemorrhagic complications, and is always used with mechanical thromboprophylaxis. The recommended aspirin dosage is 325–650 mg/day.

OTHER RECOMMENDATIONS

Pain management is the initial therapy for any patient with hip fracture. Inadequate pain control is the main cause of delirium. Epidural pain management and nerve block are recommended and are effective controlling pre- and postoperative pain and decreasing opiate requirements and subsequent delirium.

Pressure reduction mattresses are recommended because they reduce the risk of pressure injury complications.

Poor nutritional status carries increased morbidity and mortality risks; therefore, appropriate evaluation and treatment is recommended postoperatively.

To reduce the risk of infection, remove indwelling urinary catheters within 24 hours of hip replacement surgery.

Administer blood transfusion when hemoglobin is < 8 g/dL (80 g/L), unless the patient has clinical indications for earlier transfusion, such as symptoms of anemia or symptoms of active cardiac disease.

At initial presentation, do a complete assessment to identify the possible etiology of the fall. This not only helps with the patient's diagnosis but also with appropriate discharge disposition and prevention of future falls. On discharge, physical therapy is recommended across the continuum of care, including at home, to improve functional outcomes and reduce subsequent falls.

The 2014 National Osteoporosis Foundation guidelines recommend pharmacologic intervention for osteoporosis in any patient with a history of vertebral or hip fracture regardless of bone density findings. Bone densitometry is merely a tool to assess baseline and monitor treatment response; it is not necessary for the decision to initiate treatment. Realize that fragility fractures, i.e., those that result from a fall from a standing height or less, are themselves evidence of underlying weakened bone.

Bisphosphonates are the 1st line of treatment with concomitant Ca^{2+} and vitamin D replacement; smoking cessation, exercise, and avoidance of heavy alcohol intake are also important. Use of zoledronic acid with vitamin D initiated within 90 days of surgical hip repair shows significant reduction in mortality rates and vertebral fracture risks.

Older adults are very sensitive to drugs for the following reasons:

- Pharmacokinetics change with aging (affecting absorption and metabolism), causing increased drug concentrations.
- The volume of distribution for a drug increases because of the proportional increase of body fat compared to muscle.
- Excretion decreases, consistent with age-related decreases in renal and hepatic function.
- Pharmacodynamics of aging → **increased effects** of drugs, especially **opioids** and **BDZs**.

General rules for medication use in older adults:

- Start meds at a **low dose**—usually about 1/2 the dose required for the general population—and gradually titrate up to the normal therapeutic dose. (**Start low and go slow.**) If the patient gets into trouble at the therapeutic dose, try reducing the dose gradually—many older adults get satisfactory responses with lower doses.
- Assume that **any** adverse event is drug-related until proven otherwise.
- Always look to see if a prescribed drug is the cause of new symptoms before prescribing a new drug to treat the new symptoms.
- Look at a geriatric patient's medicine record for atypical antipsychotics if the patient is institutionalized and falling. (See [Delirium on page 5-13](#).) These are the most common causes of falls in nursing homes.
- Errors in self-administration increase dramatically once a patient is prescribed ≥ 3 medications. Geriatric patients may get confused with pills that look alike and with distinguishing between generic and brand names.

Some geriatric patients are dependent on low-dose BDZs or opiates. For these patients, attempt a slow withdrawal of these medications. These have often been prescribed as treatment for anxiety, insomnia, depression, chronic pain, and drug withdrawal. Slowly taper following these general principles: Taper BDZs over 3–6 months after switching to an equivalent dosage of a water-soluble BDZ, such as oxazepam (slower onset, less addictive potential). With opiate dependence, first determine the cause of pain (if any) and treat it with a nonnarcotic drug (e.g., acetaminophen, NSAID in patients without renal disease) or alternatives such as a lidocaine patch. The American Geriatrics Society recommends acetaminophen as the 1st line therapy for chronic noncancer pain. Limit dosage to ≤ 3 g in 24 hours to prevent toxicity. Avoid long half-life opiates in treating pain in the geriatric population.

Be familiar with the Beers criteria (updated every 3 years by the American Geriatric Society) to assess possible

PHARMACOLOGY

PREVIEW | REVIEW

- What should you do for an elderly woman who is on low-dose benzodiazepines for chronic anxiety?

inappropriate drug prescribing for older adults. The 2019 version includes examples of medication classes to consider avoiding in older adults and possible alternatives. Changes in this recent update included a call for caution using aspirin in patients 70 years of age or older for primary prevention of heart disease or colon cancer. Some of the other medication classes that warrant scrutiny in geriatric use are:

- First-generation antihistamines for allergies (e.g., diphenhydramine; alternative: cetirizine)
- Tricyclic antidepressants (e.g., amitriptyline; alternative: sertraline)
- Barbiturate antiseizure medications (e.g., phenobarbital; alternative: lamotrigine)
- Sleep aids (e.g., zolpidem; alternative: nonpharmacologic sleep hygiene)
- Anxiolytics (e.g., diazepam; alternative: buspirone)
- Narcotic pain relievers for acute moderate to severe pain (e.g., meperidine; alternative: tramadol)

Know that, in some studies, up to 75% of the geriatric population use herbal supplements. Many do not give information about supplements and over-the-counter medications unless you ask directly.

NUTRITION AND GASTROENTEROLOGY

PREVIEW | REVIEW

- What criteria diagnose malnutrition?
- What is the usual cause of fecal incontinence?

NUTRITION

We become less active as we age, and we lose muscle and body fat (more muscle than fat). Nutritional requirements are reduced, so generally, older people eat less. Malnutrition is still an issue, though, because of declining abilities and comorbid systemic disease.

≥ 2 of the following parameters diagnose malnutrition:

- 1) Unintentional weight loss (i.e., ≥ 10 lb/6 months)
- 2) Loss of cutaneous fat
- 3) Loss of muscle mass
- 4) Decreased functional status
- 5) Decreased calorie intake
- 6) Localized edema

When malnutrition is diagnosed, assess for modifiable risks (e.g., decreased access to nutritious food, denture or teeth problems, untreated medical illness, inability to perform IADLs [such as grocery shopping]).

The age-related decline in appetite and energy needs is often accompanied by dietary replacement of

carbohydrates with fats. Counsel geriatric patients to increase their daily fluid and fiber intake, obtain the recommended 0.8 g/kg protein/day, and eat healthy fats (i.e., monounsaturated, omega-3s)—such as olive oil, nuts, avocados, and fish. Vitamin supplements are useful in those with poor oral intake because this age group is especially vulnerable to deficiencies of vitamins D and B₁₂ and Ca²⁺.

For those > 65 years of age, the National Institute on Alcohol Abuse and Alcoholism and the American Geriatrics Society recommend lower-risk limits of no more than 2–3 drinks/day and/or 7 drinks/week, with lower amounts for people taking medications with alcohol-potentiated side effects.

DISORDERS OF SWALLOWING

Among older adults, disorders of swallowing are common, which can lead to dehydration, weight loss, aspiration pneumonia, and airway obstruction. Structural and functional causes include stroke, cancer, neurologic disorder (e.g., Parkinson, dementia, myopathy), gastroesophageal reflux disease (GERD), esophageal dysmotility, medication side effects (e.g., antipsychotics, antihistamines, antidepressants), and inflammation or infection. Evaluate with a video fluorographic swallowing study to identify the disorder and to test therapeutic and compensatory techniques. Endoscopy is sometimes needed to further evaluate the disorder. Treatment is targeted at the underlying condition and initiation of rehabilitative measures, which can include dietary modification and adjusted swallowing techniques. Severe forms of swallowing dysfunction can require bypass of the oral cavity with a feeding tube or IV total parenteral nutrition.

CONSTIPATION

Constipation in older adults is either due to functional chronic constipation or secondary to other causes. Functional causes include slow transit, dyssynergic defecation, and irritable bowel syndrome with predominant constipation. Secondary causes include metabolic derangement, such as hypothyroidism; neurologic disorders, such as stroke and Parkinson disease; and medication side effect, especially from opiates. Treat with dietary and lifestyle modifications. Use of laxatives, stool softeners, enemas, and biofeedback are alternative options.

FECAL INCONTINENCE

Geriatric fecal incontinence is usually caused by fecal impaction and secondary overflow incontinence. The impaction is normally a result of lax muscles and neuronal degeneration. Typical presentation is an older adult with complaints of diarrhea and abdominal discomfort who has hard stool in the rectal vault on physical exam. Treatment is disimpaction and a subsequent bulking agent such as psyllium.

ENDOCRINE SYSTEM

PREVIEW | REVIEW

- What is the median age of menopause?
- What is andropause?
- What is the typical presentation of Paget disease?
- What complications are geriatric patients specifically at risk for developing as they are being treated for diabetes?
- Metformin should not be given to patients with estimated glomerular filtration rate below what calculated level?
- What are the symptoms of apathetic hyperthyroidism?

AGE-RELATED DEFICIENCIES

The only **specific** female hormonal change that occurs with aging is **ovarian failure**. The median age of menopause is 51 years of age.

The hypothalamic-pituitary-gonadal axis is also disturbed in men, but not as predictably as in women. In both sexes, the adrenal zona reticularis declines in synthesis of dehydroepiandrosterone (DHEA) and the pituitary secretion of growth hormone wanes (and, subsequently, also levels of insulin-like growth factor-1 [IGF-1]). Many other hormones are produced in normal amounts but do not function as well.

Many of these hormone perturbations are thought to occur with the aging process, but none are conclusively linked except ovarian failure. Growth hormone reduction appears to coincide with loss of muscle mass and strength; supplementation is discouraged because it has too many side effects.

The pineal gland's **melatonin** production is disrupted with aging. This can cause poor sleep and insomnia. Melatonin supplementation can help some patients.

Aging patients have reduced clearance of **thyroid hormone**, so thyroid hormone replacement for hypothyroidism can be started at a lower than usual dose. Thyroid-stimulating hormone (TSH) increases with age, especially in women (see the **Endocrinology** section), so a rising TSH without an accompanying decrease in T_4 levels does **not** merit treatment for hypothyroidism. However, most experts recommend starting treatment if the TSH > 10 mU/L.

Testosterone production decreases in the aging male, but the effect is variable. However, the **rate** of sperm production is stable from 20–70 years of age. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) also decline, but disproportionately compared to the more drastic decline in testosterone. The low testosterone production is most likely due to declining testicular function and not to hypothalamic disease.

Low testosterone is believed to be related to decreases in the following, although direct causation has not been proven:

- Sexual function
- Bone mineral density
- Muscle mass (and increased fat)
- Muscle strength
- Mentation

These symptoms, in association with reduced free testosterone, are sometimes called **andropause**. The Endocrine Society set forth treatment guidelines in 2018 for symptomatic males with testosterone deficiency who have a serum testosterone < 264 ng/dL (9.2 nmol/L) and with a treatment goal of 350–600 ng/dL (14.1–24.5 nmol/L). If there are no symptoms of low testosterone, do **not** screen. Do not treat men with low levels if they do not have symptoms. Testosterone promotes red cell proliferation and is trophic to prostate tissue. Men receiving testosterone therapy need to have periodic monitoring of their blood for polycythemia and rapid rises in PSA (prostate specific antigen).

Vitamin D deficiency is common in older adults because of decreased intake, decreased absorption (reduced melanocytes), reduced sun exposure, and poor conversion of storage to the active form of vitamin D. Vitamin D supplementation in older adults for the prevention of osteoporosis is controversial, but it appears to play an important role in the prevention of falls. Calcium supplementation in geriatric patients without osteoporosis is likewise controversial. Fracture risk appeared decreased in two meta-analyses with the use of high-dose vitamin D (≥ 800 IU/day; 2012) and when vitamin D was given together with calcium (2009).

BONE

Osteoporosis

Most women > 80 years of age have osteoporosis. According to the 2018 U.S. Preventive Services Task Force (USPSTF) guidelines, screen women ≥ 65 years of age with a dual energy x-ray absorptiometry (DEXA) scan at least once. If the patient has any risk factors for vitamin D deficiency (especially poor diet or lack of sun exposure), check stores by measuring 25-OH-D.

Paget Disease

Paget disease of bone occurs in about 1% of people > 40 years of age in the U.S. It is usually diagnosed after discovering an isolated elevation of alkaline phosphatase in an asymptomatic person. The disease results from a mismatch of osteoclast and osteoblast activity (e.g., remodeling), causing changes seen on x-ray, bone scan, CT, or MRI in localized areas. The bones are more brittle, hypervascular, and larger—leading to arthritis, high-output heart failure, nerve compression, and hearing loss (if the skull is involved).

Etiology: There is a clear genetic predisposition; other than that, the etiology is unknown.

Diagnosis is strongly suggested by a cotton-wool appearance on plain skull films that results from the disordered bony trabeculae and bone scan results. Patients with Paget disease have focal areas of marked increased uptake.

In most patients, treatment is neither required nor curative. However, treatment is often needed if heart failure, bone pain, nerve compression, or hearing loss develop.

Treatment: Bisphosphonates (e.g., risedronate, tiludronate, alendronate) given orally are effective. Give IV zoledronic acid for severe disease. Calcitonin is an alternative if the patient is intolerant to bisphosphonates.

DIABETES

With aging, there is **decreased** carbohydrate tolerance, with a slight increase in fasting glucose. Both insulin sensitivity and production decline. Older adults with diabetes get the same micro- and macrovascular complications as younger patients, but this patient group must be **specifically watched** for life-threatening hypoglycemia and drug-drug interactions.

Geriatric patients with hypoglycemia present more often with **cognitive impairment** rather than tremulousness and sweats. The most likely causes of hypoglycemia are **insulins** and the **insulin secretagogues** (e.g., sulfonylureas, meglitinides). **Glyburide** has about 2× the incidence of hypoglycemia in older adults compared to glipizide (27% vs. 14%). Sulfonylureas are not recommended by the American Diabetes Association (ADA) as 1st line medications in older adults.

Be cautious with **metformin** use in older adults because of the high prevalence of **chronic kidney disease** in this population and the increased risk of lactic acidosis (a side effect of metformin). Assess the estimated glomerular filtration rate (eGFR) prior to use of metformin in patients and do **not** give the drug to any patient with an eGFR < 30 mL/minute/1.73 m², regardless of age. Hemoglobin A1c levels ≤ 8% are acceptable in older adults with comorbidities, importantly to avoid the risk of hypoglycemia, which can affect cognition and increase fall risk.

Thiazolidinediones enhance insulin sensitivity and can help preserve some function of pancreatic beta cells. (See more on thiazolidinediones in the [Endocrinology](#) section.) Pioglitazone or rosiglitazone can cause fluid retention and precipitate heart failure. Pioglitazone can reduce recurrence of stroke but has a higher risk of bone fractures and bladder tumors.

Remember to lower insulin doses as renal function declines with age, especially as eGFR drops < 50 mL/minute/1.73 m².

THYROID DISEASE

Patients > 60 years of age with thyroid disease are more likely to have vague symptoms that can indicate either hyper- or hypothyroidism. Features of classic **hyperthyroidism**, such as hyperreflexia, heat intolerance, tremor, nervousness, polydipsia, and increased appetite, are often absent in older adults. **Apathetic hyperthyroidism, also called apathetic thyrotoxicosis**, can be seen in elderly patients and presents as apathy, fatigue, anorexia/weight loss, and tachycardia. **Subclinical hyperthyroidism** is diagnosed when TSH is low in the presence of normal serum-free T₄ and T₃; symptoms of mild hyperthyroidism may be present or absent. Confirm this biochemical diagnosis by repeating these studies at 1–3 months. If the TSH is not persistently below 0.1 mU/L and the patient is not at high risk for complications (e.g., heart disease, osteoporosis), follow with observation and repeat TSH and free T₄ and T₃ levels every 6 months.

Atrial fibrillation and anorexia can occur in older patients with **hypothyroidism**; these symptoms are rarely seen in younger patients with hypothyroidism and are possibly related to overtreatment of hypothyroidism in the geriatric population. Atrial fibrillation is more commonly seen in hyperthyroidism.

HORMONE REPLACEMENT THERAPY

According to the North American Menopause Society (NAMS), for women < 60 years of age or within 10 years of menopause, the risk:benefit ratio favors the use of hormone replacement therapy (HRT) to ease troubling vasomotor symptoms (e.g., hot flashes, night sweats) and mitigate bone loss or fracture in at-risk women. However, the risk:benefit ratio of HRT is not as favorable for women > 60 years of age or those with menopause that began more than 10–20 years prior to starting HRT because of increased risk for heart disease and stroke, venous thromboembolic disease, and dementia. For women with resistant vasomotor symptoms or bone loss, HRT is sometimes continued past 60 years of age and reassessed periodically.

Cessation or continuation of HRT after 60 years of age is best approached on an individual basis by assessing risks, considering the formulation and administration route (e.g., intravaginal instead of oral), and aiming to optimize the shortest duration and lowest dose of HRT. Individualization is tailored to risks for breast cancer, venous thromboembolism, stroke, and osteoporosis. For women with a uterus on combination (i.e., estrogen and progesterone) therapy, stopping HRT at ~ 5 years is recommended. Women on estrogen alone without a uterus can sometimes continue HRT for a few years longer if necessary because therapy-related increased risk for breast cancer has not been shown in this patient subgroup.

The Beers criteria consider hormone therapy in the form of pills and patches as a medication class potentially inappropriate for older adults. Topical estrogen creams are alternative treatments for vaginal dryness. Vasomotor symptoms can otherwise be alleviated by nonhormonal drugs such as gabapentin, selective serotonin reuptake inhibitors (SSRIs), and serotonin-norepinephrine reuptake inhibitors (SNRIs).

See more on hormone replacement therapy in the [Women's and Men's Health](#) section.

DELIRIUM

Delirium is a transient alteration in consciousness related to systemic factors. It is a common problem

in older adults. Patients with underlying dementia and/or stroke are at highest risk. The main features of delirium are:

- **Abnormal** attention span (e.g., easily distracted)
- **Disorganized** thinking (e.g., may hallucinate)
- **Altered** consciousness (with increased or decreased mental activity) that **fluctuates** during the day and typically worsens at night

Common precipitating causes of delirium include drugs (especially psychoactive medications), poor nutritional status, and acute illness (e.g., infections, volume depletion). Know that physical restraints and bladder catheters can incite delirium as well. In the post-op period, uncontrolled pain is a major cause, especially in geriatric patients with hip fractures.

1/3 of cases are caused by drugs. Medications should be particularly suspected in patients taking 5 or more drugs, called polypharmacy. Be **especially** aware of meperidine, NSAIDs, any new antimicrobial, diphenhydramine, all cardiovascular drugs and antidepressants, antiemetics, baclofen, H₂ receptor blockers, sleep inducers, and herbals (e.g., St. John's wort, valerian root). Also, acute discontinuation of alcohol, BDZs, SSRIs, and pain medications can cause **withdrawal** delirium.

Differentiate delirium from sundowning. **Sundowning** is a disturbance in behavior that occurs predictably in the evening among some patients who live in chronic care environments. It does not occur with a precipitating illness and is not delirium. With sundowning, usually the caregivers can tell you that the patient predictably deteriorates at night.

Know that in older adults, delirium can sometimes be the only manifestation of illness. Thoroughly evaluate any patient who becomes delirious for a serious precipitating cause, such as an underlying UTI or pneumonia.

Evaluate the confused patient with an objective tool such as the MMSE or the CAM ([Table 5-1 on page 5-5](#)). On the physical exam, focus on identifying an **underlying acute illness** with the potential to cause confusion (e.g., infections, hypoglycemia, drug abuse, hepatic failure, uremia, head injuries, stroke, seizures). Work up the central nervous system (imaging and lumbar puncture [LP]) if no cause is found after a thorough search.

Initial treatment of delirium is supportive, with focus on diagnosis and treatment of the underlying cause. Calendars and orienting signs, night-lights, newspapers, a radio, glasses, and hearing aids help stabilize and prevent decompensation. It is also necessary to minimize daily stress.

Pharmacologic treatment of delirium in older adults is challenging because the medications themselves can worsen the confusion. Low-dose haloperidol is an option, but watch for prolongation of the QT interval.

This increases the risk of an arrhythmia known as *torsades de pointes*, a polymorphic ventricular tachycardia. Do **not** use haloperidol in patients with parkinsonism as it can exacerbate parkinsonian symptoms. Alternative drugs include the atypical antipsychotics: risperidone, olanzapine, and quetiapine. These drugs have fewer short-term side effects but increased mortality among older adults have been reported (e.g., with their use in patients with dementia and those with pneumonia). Do not use BDZs in delirious patients because they make patients more confused and drowsy.

Use of a sitter and other nonpharmacologic interventions are always the best 1st choices. Remember to avoid physical restraint of geriatric patients at all costs because it precipitates delirium and increases the risk of injuries.

DEMENTIA

Patients with dementia have a progressive deterioration of cognitive function that is mostly insidious and chronic—but **without** altered consciousness, as with delirium. The deterioration can be either very gradual or stepwise (depending upon the underlying cause). The cognitive impairment presents as:

- Difficulty learning and remembering new information
- Decreased problem-solving of both simple and complex tasks
- Decline in spatial organization, which can lead to getting lost
- Trouble with impulse control, which can lead to unusual behavior

Some decline in cognition occurs with normal aging, but in contrast to dementia, memory loss seen in aging is mild, does not affect the patient's daily living, and is not especially noticeable by family.

Most patients in the U.S. with dementia are diagnosed with **Alzheimer** disease (80%), **multiinfarct** dementia, or Lewy body dementia (LBD). Dementia is a common development in patients with Parkinson disease as well. See the **Neurology** section for a more thorough discussion of dementia.

Depression can look like **dementia**, especially in older adults. A couple of ways to tell the **difference**: Depressed patients often present complaining of memory loss, while patients with dementia are brought in by family or friends. Depressed patients often have a depressed affect and slowing with completion of the MMSE or Mini-Cog, while patients with dementia have a more normal affect. Assessment tools can help identify the true cognitive defects of dementia. A score of < 24/30 points on the MMSE is consistent with dementia/delirium. See more under **Depression**.

The position of the USPSTF on screening for dementia is that there is insufficient evidence to recommend for or against it.

First-line treatment for Alzheimer disease is the cholinesterase inhibitors (CIs), donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). Best results with CIs are achieved in mild-to-moderate Alzheimer dementia, but other causes of dementia (e.g., multiinfarct, LBD) sometimes also improve. CIs do not help patients with Huntington disease, however. CIs can be combined with memantine (Namenda), an *N*-methyl-*D*-aspartate receptor antagonist.

CIs provide a small benefit and help some patients carry out their activities of daily living (ADLs). CIs may be particularly useful in controlling behavioral problems in patients with dementia. There are conflicting data on their long-term effects. Not every patient receives benefit. The combination of CI plus memantine appears to be better than CI alone.

CI side effects often involve the gastrointestinal tract (i.e., nausea, vomiting, diarrhea, anorexia, weight loss). Severe bradycardia due to atrioventricular (AV) block from excessive acetylcholine has been reported. The bradycardia from CIs can occur with or without syncope.

The benefit from treating Alzheimer disease is greatest early in the course of the disorder; therefore, stop CIs in patients with severe dementia or if no improvement is noted.

LBD is marked by progressive cognitive decline with concomitant hallucinations, sleep disturbances, and parkinsonian features. Use CIs. Treatment of LBD with neuroleptics can bring on a paradoxical psychosis and worsening of parkinsonism. The same can occur with the use of dopaminergic agents, making behavioral therapies preferable to medications when possible.

The American Academy of Neurology (2001; reaffirmed 2004) recommends checking TSH and B₁₂ for metabolic reversible causes in the evaluation of dementia.

DEPRESSION

Depression is the **most common** mental problem in the geriatric population. It is particularly likely to occur in those who live in institutionalized settings and/or have chronic diseases, especially just after a severe sickness or in states of chronic pain. Depressed older adults (especially men) complete 25% of the successful suicide attempts in the U.S.

Look for dysphoria, psychomotor slowing, anorexia, weight loss, and multiple aches and pains. **Insomnia** frequently occurs with depression, especially in older adults, although it is not known whether it is a symptom or a cause. Depression-associated **delusions** are more common in elderly patients than in the general population. Pay special attention to the elderly man with depressed mood, hopelessness, chronic pain, and insomnia because his suicide risk is particularly high. The best predictor of future suicide is a previous attempt. Other risk factors include male sex, substance

abuse, psychiatric disorder, recent major stressor, family history of suicide, and age > 45 years. Half of suicides in 2016 involved a firearm, and access to a firearm increases the risk of successfully completing suicide.

A host of substances and drugs can exacerbate depression, including alcohol, BDZs, opiates, and barbiturates. Untreated thyroid disease, diabetes, and pain are organic causes. Always assess thyroid function, especially if symptoms and signs of thyroid disease are present, prior to initiating antidepressant therapy.

Treatment is usually psychotherapy as a standalone modality or combined with antidepressants; electroconvulsive therapy can be considered in severe cases. **Exercise** helps, too. SSRIs are the 1st line drugs because they have fewer side effects than other choices. Watch for the side effects of hyponatremia and tremor in elderly patients on SSRIs. SSRIs can cause sexual dysfunction (in about 50% of patients) and sedation (< 20%). Patients intolerant of one SSRI can often be switched to another. See [Table 5-2 on page 5-16](#) for treatment options.

As with most medications, when using antidepressants in older adults, **always** start with low doses (typically 1/2 the normal dose) and increase **slowly** with the goal of eventually reaching the normal therapeutic dose. See patients (or call them) within 2 weeks of starting a medication. It takes about 8 weeks to see improvement; 6–12 months is the usual duration of treatment.

Depression or reduced sociability can be a sign of elder mistreatment. Victims are unlikely to report mistreatment. Unexplained injuries or a low BMI prompt you to evaluate for possible elder mistreatment. Routinely ask older patients about mistreatment and whether they feel safe.

SLEEP DISTURBANCES

Sleep disturbance is a common problem in geriatrics; normal aging is associated with more frequent awakenings. Other disturbances include difficulty falling asleep (> 30 minutes), waking too early, and feeling generally unrestored. When the disturbance also causes problems for the patient during the day (e.g., poor concentration, moodiness, sleepiness, fatigue), it is classified as **insomnia**.

Sleep disturbances that are **not** insomnia:

- Some people can sleep well for only a few hours and have no problem functioning the next day. These patients simply have **short-duration sleep**.
- People who have chosen not to sleep at night (due to work or other reasons) and easily fall asleep during the day are classified as having **insufficient sleep** (a.k.a. **sleep deprivation**), not insomnia.

Insomnia, especially in older patients, is associated with worsening of hypertension, heart disease, lung disease, urinary incontinence, chronic pain, and depression.

When taking the patient's history, focus on characterizing the sleep disturbance (sleep logs help) and identifying any untreated comorbidities and/or precipitants (e.g., napping stress, newly stopped or started medications, alcohol, caffeine, nicotine, depression).

Medications specifically linked to insomnia include corticosteroids, β -blockers, and β -agonists. Stopping sedatives or pain medications can also cause insomnia.

Labs are recommended only to diagnose potential comorbidities (e.g., hyperthyroidism, restless legs). Sleep studies are unnecessary until a patient has failed to respond to conservative management.

Direct treatment toward improving any poorly managed comorbidities and advising the patient on **good sleep hygiene**:

- Set a schedule for sleep and stick to it.
- Get in the bed only when you're sleepy, and get up when you're rested.
- Minimize excessive light and sound in the bedroom.
- Exercise during the day, at least 4 hours before bedtime.
- Maintain a bedroom environment and ambient temperature conducive to sleep.
- Avoid caffeine, nicotine, alcohol, and excessive intake of fluids near bedtime.
- Eat dinner or an evening snack to prevent bedtime hunger.
- Do not fight sleep. If you cannot sleep for > 20 minutes, get up and do something relaxing (e.g., reading, listening to music). Avoid bright lights, electronic screens, or TV.

The **most effective** treatment in patients with uncomplicated insomnia is **behavioral**—not pharmacologic. Elderly patients are especially susceptible to bad outcomes from sleep drugs.

Ramelteon (Rozerem), a melatonin agonist, improves sleep for some patients. It is a **good choice** for older adults, albeit with variable efficacy.

BDZs and non-BDZ insomnia drugs (such as zolpidem [Ambien], zaleplon [Sonata], and eszopiclone [Lunesta]) in **older adults** can cause confusion, wandering, imbalance, and daytime grogginess—hence, **avoid** both drug classes in geriatric patients.

Stay away from 1st generation antidepressants (e.g., amitriptyline), diphenhydramine, haloperidol, and barbiturates because of side effects.

RESTLESS LEG SYNDROME

Restless leg syndrome (RLS) is a common sleep disorder in older adults (prevalence = 20% in those > 80 years of age). The hallmark of RLS is leg discomfort +/- paresthesias at rest, relieved immediately with movement. Usually, pain is deep seated and localized below the knees. Symptoms are worse in the evening and at night.

RLS can be primary or caused by other conditions, such as iron deficiency (even without anemia), dialysis, diabetic neuropathy, multiple sclerosis, and Parkinson disease. Make sure that the patient's complaints aren't due to akathisia caused by medications (e.g., phenothiazines, SSRIs).

Diagnosis is based on clinical history, a normal neurologic exam, and absence of kidney disease. Always check ferritin level to rule out iron deficiency, even if the patient does not have anemia.

Table 5-2: Antidepressants and SSRIs

Drug	Half-Life (Hours)	Mechanism of Action / Blocks	Drug of Choice for...	Notes	Caution (!) in Patients...
Fluoxetine* (Lexicomp)	72	SSRI		Can cause anxiety and insomnia	With insomnia
Paroxetine (Paxil, Pexeva)*	20	SSRI		Most anticholinergic of the SSRIs Sedating in some Weight gain more common Worst for SSRI withdrawal symptoms	In whom anticholinergics are to be avoided With insomnia
Sertraline (Zoloft)*	25	SSRI		GI discomfort is common.	With insomnia With irritable bowel
Fluvoxamine (Luvox)*	15	SSRI	Patients with agitation, insomnia, or obsessive-compulsive disorder	Most sedating of the SSRIs	With irritable bowel
Citalopram (Celexa)*	35	SSRI		Can cause anxiety and insomnia, N/V, headache, and QT prolongation	With long QT syndrome
Escitalopram (Lexapro)	30	SSRI		S enantiomer of citalopram; can cause QT prolongation	With long QT syndrome
Nefazodone (Serzone)	3†	SSRI and 5-HT ₂ Has anti- α -adrenergic activity	Patients with insomnia; to maintain sexual activity	Maintains sleep architecture Sexual dysfunction unlikely	On BDZs or antihistamines (interact with cytochrome P-450 system)*
Venlafaxine (Effexor)	4	SSRI and norepinephrine reuptake and some dopamine reuptake			With insomnia; With HTN—usually increases blood pressure, so not used in these patients
Duloxetine (Cymbalta, Irenka)	12	SSRI and norepinephrine reuptake and some dopamine reuptake	Patients with chronic pain syndromes	Also indicated for fibromyalgia	
Bupropion	15	Reuptake of dopamine and some norepinephrine		Sedation and sexual dysfunction unlikely	With insomnia With HTN—may increase blood pressure
Mirtazapine (Remeron, Remeron SolTab)	20	Presynaptic α_2 -receptor (increases serotonin and norepinephrine release) and 5-HT ₂ and 5-HT ₃	Patients with insomnia; to maintain sexual activity	Agitation and sexual dysfunction unlikely Good for insomniacs Weight gain more common	Most anticholinergic of all these With HTN—may increase blood pressure

Note: Bupirone is a 5-HT_{1A} agonist that can be combined with an SSRI to decrease the dose or improve efficacy.

* All the SSRIs tend to cause agitation, sedation, and sexual dysfunction. Pure SSRIs are not likely to increase blood pressure.

† Half-life is higher than this in older adults, especially women.

‡ Can use loratadine (Claritin) or lorazepam (Ativan) with nefazodone

Treatment of RLS:

- **Intermittent symptoms:** Try nonpharmacologic therapy first—iron-replacement therapy; mentally stimulating activities (such as video games or crosswords); avoidance of caffeine, nicotine, and alcohol. Then, if needed, try 1 of the following:
 - Dopamine agonists (e.g., pramipexole or ropinirole) are usually the drugs of choice.
 - Levodopa: Be careful—can cause augmentation (worsened symptoms or rebound).
 - BDZs (generally avoided)
 - Low-potency opioids (generally avoided)
- **Daily symptoms:** Try nonpharmacologic therapy first, then dopamine agonists, gabapentin, and, lastly, low-potency opioids.
- **Refractory symptoms** to dopamine agonists: Try gabapentin, a different dopamine agonist, combination therapy, then tramadol, and, lastly, high-potency opioids.

PERIODIC LIMB MOVEMENT OF SLEEP

Periodic limb movements of sleep (PLMS) are periodic episodes of repetitive movements lasting 1–10 seconds separated by intervals of 20–40 seconds. They occur in 60% of older adults and 80% of patients with RLS. The diagnosis is made on polysomnography showing excessive limb movement beyond what is expected as physiologic limb movement of sleep. Treatment of PLMS uses the same approach as RLS.

DIZZINESS

Dizziness is common in older adults but is **not** a normal consequence of aging. Probe patient complaints of dizziness diligently, remembering the risks and consequences of falls and fractures in this age group. Take a good **history** (more accurate in making the diagnosis than physical exam, labs, or studies) to determine which of the following the patient is describing:

- Vertigo: spinning, whirling, or moving of either the patient or the environment that is often worse with head movement and can occur in spells (days to weeks), then eventually resolves. A complete discussion about the workup of vertigo is included in the **Neurology** section.
- Presyncope: almost fainting or blacking out while either standing or seated (not supine), possibly with sweating, a sensation of warming, visual blurriness, and nausea
- Disequilibrium: imbalance with standing and walking, especially with turning
- Nonspecific dizziness: unable to characterize into one of the other categories

Presyncope: Dizziness that sounds like presyncope or faintness should be taken seriously and evaluated with a cardiovascular workup, especially if the patient has known heart disease, palpitations, or a history of true syncope. However, some causes of presyncope can be diagnosed by the history and physical examination (e.g., postural hypotension).

Multisensory deficits: Think about multisensory deficits as a cause for disequilibrium in the patient with a mix of visual, hearing, orthopedic, and neuropathic impairments. (This form of dizziness is sometimes called benign disequilibrium of aging.) Multisensory deficits causing disequilibrium and benign positional vertigo are common. In geriatric patients, the cause is more often **vestibular** than in other patient groups. The history is of feeling unsteady, which improves with a walker or when someone holds the individual's arm. Treat disequilibrium by maximizing support for each sensory impairment and providing assistance devices (e.g., canes, walkers).

Benign paroxysmal positional vertigo (BPPV) presents as recurrent (lasts for weeks in spells), short-lived (< 1 minute) episodes of vertigo that predominantly occur when the patient changes head position. The vertigo can be bad enough to cause nausea and vomiting, but otherwise, the patient has no symptoms (e.g., hearing loss, headaches). BPPV can occur with aging, head trauma, labyrinthitis, giant cell arteritis, migraine, hypertension, hyperlipidemia, and stroke. Be sure to take a good history in the dizzy elderly patient to determine whether symptoms of vasculitis or polymyalgia rheumatica are also present (e.g., weight loss, fevers, musculoskeletal pain).

In **uncertain** cases, BPPV can be diagnosed by the Dix-Hallpike test. This maneuver involves turning the patient's head, then rapidly tilting the patient backwards for 30 seconds, then upright again, with subsequent observation for nystagmus. Repeat the maneuver with the head turned in the opposite direction. A positive test is visible nystagmus in either the recumbent or the upright position. Warn patients ahead of time that the maneuver sometimes triggers nausea and vomiting.

In BPPV, the differential diagnosis includes **central causes of vertigo** such as cerebellar lesions (i.e., strokes, masses). So, if the history is suggestive (e.g., diplopia and ataxia or cerebellar signs), do further workup with imaging and electronystagmography (i.e., water calorics).

Treatment of BPPV can be accomplished through maneuvers; Epley or Semont. Both are equivalent in efficacy and designed to reposition the misplaced otoliths thought responsible for the vertigo. The maneuvers are extensions of the Dix-Hallpike test. Alternatively, home exercises can be prescribed that aim to have the same result (but are less effective). No drugs are used to treat BPPV.

CARDIOVASCULAR SYSTEM

Walking > 4 hours per week is associated with a dramatic decrease in cardiovascular-related hospitalizations in persons > 65 years of age.

Isolated systolic hypertension is a common finding in elderly patients. It increases the risk of myocardial infarction and stroke 2–4×. Several studies show these patients benefit from treatment as long as the diastolic pressure does not fall below 60 mmHg. Low diastolic pressures have been associated with increased cardiovascular events.

In older patients with hypertension, start with about 1/2 the standard dose of any 1 of the following:

- 1) Thiazide diuretics (e.g., chlorthalidone)
- 2) Dihydropyridine calcium channel blockers (e.g., amlodipine)
- 3) Angiotensin-converting enzyme (ACE) inhibitors/angiotensin II receptor blockers

Avoid β-blockers for treatment of **systolic** hypertension in **older adults** because they are less effective than other treatments and have been associated with increased mortality.

The 6-month mortality rate after a myocardial infarction (MI) increases with age (e.g., from 4% at 66 years of age to 12% when > 80 years of age), with 1st MI, with thrombolytics, and when discharged from the hospital. Only about 75% of eligible patients receive aspirin on discharge from the hospital and about 1/3 are referred for cardiac rehabilitation—both interventions after MI markedly reduce the risk of death. Be sure to prescribe an antiplatelet drug to these patients and ensure their participation in cardiac rehabilitation!

Heart failure: The prevalence of heart failure (HF) is increasing due to the aging of the population. It is the **#1 cause of hospitalizations** in older adults. (#2 is pneumonia.)

Treat HF itself primarily with diet, diuretics, β-blockers (specifically metoprolol, carvedilol, or bisoprolol), and ACE inhibitors. Spironolactone lowers mortality for systolic HF. Digoxin is indicated only for more severe HF and reduces hospitalizations but **not** overall mortality. Isosorbide dinitrate and hydralazine lower mortality, especially in African Americans with systolic HF. The use of NSAIDs is an important precipitant of HF in older patients who already have risk factors for HF.

Note: ACE inhibitors, β-blockers, and low-dose spironolactone lower mortality rates in HF. If you prescribe spironolactone, follow K⁺ closely. Spironolactone provides benefit in patients with Class III or IV heart failure with ejection fraction (EF) of ≤ 35%.

PULMONARY SYSTEM

PREVIEW | REVIEW

- What is an important comorbidity to know about in treating asthma?
- What happens with spirometry results as we age?

ASTHMA

Geriatric patients with asthma can have long-standing disease acquired in childhood or young adulthood, or asthma that developed during aging adulthood. Around 8% of adults > 65 years of age are diagnosed with adult-onset asthma. Be aware that it is **commonly misdiagnosed** as chronic obstructive pulmonary disease (COPD) because COPD is more likely to occur in this age group.

Risks for development of adult-onset asthma are the same as for younger patients: allergens and irritants (e.g., tobacco smoke, occupational vapors, air pollution).

Comorbidities are important—especially coronary artery disease because treatment of asthma with β-agonists can cause myocardial ischemia. Also, β-blockers used as anti-hypertensive drugs can exacerbate airway obstruction, although this is primarily the case with older, nonselective β-blockers.

Asthma in the older patient can present the same as in the younger patient, although older patients tend to have **fewer symptoms** with the same amount of disease. Definitive diagnosis is made with **spirometry**, when the FEV₁ and FEV₁/FVC are reduced.

A response to bronchodilators is still expected for the diagnosis of airway reversibility, as per the Global Initiative for Chronic Obstructive Lung Disease (GOLD) criteria: > 200 mL increase in FEV₁ after bronchodilator and > 12% of predicted.

Separating COPD and COPD with overlap syndrome from asthma alone can be difficult in geriatric patients, where rates of underlying COPD are high. All lung volumes decrease with age and the chest wall gets stiffer; therefore, even in an elderly patient with no prior smoking history, the PFTs tend to overdiagnose airflow obstruction. Know: Reversible obstruction is consistent with asthma, and a low diffusing capacity of the lungs for carbon monoxide (DLCO) with airflow obstruction is consistent with emphysematous COPD.

Bronchoprovocation is used to diagnose asthma in older patients with normal spirometry, the same way it is used in younger people.

Management of geriatric asthma is the same as for younger patients, but theophylline is not recommended, even as an alternative drug, because of the significant potential for toxicity.

SLEEP APNEA

Think about sleep apnea as a potential cause of reduced cognition in geriatric patients. Know that apnea that results in poor sleep and excessive daytime somnolence carries a higher rate of morbidity in patients who are frail and already prone to falls. Untreated, sleep apnea in older adults carries an increased risk for ischemic stroke and coronary artery disease. Diagnosis and management is the same as in younger patients.

UROLOGIC SYSTEM

PREVIEW | REVIEW

- Is urinary incontinence considered a normal consequence of aging?
- What are the 4 types of incontinence?
- What is the best treatment for urge incontinence?
- What is the best initial treatment for stress urinary incontinence?
- What is a common cause for incomplete bladder emptying in males?
- What is the role of bladder catheterization in the treatment of geriatric incontinence?
- What are symptoms of UTI in older adults?
- How is UTI in older adults treated?

URINARY INCONTINENCE

Normal micturition is dependent on an intact neurologic pathway from the brainstem to the bladder, which causes relaxation of the sphincter muscle's tonic contractile state just milliseconds before contraction of the detrusor (bladder muscle). Additionally, voluntary control of micturition requires communication between the cerebral cortex and the brainstem.

Urinary incontinence, although a common geriatric problem, is always considered a pathologic condition that is **not** a normal consequence of aging! Always consider the possibility that the patient has a serious underlying condition responsible for the leakage.

Normal, age-related changes to the urinary tract include **decreased** flow rate, decreased bladder capacity, and **increased** residual volume. As a function of these changes, it is normal for patients to get up once during the night to void. Patients can have **functional incontinence** caused by physical or mental impairment that limits their ability to reach the bathroom in time.

Urinary incontinence can be thought of as either a storage problem (detrusor or bladder over- and under-contraction) or an outflow problem (outlet obstruction or incompetence). Remember too that lifestyle factors—obesity, excess beverage consumption (especially carbonated, caffeinated, and alcoholic drinks), smoking, and for some, constipation—can contribute to or worsen incontinence.

There are 4 types of urinary incontinence:

- 1) **Urge** = leakage (a lot or a little) with the feeling of urgency
- 2) **Stress** = leakage with increased intraabdominal pressure (e.g., coughing, sneezing)
- 3) **Mixed** = leakage with both an urgency and increased intraabdominal pressure
- 4) **Incomplete bladder emptying** (overflow) = leakage (a lot or a little) after voiding

Urge Incontinence

Urge incontinence (UI) is a **common** cause of geriatric incontinence. With UI, there is passage of either **small** or **large** amounts of urine, with a sense of urgency often set off by a **precipitating stimulus** (e.g., hearing running water, unlocking the door to the house, entering cold environments).

UI is related to overactive bladder. They are both caused by uncontrollable bladder contractions (**detrusor instability**)—usually caused by **CNS problems** (termed detrusor hyperreflexia) but sometimes caused by **cystitis**.

Detrusor hyperreflexia is due to progressive loss of communication between the frontal lobes and the micturition center in the brainstem. As the bladder loses the modulating influence from the brain, it tends to spasm more often.

After ruling out a bladder infection, treat UI with behavioral therapy, called bladder training. When an urge to void becomes intense, the patient is instructed to attempt relaxation techniques that help the urge subside and allow short-term voiding delay. Once the urge is controlled, the patient can walk calmly to the restroom and urinate. The eventual goal is to delay voiding to every 4 hours with no interval leakage.

Bladder training is more effective than the more commonly prescribed therapy of antimuscarinic agents (e.g., oxybutynin, tolterodine, fesoterodine, trospium, darifenacin, hyoscyamine, tricyclic antidepressants), all of which relax the bladder muscle and are equivalent in efficacy. They have **anticholinergic** side effects (e.g., dry mouth, tachycardia, constipation).

Remember that anticholinergics can precipitate acute angle-closure glaucoma! Also, do not use them for incontinence in patients who are taking cholinesterase inhibitors for dementia because the combination **accelerates** cognitive decline. Even so, these antimuscarinic agents are helpful when used as an adjunct to bladder training—short term, as needed. Consider a β_3 -agonist, mirabegron. Also consider intravesicular botulinum toxin injections in refractory cases.

Pelvic muscle exercises (Kegel exercises) and lifestyle modifications such as weight loss in obese patients are also helpful for UI.

Stress Urinary Incontinence

Stress urinary incontinence (SUI) is the 2nd most common cause of urinary incontinence in elderly **women**. With SUI, the urethra cannot maintain the pressure gradient required for urinary control when there is an increase in intraabdominal pressure (e.g., coughing, jumping). SUI is associated with multiple vaginal deliveries, pelvic surgery, postmenopausal hormonal changes (low estrogen → atrophic relaxation of the vaginal wall → lack of support for the urethra), but SUI is sometimes seen in males after prostatectomy. During the physical exam, focus on the presence of uterine prolapse/cystocele, pelvic floor laxity, and cough leak.

Stress incontinence is best treated initially with behavioral therapy, especially **Kegel exercises** (i.e., perineal muscle contractions). Referral to a pelvic floor physical therapy specialist can be helpful in effective teaching of Kegel exercises. Note that some women with urinary incontinence have a mixture of SUI and UI. Vaginal pessary devices, usually made of silicone, are nonsurgical options that can be used as a therapy adjunct or for certain situations to avoid incontinence incidents. Impressa is a disposable over-the-counter option that can be self-inserted and does not require fitting by a health care provider. Although surgery has high cure rates, it also has high risk of complications.

Patient **history** gives you the clues to determine whether incontinence is due to urge or stress incontinence—ask about the stimuli that precipitate leakage in a patient with UI and look for leakage associated with increased intraabdominal pressure with SUI.

Mixed Incontinence

Mixed incontinence is a combination of UI and SUI. The etiology is unknown. Bladder training and Kegel exercises help these patients.

Incomplete Bladder Emptying

Incomplete bladder emptying is sometimes still called **overflow incontinence**. It is caused by either an overactive bladder +/- an outlet obstruction or by an underactive bladder that has trouble contracting (e.g., diabetes, Parkinson's, multiple sclerosis, alcohol abuse).

Incomplete emptying is rare in females. In males, it is usually caused by prostatic hyperplasia. The **outlet obstruction** causes a distended bladder and high-volume postvoid retention. Physical exam may show a distended bladder, an enlarged prostate, and a postvoid residual volume that is ≥ 150 mL. Anticholinergic drugs are the most common causes of drug-induced incomplete emptying. Psychogenic retention can also be a cause.

Treat the underlying cause if possible; use intermittent catheterization for neurogenic bladder and diaper-like garments if needed. Treat men with benign prostatic hyperplasia (BPH) with α -blockers and/or 5- α reductase inhibitors and consider surgical consultation.

Review of Treatment

Treatment includes:

- Bladder training, lifestyle modifications, and Kegel exercises: urge, stress, and mixed
- Drugs for urge and mixed incontinence: anticholinergics with antimuscarinic effects, β 3-agonist, botulinum toxin
- Drugs for stress incontinence: None! Bladder training, pessaries, lifestyle modifications, and Kegel exercises only!
- Surgery: last resort for refractory incontinence of all types

Note: Asymptomatic bacteriuria, common in older adults, is **not** a cause of incontinence. Also, incontinence is **never** an indication for a long-term bladder catheter.

URINARY TRACT INFECTION

The most common infectious illness among older adults is urinary tract infection (UTI). Because the geriatric population often has noninfectious causes of urinary symptoms such as incontinence or prostatic hyperplasia, making a diagnosis of UTI is sometimes difficult. Another confounder is the increased prevalence of asymptomatic bacteriuria with aging. Older adults living or participating in communal settings such as care facilities or senior daycare are at higher risk for UTIs. Also at higher risk are older adults with underlying conditions known for impaired immunity, such as diabetes and chronic heart failure. Symptoms can be nonspecific to the urinary tract or present as fever, dysuria, gross hematuria, worsening incontinence, and suprapubic or costovertebral angle pain. Know that in especially in frail older adults, fever can be low-grade (i.e., 99°F) or absent. In geriatric patients, symptoms of UTI may present as confusion or altered mental status and can be masked by presentation as a fall.

If nitrites or leukocyte esterase are positive by urinalysis, order a urine culture and sensitivity. Diagnose asymptomatic bacteriuria when bacteria are cultured from 2 sequential specimens but without the development of any new urinary tract-related symptoms. Uncomplicated lower UTI can be treated with antibiotics for 3–6 days, while complicated lower UTI (UTIs among men are considered complicated) requires a longer course of antibiotics (10–14 days). Do not treat asymptomatic bacteriuria with antibiotics.

SEXUAL DYSFUNCTION

Sexual dysfunction increases with aging. Men and women experience decline in libido, sexual responsiveness, comfort level, and sexual frequency. Many factors are causal, including lower levels of testosterone. Other comorbid conditions, medications, and psychosocial stressors impact sexual dysfunction among older adults. Sexual disorders in men are usually erectile dysfunction and delayed ejaculation. In women, they include arousal and orgasmic

disorders and pain with intercourse. Treatment includes reassurance, sex therapy, and medications. See the [Women's and Men's Health](#) section for more information.

ELDER MISTREATMENT

PREVIEW | REVIEW

- What is the definition of elder mistreatment?
- What are the various forms of elder mistreatment?
- What are the risk factors for elder mistreatment for victims? For caregivers?
- What physical exam findings suggest elder mistreatment?
- What are the management principles of elder mistreatment in a victim who lacks decision-making capacity?

OVERVIEW

Elder mistreatment in individuals > 65 years of age (a.k.a. elder abuse) is less recognized by health care providers than child abuse.

Passed in 2010 to combat elder abuse, the Elder Justice Act provides for freedom from abuse and exploitation.

The World Health Organization defines elder mistreatment as a single or repeated act or lack of appropriate action occurring within any relationship where there is an expectation of trust that causes distress or harm to an elderly person.

Elder **neglect** refers to the withholding of physical, psychological, or financial resources that the elderly person needs to be happy and healthy.

Many people prefer to avoid the use of terms like elder mistreatment, elder abuse, and elder neglect, instead preferring terms like inadequate care of the elderly or mistreatment of the elderly to refer to both acts of omission and commission that result in harm or potential harm to older individuals.

Forms of elder mistreatment:

- Physical abuse is the use of physical force that can result in bodily injury, physical pain, and/or physical impairment.
- Sexual abuse is nonconsensual sexual contact. This can be sexual contact of any kind.
- Emotional or psychological abuse is the act of inflicting anguish, pain, or distress through verbal or nonverbal activities.
- Financial/Material exploitation is the illegal or improper use of financial resources, including funds, property, or other assets.
- Neglect is the refusal or failure to fulfill any part of a person's obligations or duties to a person they are caring for.

- Self-neglect is behavior that threatens an individual's own health or safety.
- Abandonment is the desertion of a person by an individual who has physical custody of the individual or by a person who has responsibility for providing care to the individual.
- Institutional abuse is physical, psychological, sexual, or neglect that occurs in institutional settings where care is provided.

INCIDENCE OF ELDER MISTREATMENT

The National Council on Aging reports that 10% of older adults suffer from elder mistreatment. The most common form of elder mistreatment is verbal abuse followed by financial abuse. Physical abuse is the least common form of elder mistreatment.

Victim-related risk factors for elder mistreatment include:

- Female sex
- Advanced age
- Total dependence on caregiver
- Social isolation
- Behavioral disorders
- Physical and cognitive impairment
- Dementia

Caregiver-related risk factors for elder mistreatment include:

- Use of alcohol or illegal drugs
- History of abuse as a child
- Financial dependency on the victim
- Inexperience in providing care
- Unrealistic expectations and overwhelming situations
- Psychiatric diseases
- Economic or other life stresses
- History of violent behavior

When caring for older adults, it is important to consider elder mistreatment when something in the clinical picture doesn't make sense. Look for incongruity between what the patient says is happening and what appears to actually be happening (e.g., they report all is well at home, yet they appear disheveled with poor hygiene). Screening for elder abuse was included in the 2018 update of the U.S. Preventive Services Task Force recommendations. In 2007, the AMA recommended screening for elder abuse in all clinical settings. The AMA has made routine screening for psychological, physical, and sexual abuse part of its Code of Ethics. Observations suggestive of elder mistreatment include:

- Poor supervision by caregiver
- Delays in seeking medical care
- Unexplained injuries
- Missed medical appointments

- Inconsistency of history between patient and caregiver
- Discrepancy of lab results and patient history
- Reluctance to answer questions and vague explanations
- Recurrent hospitalizations
- Attempts by caregiver to prevent interaction between patient and health care provider
- Extreme fear of the caregiver by the patient
- Living arrangements not compatible with assets
- Unexplained withdrawals from bank account of the elderly individual
- Presentation of a frail elderly patient without a designated caregiver

It is very important to obtain a good history in an environment where the elderly individual feels secure. Questions to ask:

- Do you feel safe where you live?
- Who prepares your meals?
- Do you have to wait long or ask for food or medication?
- Who handles your finances?
- Is anyone trying to hurt you, or are you afraid of anyone?
- Has anyone touched you in a way that makes you feel uncomfortable?
- Have you been slapped, punched, kicked, or otherwise physically hurt?
- Have you been yelled at?
- Have you been closed in a room alone for a long period of time?

It is also important to speak to the caregivers and ask them questions to investigate suspicions of elder mistreatment. Handle these situations with the appropriate delicateness, consult other members of the care team, and engage social services to help if indicated.

You must perform a good physical examination when elder mistreatment is suspected. The following physical examination findings can be seen in victims of elder mistreatment:

- General appearance
 - Problems with hygiene, dressing, and cleanliness
- Skin and mucous membranes
 - Skin lesions and bruises in various stages
 - Signs of dehydration and deficient care of established skin lesions
- Head and neck
 - Hematoma on the scalp
 - Traumatic alopecia
 - Lacerations and abrasions on the head and neck area
- Eyes, nose, and throat
 - Subconjunctival or vitreous hemorrhage
 - Whiplash injuries from repeated shaking
 - Deviated septum from repeated trauma

- Oral cavity
 - Tooth fractures
 - Oral lesions suggestive of sexually transmitted diseases
 - Cigarette burns on lips
- Chest
 - Bruises and rib fractures
- Abdomen
 - Unexplained rectal bleeding
 - Bruises and intraabdominal hemorrhage
- Pelvic
 - Unexplained vaginal bleeding
 - Foreign bodies in the vulva or rectum
- Extremities
 - Signs of restraint use on wrists or ankles
- Musculoskeletal system
 - Occult fractures
 - Unexplained pain
- Neuropsychiatric examination
 - Rapidly worsening cognitive impairment
 - Worsening depressive symptoms
 - Severe anxiety

MANAGEMENT OF ELDER MISTREATMENT

It is important that when elder mistreatment is recognized that the patient be placed in a safe environment, including potential hospitalization. Adult Protective Services should be called immediately. In certain regions, there are designated area agencies of aging to deal with such complicated matters.

However, the situation is often complicated by the elderly individuals refusing any intervention. If they are capable of making their own decisions, then honor their wishes but educate them about the various resources available. It is important to make them aware that the abuse may escalate in the future and is unlikely to end without any intervention. For victims who do not have decision-making capacity, take steps to safeguard them as soon as possible. The American Bar Association recommends contacting state adult protective services (in most states it's a law, and failure to report is a crime), which can arrange for safe care, as well as be an important source for evidence keeping.

It is very important to document the event(s) accurately. As far as possible, use the patient's own words during documentation to avoid errors in translation. For health care providers, it is important to know that reporting elder mistreatment is confidential, and you are protected from litigation unless the complaint was made maliciously.

Every clinician must know how to get in touch with their local area agency for aging. It is important that you take a nonconfrontational, nonjudgmental, and methodical approach and involve a multidisciplinary team to assess and handle situations where elder mistreatment is suspected.

OLDER ADULTS AND DRIVING

PREVIEW | REVIEW

- What are the physiologic changes that affect driving in elderly individuals?
- What are important points to consider while examining the patient to assess their ability to drive?
- What are the steps you can take when you suspect your patient is an unsafe driver?

OVERVIEW

Driving is an important factor in the independence and freedom in American life. The primary goal of the health care provider is to maximize older patients' potential for independent functioning and living. However, the patients' autonomy cannot override concerns for their safety and the public's safety in general.

The rate of motor vehicle crashes is lowest between 20 and 65 years of age. After 65 years of age, it gradually increases, and the crash risk for drivers > 85 years of age is 2.5× the average risk. Traffic violations involving right of way or sign errors are early indications of problems affecting driving in older adults. The most common form of driving accidents involving older adults take place while turning at intersections, especially when making left turns against oncoming traffic.

Physiologic changes with aging and pathologic processes that may adversely affect driving:

- Physiologic changes
 - Visual
 - Presbyopia
 - Diminished visual acuity
 - Decreased visual fields
 - Decreased resistance to glare
 - Delayed response to accommodation and light reflexes
 - Auditory
 - Presbycusis
 - Cognitive
 - Slower reaction times
- Medical illnesses and medications
 - Arthritis
 - Cardiovascular diseases
 - Cerebrovascular diseases
 - Dementia
 - Diabetes, especially diabetic retinopathy and diabetic neuropathy
 - Parkinson disease
 - Sleep apnea
 - Alcohol
 - Psychotropic medications

Perform a comprehensive geriatric examination in individuals when driving is a concern, focusing on the following:

- Complete history
- Detailed physical examination, including:
 - Visual acuity and visual field assessment
 - Joint range of motion, especially in the neck
 - Gait and balance evaluation
- Mental status examination
- Driving history
- Driving simulation with an occupational therapist

CLINICAL PEARLS

Elderly patients are very sensitive to even small amounts of alcohol. Alcohol has a significant effect on driving in older people, even if the levels are less than the legal limits allowed.

Many older adults take medications, including BDZs, psychotropic medications, anticholinergic medications, and/or diphenhydramine, which cause significant mental impairment adversely affecting their driving.

REGULATIONS AND DRIVING

Governmental regulations concerning elderly drivers vary from state to state in the U.S. In most states, physicians do not face liability issues if they report the patient to the Department of Motor Vehicles (DMV) for concerns with driving. However, in some states, physicians are not protected from liability for such reporting, and must decide between liability in disclosing patient confidentiality and public safety. Have a detailed discussion with the patient and family members and, when appropriate, report concerns to the DMV or other pertinent authorities. The physician can order a driving test that is necessary for the patient to maintain their driver's license.

It is worth noting that some of your elderly patients may not care if they have a license and continue to drive, especially if they have mild cognitive impairment or early dementia. In such cases, the family may need to get involved by cutting off access to the vehicle by removing the keys and/or the vehicle itself.

When possible, it is important to make every effort to maximize the patient's ability to drive safely. It has been found that the rates of depression and other medical illnesses significantly increase in patients who have their ability to drive taken away from them. Therefore, consider psychological support for your patients when they lose their ability to drive independently. Remind families and patients that their local independence can be maintained through alternative means (e.g., rideshares, senior driving programs).

TAKE-HOME MESSAGE

Loss of driving is equal to loss of freedom for many patients. Deterioration of vision and slowing of reflexes are 2 of the most significant physiologic changes that occur in older adults and can impact their ability to drive. Diminished hearing capacity, arthritis, and cognitive decline are other important contributing factors. Evaluate the elderly patient for the capacity to drive safely, and when they cannot, you need to have this important discussion with the patient and their family.

HOME HEALTH CARE

PREVIEW | REVIEW

- What is home health care?
- What is skilled home health care?
- What is the role of home health aides?

Home health care is medical treatment or assisted care for patients who do not require hospitalization or facility care but do need additional support to live safely at home. The goal of home health care is to treat patients in the emotional comfort of their home while helping them to become self-sufficient and regain their independence in their ADLs (including bathing, transferring, toileting, and eating) and IADLs (including daily tasks of light work, meal preparation, grocery shopping, transportation, and medication management).

In the U.S., most people receiving home care are > 65 years of age.

Since the 1980s, the types of services offered by home care have expanded, with the inclusion of intravenous antibiotics, oncology, hemodialysis, and parenteral and ventilator care. Hospice care is also included for terminally ill patients with a life expectancy of < 6 months; this service includes a bigger team of integrated medical professionals. Provision of any of these services requires prescription from a licensed physician.

Home health care is divided into skilled and unskilled care.

Skilled home health care is medical treatment provided by medical professionals, including registered nurses, licensed practical nurses, physical/occupational therapists, and speech therapists. Examples of skilled home health care include wound care (e.g., after surgery, pressure ulcers), monitoring serious illness and unstable health status (e.g., heart failure), patient and caregiver education, injections, and intravenous or nutrition therapy.

Unskilled home health care is provided by home health aides. Home health aides are trained and certified health workers who provide assistance to patients in their homes. Their various roles include help with personal care (e.g., hygiene, grooming, activities) and

light household help (e.g., grocery shopping, meal preparation). They also help monitor the patient's clinical condition, even though they cannot provide formal medical care. Family members continue to be the main caregivers, as home health aides only provide care for certain hours in a week, depending on the patient's need.

Home health telemonitoring has shown benefit for patients with chronic conditions, such as heart failure, to reduce hospital readmissions and decrease overall health care expenditure.

While we've focused here on formal home health care, note that most home health care is unpaid and provided by families and friends of the patients. Without these caregivers, the health system would probably become insolvent.

The government and insurance providers are funding this level of formal care as an alternative for inpatient care and long-term facilities. While 48% of older adults receiving paid care will require less than a year of such care, 19% will need it for 1–2 years, 21% for 2–5 years, and 13% for 5 or more years. As the elderly population grows, so does the government health expenditure. The Centers for Medicare & Medicaid Services spent \$102.2 billion on home health care in 2018.

NURSING HOME CARE

PREVIEW | REVIEW

- What are the 3 categories of nursing home care?
- What is the tool used to assess the acuity of illness for nursing home patients?
- What are the negative impacts of using restraints in nursing home patients?
- What is the average infection rate in nursing home residents?

OVERVIEW

The geriatric population in the U.S. is growing, and the highest growth rate is among those ≥ 85 years of age. This is significant because nursing home utilization rates are 4% for those > 65 years of age but dramatically rise to 17% for those > 85 years of age. Even though nursing home care is heavily regulated and utilizes a significant proportion of health care dollars, quality care continues to be a struggle. Nursing home care is an integral part of patient care today and acts as a bridge between hospital care and home care.

Nursing home care can be divided into 3 categories:

- 1) Long-term care (~ 6%)
- 2) Subacute care
- 3) Specialized care

Long-term care is appropriate for individuals who suffer from multiple chronic diseases and are no longer able to care for themselves. Nursing homes provide custodial care for these patients for the remaining duration of their lives. The most common reason for seeking placement in long-term care is the caregivers' inability to provide optimal help with ADLs. These include incontinence care, worsening neurologic function, and significant dementia-related behaviors. This type of care is not reimbursed by Medicare. Consequently, patients must pay out of pocket for their care until they meet income levels to qualify for Medicaid.

In contrast, **subacute care** is designed for posthospital patients. Typically, these patients stay for a short time in nursing homes, and the ultimate discharge plan is usually back to the home. Rehabilitative care, complex medical care, and wound care are among the diagnoses that qualify patients for subacute nursing care. The most common reasons for subacute nursing care admission are orthopedic surgeries (e.g., after hip and knee replacements), stroke, heart failure, COPD and other pulmonary disorders, and care for pressure ulcers.

Specialized care is designated for specific programs, such as dementia care, dialysis, and hospice, in a smaller category of patients.

Nursing home care is increasingly being used by non-geriatric patients (<65 years of age), predominantly for mental health care.

In 2016, the average length of stay of older adult nursing home residents was 485 days with 43% staying less than 100 days and 57% staying 100 days or longer. Women make up 60–68% of nursing home patients, primarily because women have a higher life expectancy compared to men. On average, women need longer care than men.

ADMISSION EVALUATION

During the nursing home admission process, all patients need an individualized focused care plan, which should be reviewed on a regular basis. This requires a comprehensive geriatric assessment of all elderly patients evaluating functional, physical, cognitive, emotional, and psychological well-being. The Minimum Data Set (MDS) is the universal tool used at the time of admission, as well as for quarterly reassessments for long-term residents, to define complexity of care in nursing home patients. It includes a comprehensive assessment of the patient's functional, cognitive, psychosocial, and overall health status. The MDS includes assessment of cognition, vision, hearing, communication, physical functioning, continence, and psychological and nutritional status—besides, of course, disease diagnoses and associated treatment needs.

The care goals in a nursing home setting differ from the hospital setting. Nursing homes emphasize maximizing function and improving quality of life, rather than curing a disease. It is very important to communicate with patients and their families periodically. Typically,

this communication occurs once a week, or every 2 weeks for subacute patients, or every 2 months for long-term care patients.

The goal of long-term care admission planning is to maintain the best possible quality of life.

ADVANCED DIRECTIVES AND LIVING WILLS

A conversation regarding advanced directives is the most important step to initiate quality care at admission. First and foremost, evaluate patients for medical decision-making capacity. If they have the competency to do so, then talk about a **living will** and **health care proxy appointment**. Both are prepared in case the patient later loses the capacity to make decisions on their own. A living will consists of instructions regarding a person's desired future care. A health care proxy is a trusted agent and alternative agent who have been appointed to make health care decisions on the patient's behalf.

Discuss and clearly document patients' wishes regarding resuscitation, rehospitalization, and medical interventions. Several states have forms to document these decisions, including allow natural death (AND), do not resuscitate (DNR), and physician orders for life-sustaining treatment (POLST), and questions regarding intubation, artificial feeding, dialysis, and the use of invasive procedures. This information is important to make sure that the medical personnel respect patients' known wishes and values.

USE OF RESTRAINTS

The use of physical and chemical restraints is not infrequent in nursing home care, but increasingly, nursing homes are going restraint free. If restraints are used, Joint Commission standards must be followed. This certainly comes with a lot of controversy.

Restraints are used as a modality to:

- Promote safety
- Control violent behavior

The negative impacts of restraints include:

- An associated increased risk of injury
- Increased mental impairment
- Decubitus ulcers
- Nosocomial infections
- Agitation
- Loss of dignity for the patient

Use **physical** restraints only as a last resort after demonstrating that less restrictive measures were unsuccessful. **Chemical** restraints refer to the use of psychoactive medications. Use these only to treat specific symptoms, such as psychosis, and when there are clear behaviors that cause the patient to be a danger both to others and themselves.

Never use restraints to control patient behavior solely for the convenience of the nursing home personnel. Nursing home personnel should receive appropriate education and adhere to monitoring guidelines when overseeing residents. Establish interdisciplinary teams to minimize the use of restraints. When needed, obtain a psychiatric consultation, especially with a geropsychiatrist (if available).

PREVENTIVE CARE

Preserving function and maintaining quality of life are the most important preventive interventions in a nursing home. For long-term care residents, continue routine use of appropriate clinical and laboratory screening unless the patient's life expectancy is < 5 years. (If life expectancy is < 5 years, cancer screening is not needed.) Nursing home patients need certain specific screenings, including screening for hearing problems, cognitive impairment, gait impairment, nutrition, and incontinence. In addition, optometry, podiatry, and dental needs must be addressed.

Prevention of infectious diseases in nursing homes is very important. Screen all nursing home residents with purified protein derivative (PPD) for tuberculosis. Tetanus and diphtheria vaccinations are recommended in the absence of appropriate vaccination history. All nursing home residents should receive appropriate influenza and pneumococcal vaccinations. For vaccine schedules, see the [Infectious Disease](#) section.

When influenza outbreaks occur, oseltamivir is effective in early treatment and prevention of influenza. When influenza is diagnosed or strongly suspected, treat with oseltamivir at 2×/day dosing (dose adjustment is needed for renal failure). Chemoprophylaxis with oseltamivir once a day is recommended for all nursing home residents in case of an epidemic. Once-daily oseltamivir should be given to all nursing home residents when an epidemic starts and should be continued for a minimum of 14 days and a week after the last case of influenza in the nursing home.

INFECTION CONTROL

The institutionalized elderly are at significant risk for infections given their decreased immunity, advanced age, and comorbid diseases. Subacute patients from acute hospital settings can harbor virulent and resistant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA), carbapenem-resistant Enterobacteriaceae (CRE), vancomycin-resistant *Enterococcus* (VRE), and *Clostridioides difficile* (formerly known as *Clostridium difficile*). The average incidence of infections in nursing homes in the U.S. is 1–2 infections/resident/year. These infections increase not only rehospitalizations but also patient morbidity and mortality rates.

For successful infection control programs, include appropriate screening of patients and procedures for preventing, identifying, and treating infections. Staff must be educated on the use of universal precautions, especially simple handwashing, aseptic techniques, and appropriate disposal of contaminated materials. Ideally, all facilities should have an infection control nurse.

THE MEDSTUDY HUB: YOUR GUIDELINES AND REVIEW ARTICLES RESOURCE

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub at

medstudy.com/hub

The Hub contains the **only** online consolidated list of **all** current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source. MedStudy maintains the Hub as a service to the medical community and makes it available to anyone and everyone at no cost to users.

DIAGNOSTIC TESTS

PREVIEW | REVIEW

- What are the primary computed tomography (CT) chest types, and which has the highest radiation exposure?
- Which conditions are diagnosed by high-resolution CT (HRCT) scan?
- What are the results of VC, TLC, FEV₁, and FEV₁/FVC in patients with intrathoracic restriction? In extrathoracic restriction?
- What are the results of VC, TLC, FEV₁/FVC and RV in patients with obstruction?
- What is VC? Which smaller lung volumes make up VC?
- Characterize the differences in the flow-volume loops for obstructive and restrictive airway diseases. (See Figure 6-2 on page 6-4, Figure 6-3 on page 6-4, Figure 6-4 on page 6-4, Figure 6-5 on page 6-5.)
- When is the methacholine bronchoprovocation test performed?

COMPUTED TOMOGRAPHY (CT) CHEST

Table 6-1 reviews the most common types of chest computed tomography (CT) scans, including radiation dose exposure. For reference regarding comparative effective radiation dose exposure in millisieverts (mSv), a 2-view chest radiograph has a score of 0.02 mSv and a transcontinental airline flight scores 0.02 mSv.

HRCT assesses the lung parenchyma rather than the vasculature or other tissues of the thorax. Certain HRCT patterns and distributions can correlate well

with histopathology in some instances of ILD. In some cases, a diagnosis can be made using characteristic HRCT findings without a lung biopsy (the diagnostic gold standard).

HRCT is used when disease is suspected by history and physical exam but the chest x-ray is normal, has a subtle abnormality, and/or considerable detail is needed to characterize the disease further. Such instances include interstitial lung diseases (ILDs), emphysema from α_1 -antitrypsin deficiency, bronchiectasis, and lymphangitic spread of malignancy. If you suspect ILD or bronchiectasis, make HRCT the initial study.

Obtain prone positioning and end-inspiratory images to distinguish dependent atelectasis from ILD. Obtain images at the end of inspiration and expiration to evaluate for air-trapping in the lung. In contrast, when acquiring CT images, patients hold their breath at the end of inspiration.

HRCT is sometimes used to guide biopsies of focal diseases, such as solitary pulmonary nodules or localized parenchymal abnormalities.

MAGNETIC RESONANCE IMAGING (MRI)

MRI is useful only in the following specific situations when evaluating for pulmonary disease:

- Evaluation of tumors near adjacent blood vessels or nerves
- Differentiation of tumors and nonneoplastic entities; examples include tumors of the superior sulcus, brachial plexus, mediastinum, and tumors near the aorta, spine, or heart.
- Evaluation of venous thrombosis with magnetic resonance angiography (MRA) and magnetic resonance venography (MRV). These are used in very few centers.

Table 6-1: Common Chest CT Scans

Type	Millisieverts (mSv)	Key Imaging Protocol Features	Important Points About When to Use
CTPA	15 mSv	Uses a rapid-timed infusion of IV contrast dye to enhance the imaging of the pulmonary vasculature	Diagnosis of PE during the bolus phase
CT chest without contrast	8 mSv	Usually ≤ 5 mm for the mediastinal and lung sections	• Assesses the mediastinum, pleura, and parenchyma • Workup of a solitary pulmonary nodule (CT > HRCT)
LDCT	1.5 mSv	Uses no contrast and 1 breath hold	Screening tool for lung cancer and follow-up imaging of identified abnormalities during screening regime
HRCT	Dose can be > or < conventional CT, varying with protocol used, but < CTPA	Uses thinner slices, 1.5 mm, and no contrast	• Diagnosis of ILD or bronchiectasis • Workup of a solitary pulmonary nodule (CT > HRCT) • Do not select HRCT to diagnose a PE!

CT = computed tomography
CTPA = CT pulmonary angiography
HRCT = high-resolution CT
ILD = interstitial lung disease
LDCT = low-dose CT
PE = pulmonary embolism

LUNG BIOPSY

Consider using a lung biopsy to assist in diagnosing ILD with **atypical** clinical and HRCT features, especially when you need to differentiate among forms of ILD or to exclude infectious and other causes of an interstitial pattern. Choose a lung biopsy technique based on the type, extent, and location of the pulmonary abnormalities. Use chest x-ray and HRCT findings to guide this choice. For example, in sarcoidosis, transbronchial biopsy yield is highest when infiltrates are obvious on the chest x-ray and lowest when hilar adenopathy is the only abnormality. Lung biopsy is generally pursued in consultation with a pulmonary specialist.

Bronchoscopic transbronchial biopsy is useful in the diagnosis of suspected sarcoidosis, some cases of cryptogenic organizing pneumonia (COP), lymphocytic interstitial pneumonia, eosinophilic pneumonia, lymphangitic spread of cancer (though this is generally suggested by the clinical picture and CT appearance), and certain infections. The chief problem with transbronchial biopsy is the small amount of tissue afforded by the biopsy forceps, with resulting low sensitivity and low specificity from sampling error. Cryobiopsy is another option performed at specialized centers and is performed via bronchoscope. Sample size is larger but comes at higher risk for pneumothorax.

If the diagnosis is not obtained or unlikely to be obtained bronchoscopically or radiologically, **open lung biopsy** or **video-assisted thoracoscopic surgery (VATS)**

may be pursued. This step is dependent upon the clinical condition of the patient, the risks and benefits of such an operation, and whether empiric treatment is problematic. The surgeon obtains multiple biopsies at different affected sites. These biopsies yield larger tissue samples than transbronchial biopsies.

The radiographic pattern on HRCT has increasingly obviated the need for lung biopsy in classic or typical cases of idiopathic pulmonary fibrosis (IPF).

OTHER PULMONARY TESTS

Bronchoalveolar lavage (BAL) is an important pulmonary diagnostic tool. It is used to obtain material for microbiologic data, cytology, and leukocyte count with differential from the lung. Know [Table 6-2](#). BAL with cell count and differential can be used to diagnose eosinophilic pneumonia. In cases of suspected sarcoidosis or berylliosis, a CD4:CD8 ratio of > 4 in BAL lymphocytes is suggestive in the absence of an increased proportion of other inflammatory cell types in BAL. If the ratio is reversed, consider hypersensitivity pneumonitis, silicosis, COP, or drug reaction. Examining the BAL effluent is useful for alveolar proteinosis (periodic acid-Schiff positive) as well as pulmonary hemorrhage.

Endobronchial ultrasound (EBUS) is used to guide biopsy of suspicious or enlarged central lymph nodes. In experienced hands, it is increasingly regarded as the procedure of choice for staging of lung cancer.

Table 6-2: Findings in Bronchoalveolar Lavage (BAL)

Results	Causes
< 1% neutrophils, < 16% lymphocytes, no eosinophils	Normal findings
Increased neutrophils	IPF, collagen vascular disease, asbestosis, suppurative infections, GPA, and ARDS
Increased lymphocytes	Hypersensitivity pneumonitis and sarcoidosis, but also COP, nonspecific interstitial pneumonitis, and collagen vascular disease with lung involvement
Increased eosinophils	Acute and chronic eosinophilic pneumonia, some ARDS, EGPA, Löffler syndrome, tropical eosinophilia, parasite infection (esp. ascariasis), TB, collagen vascular disease, malignancy (esp. lymphoma), asthma, bone marrow transplant, and drug reactions
Diagnosis of specific types of pneumonias and other infectious diseases	95% sensitive for PJP in AIDS patients* CMV pneumonia (identifies inclusion bodies)* TB or fungal infection* Pneumonia in ARDS patients*
Turbid, periodic acid-Schiff (PAS)-positive material	Alveolar proteinosis*
Langerhans cells	Langerhans cell histiocytosis*
Bloody with a large amount of hemosiderin in the alveolar macrophages (increase with serial aliquots)	Diffuse alveolar hemorrhage*
Hyperplastic and atypical Type 2 pneumocytes	Cytotoxic lung injury*
Foamy changes with lamellar inclusions	Amiodarone exposure: seen with and without lung disease
* In these, BAL results are sufficient for diagnosis.	
ARDS = acute respiratory distress syndrome EGPA = eosinophilic granulomatosis with polyangiitis IPF = idiopathic pulmonary fibrosis CMV = cytomegalovirus GPA = granulomatosis with polyangiitis PJP = <i>Pneumocystis jiroveci</i> pneumonia COP = cryptogenic organizing pneumonia TB = tuberculosis	

Transthoracic needle biopsy is done with CT guidance for peripheral lesions, such as suspicious lung nodules.

Pulmonary angiogram was considered the gold standard for the diagnosis of pulmonary embolism; however, it is **rarely required** anymore because CTPA has high sensitivity and specificity for diagnosing acute pulmonary embolism. When chronic thromboemboli are suspected, such as during the workup of pulmonary hypertension, ventilation/perfusion scan (a.k.a. V/Q scan) is recommended.

PET (positron emission tomography)/CT scan is useful in differentiating some benign lesions, such as scars, from pulmonary lesions that are malignant, infectious, or inflammatory. Note that PET cannot distinguish between malignant, infectious, and inflammatory lesions, but the intensity of the 18F-fluorodeoxyglucose (FDG) uptake can guide clinical decision-making. The PET scan is paired with a CT to localize FDG avidity by metabolically active cells. PET/CT is most useful with nodules > 1-2 cm but has a lower limit of resolution of approximately 8 mm. This study is also used to identify suspicious lymph nodes for biopsy in cases of suspected lung cancer or other cancers. False negatives can occur (e.g., adenocarcinoma in situ, renal cell metastasis, carcinoid tumors).

Pulmonary function tests (PFTs) are outlined under [Pulmonary Function Tests \(PFTs\)](#), **V/Q scan** is discussed under [Review of Lab and Radiological Tests for PE on page 6-41](#), and **thoracentesis** is covered under [Exudative vs. Transudative on page 6-49](#).

PULMONARY FUNCTION TESTS (PFTs)

Using spirometry in the office, you can determine vital capacity (VC), forced vital capacity (FVC), tidal volume (TV), inspiratory reserve volume (IRV), expiratory reserve volume (ERV), expiratory flows, and flow-volume loops and also assess bronchodilator response. Spirometry cannot measure reserve volume. Indications for spirometry:

- Aid in diagnosis of dyspnea or lung disease
- Assess the severity of a known lung disease in many cases
- Evaluate variability of lung disease (e.g., asthma)
- Evaluate the impact of prescribed treatment
- Assess the role of environmental exposures

- Assess the impact of exercise on airflow
- Evaluate for potential respiratory disability (generally with full PFTs)
- Assess for possible restrictive vs. obstructive disease

A pulmonary function lab is needed for:

- Total lung capacity (TLC) determination
- Residual volume (RV) determination and its derived values, including TLC and functional reserve capacity
- Diffusing capacity of the lungs for carbon monoxide (DLCO) determination
- Methacholine or other challenge tests (specific training of technicians needed)

For FEV_1 , FVC, and TLC, **< 80%** is generally considered abnormal and for RV > 120% also may be significant.

When reviewing PFT results, keep in mind the following:

- **TLC** is decreased in restrictive lung disease, and degree of restriction is determined by FVC.
- Expiratory flow rate (ratio of forced expiratory volume in 1 second to FVC [FEV_1/FVC]) is used to assess **obstructive** lung disease. Airway obstruction is diagnosed when the FEV_1/FVC is **< 70% or less than a lower limit of normal (LLN)** provided by the laboratory.

For a summary of typical PFT results for restrictive and obstructive lung disease, see [Table 6-3](#).

Lung Volumes

Review the lung volumes diagram in [Figure 6-1 on page 6-4](#). The lung is made of 4 basic functional volumes:

- 1) Inspiratory reserve volume (IRV) = normal unforced end-inspiration to maximum end-inspiration
- 2) Tidal volume (TV) = volume used in normal unforced ventilation
- 3) Expiratory reserve volume (ERV) = from the lowest point of tidal volume exhalation to maximum forced end-expiration
- 4) Residual volume (RV) = unused space

A capacity is ≥ 2 of these basic volumes and gives even more functional significance to them. For example, VC is the volume you have available for breathing (makes sense) and is comprised of the IRV, TV, and ERV.

Table 6-3: Typical Pulmonary Function Test (PFT) Results

	VC	TLC	FEV_1	FEV_1/FVC	RV	DLCO
Restrictive Intrathoracic	↓	↓ (< 80%)	↓ or normal	NI	↓	↓
Restrictive Extrathoracic	↓	↓ (< 80%)	↓ or normal	NI	↓	NI
Obstructive	↓	NI to ↑	↓	↓ (< 70% or less than LLN)	↑↑	NI to ↓

DLCO = diffusing capacity of the lung for carbon monoxide
 FEV_1 = forced expiratory volume in 1 second
 FVC = forced vital capacity
 LLN = lower limit of normal

NI = normal
 RV = residual volume
 TLC = total lung capacity
 VC = vital capacity

Figure 6-1: Lung volumes

The TLC is the sum of the VC and RV. In severe chronic obstructive pulmonary disease (COPD), TLC is increased (even though VC is decreased) due to a greatly increased RV—air trapping—seen as a barrel chest. In restrictive disease, the TLC is decreased due to both a decreased VC and RV. TLC is determined in the lab by helium dilution, nitrogen wash-out, or plethysmography (the latter provides more accurate results in patients with airflow obstruction).

The tracing in Figure 6-1 shows a forced expiration from maximum inspiration. Figure 6-2 shows a comparison of similar expirations for patients with normal, restrictive, and obstructive airways. This is an easy test and an important result, but you will not usually see it diagrammed this way.

Figure 6-2: Forced expiratory volumes and FEV₁/FVC

Although the TLC cannot be determined from spirometry (you must know the RV, which is calculated and not measured), you can determine the presence of **obstruction** by the ratio **FEV₁/FVC**. In a patient with a healthy lung, the ratio is about 0.8. It is always less than 0.7 or below the LLN in a patient with COPD or a patient with asthma experiencing bronchospasm. It may be normal or increased in a patient with restrictive disease—even though the VC is small—because this patient has no trouble getting air out. A patient with asthma has reversible disease and, if not having active bronchospasm, can have a normal FEV₁/FVC, a common situation with intermittent asthma,

Flow-Volume Loops

The diagrams of flow-volume loops shown in Figure 6-3, Figure 6-4, and Figure 6-5 are a more common way of expressing airflow in the different lung diseases. These

loops are derived from the spirometry data and are calculated and plotted by an attached computer, where the FEV₁/FVC is automatically determined. Note that the y-axis illustrates the flow rate.

Figure 6-3: Flow-volume loops—normal vs. obstructive

Figure 6-4: Upper airway obstruction

Because you cannot determine RV from spirometry, you get most of your information from the **shape** of the loop. The exception is in restrictive disease. Although the shape is similar to normal, the VC (represented by the curve from TLC to RV or the loop width) is much smaller than normal.

Figure 6-3 compares normal and obstructive lung-flow loops. Figure 6-4 compares the different types of obstructive disease. Figure 6-5 includes restrictive diseases. Know the shapes and sizes of these loops!

In obstructive disease (Figure 6-3), increased expiratory airway resistance causes a decreased expiratory flow rate. Again, while normal FEV₁/FVC = 80%, obstruction is defined as **< 0.7 or below the LLN**. (In very severe obstruction, it may be even < 35%!) Additionally, there is a **scooping or concavity** of the tracing in the latter half of expiration. Common causes of lower airway obstruction include asthma, COPD, bronchiectasis, and cystic fibrosis (CF).

Figure 6-5: Flow-volume loops—all

When analyzing an obstructive disease of the **upper airway** (from the pharynx to the origin of the mainstem bronchi), you can derive much information from the **shape** of the flow-volume loop. See Figure 6-4.

Fixed upper-airway obstruction: If the upper-airway obstruction is fixed, the graph is flattened on the bottom **and** the top; i.e., during both inspiration and expiration. Examples of fixed obstruction are conditions due to compressive tumors (e.g., thyroid tumors) and tracheal stenosis (e.g., history of intubation).

Dynamic upper-airway obstruction: With dynamic **extra-thoracic** obstruction, such as in tracheomalacia and vocal cord paralysis, the obstruction occurs on inspiration. Think of a thin rubber wall in the neck (instead of the normal trachea) collapsing from the negative pressure of inspiration.

If the tracheomalacia is **intrathoracic**, the flow is impeded on expiration due to the increased intrathoracic pressure pressing on the malacic trachea.

Restrictive disease is shown in Figure 6-5. Note that in intrathoracic restrictive disease (e.g., parenchymal disease, ILD), the RV is decreased, unless there is concomitant marked obstructive disease. In extrathoracic restrictive disease states (e.g., obesity, kyphosis), the RV can be normal, but the loop shape and size are similar.

Bronchodilation

Bronchodilator response during pulmonary function testing is done for 2 reasons:

- 1) To determine if the obstruction is responsive to β_2 -agonists. Before testing, withhold β_2 -agonists for 8 hours and theophylline for 12-24 hours.
- 2) To test for the efficacy of a current regimen. In this case, medications are not withheld. If treated patients have a response to β_2 -agonists, it suggests they are not on an optimum regimen or are not using them properly.

Methacholine or other bronchoprovocation challenges determine if patients have **bronchial hyperreactivity**. This testing is done in patients with normal spirometry and intermittent asthma-like symptoms (or other symptoms suggestive of airflow obstruction). It is often done in the workup of **chronic cough** (see **Asthma** on page 6-11) and occasionally in patients with cold air-induced or exercise-related bronchospasm.

Protocols using inhaled escalating doses of methacholine or histamine are given to the patient while monitoring for a 20% drop in FEV_1 . Know that patients with asthma bronchoconstrict at a **very low dose** of the irritant, whereas those without asthma do not.

Also know that PFTs are always the 1st test in the evaluation of possible COPD or asthma. Bronchoprovocation should be done **only** when initial PFTs are **normal** and the **diagnosis remains obscure**.

Pre-Op

PFTs are **not** routinely indicated in preoperative evaluation.

PFTs with or without arterial blood gases (ABGs) **may be** indicated in the following circumstances:

- If the surgical procedure is close to the diaphragm (e.g., gallbladder)
- If the patient has moderate or severe lung disease. In these cases, an $FEV_1 < 1$ L or an **elevated pCO_2** indicates that the patient is at risk for postoperative pulmonary complications.
- If the patient requires presurgical evaluation for lung **cancer** or lung **resection**. Assuming a worst-case scenario (pneumonectomy), the patient must still have adequate lung function postoperatively. High risk of postoperative morbidity is suggested by a predicted $FEV_1 \leq 0.8$ L after surgery.
- If a patient has a preoperative FEV_1 of, for example, ≤ 1.6 L, you can estimate the postoperative FEV_1 by obtaining a quantitative ventilation and perfusion lung scan. You then multiply the percent perfusion (or ventilation) to the lobe to be removed by the FEV_1 in order to obtain the estimated postoperative FEV_1 .

Now, let's look at what PFTs show in the major lung diseases. In subsequent discussions, we focus on the clinical aspects of the major lung diseases.

PFTs for Specific Lung Diseases

The following lists detail potential PFT findings for common chronic pulmonary diseases, but not all features may be present:

- Emphysema
 - Decreased expiratory flow volume (a shortened top portion of the flow-volume loop)
 - Concave expiratory flow-volume loop tracing, if there is concomitant obstructive airway disease

- Minimal response to β_2 -agonists ($< 12\%$ improvement or < 200 mL improvement in FEV_1 or FVC)
- Increased TLC with reduced VC (hyperinflation with trapped air)
- DLCO is **decreased** due to the destruction of the alveolar-capillary interface.
- Early on, patients may have low DLCO and radiographically demonstrable emphysema but relatively normal spirometry and lung volumes.
- Chronic bronchitis
 - Decreased expiratory flow volume
 - Concave expiratory flow-volume loop tracing, if concomitant obstructive disease
 - Variable response to β_2 -agonists
 - Normal or only slight increase in TLC (normal or slightly reduced VC)
 - DLCO is **normal** to slightly decreased, but it is not as low as in patients with emphysema. Remember: DLCO is the test that allows you to differentiate emphysema from chronic bronchitis and asthma. Understand that most cases of COPD have mixed physiology, with components of both chronic bronchitis and emphysema.
- Asthma
 - PFTs can be normal if there is no active bronchoconstriction at the time of testing, as occurs in intermittent asthma.
 - Decreased expiratory flow volume
 - Concave expiratory flow-volume loop tracing, if active bronchoconstriction present
 - Significant response to β_2 -agonists
 - Normal or increased TLC (due to hyperinflation) and a normal or reduced VC
 - **Normal** DLCO
- Interstitial lung disease
 - Normal to increased FEV_1/FVC
 - Straight or slightly convex expiratory flow-volume loop tracing
 - Proportional decreases in all lung volumes, that is, restriction
 - DLCO is **reduced** (due to the thickening of the alveolar-capillary interface) and is the 1st pulmonary parameter to change with disease progression.

When approaching a PFT scenario, think in terms of:

- Expiratory flow
- Lung volumes
- Diffusion capacity
- Response to bronchodilators

FVC, FEV_1 , or TLC $< 80\%$ of predicted is an abnormal finding. Generally, the actual FEV_1/FVC value is used. FEV_1/FVC is age adjusted. The percent predicted is sex, age, race, and height adjusted. (Note: If a patient is unable to stand, height can be estimated by measuring the arm span; i.e., both arms spread in parallel.)

Review the following 4 steps and apply them to the 6 sets of PFT results in Table 6-4. Write your conclusions in the Analysis column. Remember, we are looking for normal findings, restrictive disease, or obstructive disease.

1) Look for all normals:

- Circle everything $\geq 80\%$. Label these values **normal**.
- If all the values are $\geq 80\%$, the results are normal.
- Remember that most smokers have **normal** values.

2) Look for restrictive disease:

- Any TLC $< 80\%$ is by definition restrictive. Label these results as **restrictive**. If the TLC is not known, restrictive disease is reflected in a proportional decrease in both the FEV_1 and FVC (i.e., $FEV_1/FVC = 80\%$ but the FVC is $< 80\%$).
- If restrictive, check the DLCO. This determines if it is extrathoracic or intrathoracic.
 - If the decrease in the DLCO is **proportional** to the decrease in the TLC, the restriction is commonly caused by an extrathoracic origin. Label it **extrathoracic** and think of obesity, neuromuscular disease, or kyphosis. **Pulmonary resection** can also cause this.
 - If the decrease in the DLCO is **disproportionately** low compared to the decrease in the TLC, label it **intrathoracic** and think of parenchymal disease or ILD.

3) Look for obstructive disease:

- Obstruction is defined by a disproportionately low FEV_1 . So, both the FEV_1 and FEV_1/FVC are low, $< 70\%$ or below the LLN. Label these lines **obstructive**.
- If obstructive, check the TLC, DLCO, and reactivity to β_2 -agonists.
 - Label it **emphysema** if the TLC is high but the DLCO is low. There is minimal to no response to β_2 -agonists.
 - Label it **asthma** if the DLCO is normal. There is typically improvement with β_2 -agonists.

4) In some instances, results represent combinations of obstructive and restrictive diseases, such as in:

- patients with concomitant asthma and obesity or
- patients with concomitant asthma and certain diseases, especially sarcoidosis, lymphangioleiomyomatosis, and Langerhans cell histiocytosis.

Okay, now look at your completed table of PFT results. **Know!** This is not only for exam questions but also for clinical practice. PFT results are shown as a percentage of predicted. Remember that for FVC, FEV_1 , and TLC, $< 80\%$ of predicted is abnormal. If a percent predicted for FEV_1/FVC rather than the actual ratio is given, a value $< 80\%$ of predicted would be abnormal. Confusingly, the actual FEV_1/FVC is often also reported as a percentage rather than as an actual ratio, so it is important to note the difference.

Table 6-4: Pulmonary Function Test (PFT) Analysis*

Set	% FEV ₁	% FVC	FEV ₁ / FVC	% TLC	% DLCO	Analysis
1	83	89	93	92	85	
2	58	62	93	68	64	
3	52	80	65	110	65	
4	55	87	63	100	88	
5	57	87	65	70	68	
6	66	72	92	75	33	

* Except for the FEV₁/FVC ratio, results are reported as a percentage of predicted values.

DLCO = diffusing capacity of the lung for carbon monoxide

FEV₁ = forced expiratory volume in 1 second

FVC = forced vital capacity, TLC = total lung capacity

Set 1: You should have all these values circled. These are, of course, normal. Remember that normal results are seen in most smokers!

Set 2: Extrathoracic restrictive mechanics (non-parenchymal).

All restrictions, intra- and extrathoracic, are defined by a decrease in the TLC. The normal FEV₁/FVC ratio proves that there is no obstructive mechanism involved. The FEV₁ is decreased in proportion to the decrease in FVC, so the FEV₁/FVC is $\geq 80\%$. Extrathoracic involvement is indicated by the proportional decrease in the TLC and the DLCO—that is, the decrease in the DLCO is due to the decrease in the TLC.

Pure extrathoracic restriction is seen with **kyphosis** and **obesity**. Kyphoscoliosis is usually a result of compression fractures of the thoracic vertebral bodies, secondary to long-standing osteoporosis. It also occurs in a small percentage of neurofibromatosis (von Recklinghausen disease) and tuberculosis patients who have thoracic vertebrae involvement. Obesity may be associated with a reduced ERV.

If a patient is post-CABG (coronary artery bypass graft) and suffering from orthopnea, check PFTs, but also check FVC values while the patient is both standing and lying down. If the patient has extrathoracic restrictive mechanics and the difference in the FVC values is $> 20\%$ (decreases with lying down), consider bilateral hemidiaphragmatic paralysis from the cold cardioplegia. (This is exam-question specific—a chest x-ray will tell you this!) Unilateral phrenic nerve problems can be diagnosed by a sniff test with fluoroscopy or with bedside ultrasound evaluation. Also note that a decrease in FVC (from standing to lying) in the high-to-normal range (15–20%) is commonly seen with obesity. Maximum inspiratory pressure (MIP), measured in the PFT lab, may be reduced. The DLCO can be disproportionately low (say, 54%) if this post-CABG patient also has some postoperative atelectasis.

Question: Besides cold cardioplegia, what are the other possible causes of a bilateral elevated hemidiaphragm? Answer: Poor inspiration, systemic lupus erythematosus (SLE), bilateral phrenic nerve paralysis such as from spinal injury, tumors, neurological disorders, diaphragmatic weakness from amyotrophic lateral sclerosis (ALS), large-volume ascites, and bilateral subpulmonic effusions can all cause bilateral elevated hemidiaphragms. These all make sense, so just think about them, but do not memorize them!

Set 3: Pure obstruction with low DLCO and a high TLC.

The FEV₁/FVC is $< 70\%$. The TLC is high and the DLCO is disproportionately low, indicating a loss of alveolar-capillary units. Emphysema (from either smoking or α_1 -antitrypsin deficiency) with COPD is the most common cause of this finding.

Set 4: Pure obstruction with normal DLCO.

It is the same as Set 3, except the DLCO is normal, indicating asthma. In both Sets 3 and 4, the FVC can be low if the obstruction is so severe that the patient does not have enough time to fully expire before getting short of breath. The FEV₁/FVC remains $< 70\%$.

Set 5: Combined obstruction and extrathoracic restriction.

The low FEV₁/FVC indicates obstruction. The low TLC indicates restriction, while the proportionate decrease in the DLCO narrows it to an extrathoracic etiology. Possible etiologies include an obese patient with asthma or an osteoporotic, kyphotic patient with asthma.

Set 6: Intrathoracic restriction.

As in extrathoracic restriction, the FEV₁ and the FVC are **proportionately low** (so the FEV₁/FVC is $> 80\%$). Contrary to extrathoracic restriction, DLCO is disproportionately lower than the decrease in the TLC in intrathoracic restriction. This is seen with many forms of ILD.

RESPIRATORY PHYSIOLOGY

PREVIEW | REVIEW

- In which diseases do you see a reduced diffusing capacity of the lung for carbon monoxide (DLCO)?
- What is a simple formula for calculating the A-a gradient?
- Name 3 factors that, for a specific P_aO₂, cause a decrease in hemoglobin O₂ saturation.
- What does CO poisoning do to the oxyhemoglobin dissociation curve?
- What are the symptoms of methemoglobinemia?
- What is the treatment for methemoglobinemia?
- What is the DLCO in ILD? In asthma? In emphysema?

NOTES

Acid-base analysis is covered in depth in the [Nephrology](#) section.

Know **respiratory physiology well**. The information is used extensively in clinical practice and is often tested on exams.

SHORT REVIEW

Atmospheric pressure (P_b) varies. At sea level, at 59.0°F (15.0°C), it is 760 mmHg (29.92 inches Hg). The medical standard is to use mmHg. Atmospheric pressure decreases as you get further away from the surface of the earth and also as the temperature increases. The component gases of the atmosphere each exert a consistent partial pressure to the atmospheric pressure. For example:

$$\begin{aligned}\text{Partial pressure } O_2 &= F_{iO_2} \times P_b \\ &= 0.209 \times 760 \text{ mmHg}\end{aligned}$$

F_{iO_2} = fraction of inspired oxygen

P_b = atmospheric pressure

The partial pressure $O_2 = 158.84$ mmHg in the air surrounding us at sea level at 59.0°F (15.0°C). This pressure is called the P_{iO_2} (inspired). This fraction of 20.9% remains constant as atmospheric pressure decreases with increasing altitude.

The following is the **alveolar gas equation**, which calculates the partial pressure of O_2 in the alveoli:

$$P_{AO_2} = [(P_b - P_{H_2O}) \times F_{iO_2}] - [P_aCO_2/0.8]$$

This equation looks different from the simpler P_{iO_2} equation just discussed. The reason is that the partial pressure of inspired gases changes a little when it gets into the damp alveoli where the $O_2 \leftrightarrow CO_2$ exchange occurs. Here, you must account for the additional partial pressure of water vapor P_{H_2O} (47 mmHg at sea level) and the shifts in the concentrations of O_2 and CO_2 in the alveoli. The respiratory quotient (0.8) is the production of CO_2 /minute by the consumption of O_2 . This quotient allows you to use the measurable P_aCO_2 (arterial) in the alveolar gas equation instead of the P_aCO_2 (alveolar), which you cannot readily measure.

So, to get back to the alveolar gas equation ...

$$P_{AO_2} = [(P_b - P_{H_2O}) \times F_{iO_2}] - [P_aCO_2/0.8]$$

The P_b is still multiplied by the F_{iO_2} but only after its value is decreased to account for the water vapor. The second term decreases this product by an amount that takes into account the $O_2 \leftrightarrow CO_2$ exchange in the alveoli.

Other terms:

- P_aO_2 = partial pressure of oxygen in the arterial blood; commonly called the **pO₂**
- P_aCO_2 = partial pressure of carbon dioxide in the arterial blood; commonly called the **pCO₂**
- S_aO_2 = oxygen saturation of hemoglobin in the arterial blood

- S_vO_2 = oxygen saturation of mixed venous blood. Mixed venous blood is in the pulmonary artery.
- $S_{cv}O_2$ = oxygen saturation of central venous blood. Central venous blood is obtained from the superior vena cava.

HYPOXEMIA

Hypoxemia (low oxygen tension) has 6 causes:

- 1) **Ventilation/Perfusion (V/Q) mismatch** is the main cause of hypoxemia in chronic lung diseases and responds well to 100% O_2 . It is due to inadequately perfused airspaces or perfused areas that are inadequately ventilated. Examples include asthma, COPD, alveolar disease (e.g., pneumonia), interstitial disease, and pulmonary vascular disease (e.g., pulmonary hypertension, pulmonary embolism). The hypoxemia improves after oxygen administration.
- 2) **Right-to-left (R-to-L) shunting** is seen in, for example, acute respiratory distress syndrome (ARDS), where hypoxemia is due to perfusion of nonventilated alveoli. ARDS does **not** respond well to 100% O_2 but responds better to positive end-expiratory pressure (PEEP). See [Ventilator Support for ARDS on page 6-77](#). Other causes of R-to-L shunting, besides alveolar collapse, include intraalveolar filling (e.g., pneumonia, pulmonary edema), atelectasis, intracardiac shunt, and vascular shunt. PEEP can worsen a R-to-L intracardiac shunt by increasing the shunt fraction as a result of increased right-sided pressures.
- 3) **Decreased alveolar ventilation** is seen with decreased tidal volumes, low respiratory rates, and apnea. By definition, decreased alveolar ventilation **always** has a high P_aCO_2 with hypoxemia. The A-a gradient ($D_{A-a}O_2$, discussed below) is normal. Common causes are drug overdose, neuromuscular diseases, and CNS disorders.
- 4) **Decreased diffusion** actually has **little** effect on hypoxemia at rest, but it can play a role in exercise-induced desaturations. It takes a **tremendous** amount of membrane thickening or loss of the alveolar-capillary interface to markedly decrease the diffusion of O_2 . The **DLCO** test measures how well inspired CO diffuses from the alveoli to the RBC hemoglobin and acts as a surrogate marker for CO_2 and oxygen diffusion. Low DLCO occurs with **ILDs** and **emphysema**, in which symptoms improve with supplemental O_2 . Other causes include pulmonary vascular disease and significant anemia. Hypoxemia at rest occurs when the DLCO is approximately $\leq 30\%$ of predicted. It can occur at higher DLCO if there is an increased cardiac output, as with a rapid heart rate or if there is additional lung pathology. With an increased cardiac output, the time for diffusion is limited, so decreased O_2 transfer occurs. **Increased** DLCO is seen with alveolar hemorrhage, polycythemia, and sometimes with acute asthma attack.

- 5) **High altitude** decreases atmospheric pressure and results in a reduced $P_{A}O_2$. The A-a gradient is normal unless lung disease is present.
- 6) **Low mixed venous O_2** (i.e., venous oxygen pressure [P_vO_2]) can decrease the P_aO_2 during resting conditions, secondary to the normal shunt that exists (~ 5%). It can also exaggerate all other causes of low P_aO_2 . A low mixed venous O_2 is caused by low cardiac output or an increased tissue extraction of oxygen. A lower P_vO_2 can induce hypoxic vasoconstriction, increasing R-to-L baseline anatomical shunting.

Again:

- Supplemental O_2 does **not** cause a significant increase in P_aO_2 when there is R-to-L shunting or shunt physiology.
- The A-a gradient is **normal** with hypoventilation and with high altitudes.

A-a GRADIENT

The alveolar-arterial gradient (A-a gradient, A-a O_2 , or $D_{A-a}O_2$) is the difference between the partial pressure of oxygen in the alveoli (A) and that in arterial blood (a):

$$D_{A-a}O_2 = P_{A}O_2 - P_{a}O_2$$

For details on the A-a gradient and how to calculate it, see [Appendix A on page 6-89](#).

Calculate the gradient for every arterial blood gas you get. It helps you to quickly identify whether hypoxemia exists because of a problem in the alveolar-capillary unit (e.g., pulmonary embolism, pneumonia) or if some other cause is to blame (e.g., hypoventilation).

OXYGEN DELIVERY TO TISSUES

Oxygen delivery to the tissues is dependent upon **both** of the following:

- The amount of oxygen transported to the tissues
- How much of the transported oxygen is taken up and subsequently utilized by the mitochondria and/or cells

For more details on oxygen transport to tissues (DO_2) and how to calculate, see [Appendix B – Oxygen Transport to Tissues on page 6-90](#).

$$DO_2 = \text{cardiac output} \times (1.34 \times \text{Hgb} \times S_aO_2)$$

Cardiac output (heart rate $\times$ stroke volume), Hgb, and S_aO_2 are the 3 factors you look at when a critically ill patient requires better oxygen delivery. In exam questions, you are typically given a critically ill patient with either a low cardiac output or an obvious anemia with an O_2 saturation of 90% and P_aO_2 of 60 mmHg. The answer is to address the obviously low hemoglobin or cardiac output—the P_aO_2 is fine because the S_aO_2 is fine!

Note: Cardiac output is the variable that can usually affect DO_2 the most, potentially doubling or tripling it, while significant differences in hemoglobin are generally less common.

Oxyhemoglobin Dissociation Curve

The oxyhemoglobin dissociation curve (or oxygen saturation curve; [Figure 6-6](#)) shows the percent of O_2 saturation of hemoglobin (S_aO_2) for a certain P_aO_2 . It is the amount of O_2 -saturated hemoglobin that is important. You can see from the graph that, everything else being normal, a P_aO_2 of 60 mmHg results in an S_aO_2 of ~ 91%.

Figure 6-6: Oxyhemoglobin dissociation curve

The actual oxygen saturation of a particular hemoglobin molecule at a particular P_aO_2 is dependent on temperature, erythrocyte 2,3-diphosphoglycerate (2,3-DPG) level, and pH status. High or low levels of serum phosphorus cause an increased or decreased 2,3-DPG level. The oxyhemoglobin dissociation curve shows the S_aO_2 for a certain P_aO_2 —given variations in these 3 factors:

- 1) Temperature
- 2) Acidosis (pH)
- 3) Phosphorus (2,3-DPG)

This gives you the mnemonic **TAP** for remembering what shifts the curve.

When the curve is shifted to the **right**, with **increased levels** of TAP, it reflects a decreased hemoglobin affinity for O_2 (i.e., a decreased O_2 uptake by the hemoglobin). The red arrow on the graph indicates a shift to the right. With this given shift, you can see that maintaining an O_2 sat of 91% now requires a P_aO_2 of 70 mmHg (vs. 60 mmHg previously). Decreased affinity promotes off-loading of the O_2 to the tissues.

With a shift to the **left**, with **decreased levels** of TAP, it reflects an increased hemoglobin affinity for O_2 (i.e., an increased S_aO_2 for a particular P_aO_2).

Note that the “TAP, TAP, TAP” on the right of the graph is to remind you of the factors that shift the graph to the right—increased temperature, acidosis, and phosphorus.

Additional Causes of Reduced Hemoglobin Oxygen Saturation

Carboxyhemoglobin occurs when CO binds tightly to hemoglobin, preventing O₂ from binding. Additionally, the binding of CO causes the other oxyhemoglobin to bind even more tightly to O₂—shifting the curve to the left. The typical noninvasive saturation test (i.e., pulse oximeter) does **not** distinguish between oxyhemoglobin and carboxyhemoglobin, so the oxyhemoglobin curve not only shifts to the left but also appears to be 100% saturated with normal P_aO₂. Patient appears pink to cherry red in color. Treatment begins with high flow oxygen. With severe CO poisoning, the majority of hemoglobin is saturated with CO, leaving little room for O₂. The **red** tracing in [Figure 6-6 on page 6-9](#) shows how the graph shifts to the **left** with increasing amounts of carboxyhemoglobin.

Methemoglobin is produced when the iron in the hemoglobin molecule is oxidized from the ferrous (Fe²⁺) to the ferric (Fe³⁺) form. The resulting methemoglobin molecule cannot hold onto O₂ or CO₂—with disastrous results to the tissues. In addition, methemoglobin causes the regular ferrous hemoglobin to hold much more tightly to O₂, thereby shifting the oxyhemoglobin dissociation curve to the **left**. A typical bedside evaluation reveals generalized cyanosis with a pulse oximetry of ~ 85%. ABGs show a normal P_aO₂. The net result is a left shift of the oxyhemoglobin saturation curve that climbs to 100% at lower P_aO₂ levels. This is similar to the carboxyhemoglobin effect, but for completely different reasons.

Methemoglobinemia can be acquired (commonly due to medications) or hereditary. Clinical effects of methemoglobinemia include:

- > 25% = perioral and peripheral cyanosis
- 35–40% = fatigue and dyspnea begin
- > 60% = coma, death

Treat methemoglobinemia by removing the cause and with 100% O₂ and **methylene blue** (which causes rapid reduction of methemoglobin back to hemoglobin). Chronic hereditary methemoglobinemia is best treated with oral methylene blue and 1–2 g of daily ascorbic acid, which is a form of vitamin C that can help with cyanotic symptoms.

Think cyanide poisoning if the history includes breath with an almond odor and lab draw with bright-red venous blood. Cyanide immediately binds to the **ferric** molecule in the mitochondrial cytochrome oxidase complexes, thereby blocking cellular aerobic metabolism. Treatment goal for cyanide poisoning is to **induce methemoglobinemia** because cyanide preferentially binds methemoglobin and produces a less toxic reaction.

Carbon monoxide poisoning and cyanide poisoning are also discussed in the [General Internal Medicine](#) section.

Know that the standard pulse oximeter, which measures the absorption of 2 wavelengths of light, is **inaccurate** when there are significant levels of **carbon monoxide** or **methemoglobin**. Also understand that the oxygen saturation reported on an arterial blood gas analysis is a calculated value, not a measured one. Measuring a true level of the different hemoglobin saturations requires inserting blood into a special CO-oximeter that uses a spectrophotometer to make the measurements of oxygen saturation, methemoglobin, carboxyhemoglobin, and sulfhemoglobin levels. (Lipemic serum results may be inaccurate because the fat potentially interferes with light absorption.)

Bottom line: Realize that the standard bedside pulse oximeter is not always helpful in CO poisoning and methemoglobinemia because the value is often falsely normal—you must order measurements of the various hemoglobins on blood samples.

For more on methemoglobinemia, see the [Hematology](#) section.

Oxygen Release to Tissues

Oxyhemoglobin Dissociation Curve

We discussed oxygen transport to the tissues. What about oxygen release to the tissues? Here again, look at the oxyhemoglobin dissociation curve as it applies to oxygenated blood in the tissues. Any factor that shifts the graph to the right/down reflects a decreased affinity between oxygen and hemoglobin and, in the local tissue environment, causes a release of oxygen to the tissues.

For example, in the vicinity of the capillaries of working muscles, there is an increase of lactic acid due to normal metabolism → **local acidemia** → decreased affinity of hemoglobin for O₂ → release of O₂ to the tissues. Recall “TAP, TAP, TAP” on the right of the graph in [Figure 6-6 on page 6-9](#). The Bohr effect is the decreased association of oxygen and hemoglobin due to acidosis resulting from carbon dioxide.

Similarly, RBCs produce 2,3-DPG as a byproduct of anaerobic metabolism. (All RBC metabolism is anaerobic.) The more 2,3-DPG there is, the more O₂ is released from hemoglobin for use by the RBCs. Similarly, patients with chronic anemia have increased 2,3-DPG.

Blood stored > 1 week has a decreased level of 2,3-DPG, and large transfusions of this blood result in a shift to the left.

When there is **systemic acidosis** (or high temperatures or high 2,3-DPG levels), the decrease in affinity for O₂ by hemoglobin results in less O₂ picked up in the lung, as well as more O₂ released in the tissues. So, although the S_aO₂ is lower for a certain P_aO₂, more of the oxygen carried by the hemoglobin is released to the tissue. The

net result is to dampen the effect of low S_aO_2 caused by acidosis, high temperatures, and high 2,3-DPG levels. It dampens but does not negate or reverse the effect.

Conditions that shift the curve to the left (e.g., alkalemia; low temperatures; low 2,3-DPG levels; CO; fetal hemoglobin; methemoglobin; myoglobin) work similarly, although more O_2 is bound by the hemoglobin and less is released to the tissues. Again, it dampens but does not negate the effect.

Diffusing Capacity of the Lung for Carbon Monoxide (DLCO)

The DLCO is **decreased** by anything that interrupts the gas-blood oxygen exchange.

A decreased DLCO implies the loss of an effective alveolar-capillary interface. It is usually seen in **emphysema** (due to the loss of alveolar-capillary units), **ILD**, and **pulmonary vascular** diseases. **Anemia** also causes a decreased DLCO.

Know that the DLCO is the 1st parameter to decrease in ILD. Thus, it is important to follow DLCO when prescribing medications that can cause ILD, such as amiodarone or lung-toxic chemotherapy. Also, DLCO may be the only abnormal pulmonary function parameter in pulmonary vascular disease.

A **normal** DLCO is typically seen in asthma and chronic bronchitis. Despite bronchoconstriction, there is **no** alveolar disease. Therefore, recognize that the DLCO is the major pulmonary function parameter that helps you to distinguish **emphysematous** COPD (**low** DLCO) from chronic bronchitis and asthma (**normal** DLCO).

An **increased** DLCO is seen in problems that increase effective blood flow to the functional lung. Examples include heart failure, diffuse alveolar hemorrhage, pulmonary infarction, acute asthma exacerbation, and idiopathic pulmonary hemosiderosis (IPH). A perforated eardrum can cause a very high DLCO value due to the leakage of CO through the ear during testing!

OBSTRUCTIVE LUNG DISEASES

OVERVIEW

Obstructive lung diseases are characterized by decreased expiratory airflow. They may exhibit air trapping on PFTs (increased TLC, RV, and/or RV/TLC). While the hallmark of COPD on pulmonary function tests is persistent airflow limitation (usually $FEV_1/FVC < 0.70$), patients with asthma may have normal PFTs, as variable airflow limitation is seen with asthma. That is, at the time of spirometric measurement, the asthma may not be active. Patients with COPD tend not to have significant bronchodilator responses, while patients with asthma can, in some cases, normalize their airflow after bronchodilator administration.

ASTHMA

PREVIEW | REVIEW

- Which skin finding is a predisposing factor for IgE-mediated asthma?
- What is the asthma triad?
- Which comorbidities exacerbate asthma?
- Which spirometry findings support a diagnosis of asthma?
- How can you diagnose exercise-induced bronchospasm (EIB)?
- In the management of asthma, the initial treatment is based on _____. After therapy is started, assessment is directed toward _____.
- What is the preferred treatment course if an asthmatic is not controlled in Step 1?
- What is the preferred strategy for Step 5 patients?
- Describe the relationship between symptom-based monitoring and the peak expiratory flow (PEF).
- What is the short-acting drug of choice for asthma exacerbations?
- What is the preferred maintenance-type drug for the chronic treatment of persistent asthma?
- When is ipratropium bromide used during inpatient treatment of an asthma exacerbation?
- What is a therapeutic level of theophylline?
- What are signs and symptoms of theophylline toxicity?
- What is the preferred treatment for patients with exercise-induced bronchospasm (EIB)?
- For patients being treated for asthma exacerbation in the emergency department, when do you consider hospitalization?
- What are 2 consequences of dynamic hyperinflation?
- Explain permissive hypercapnia.
- Which ventilator settings are appropriate for a patient intubated for a severe exacerbation of asthma?

Asthma is a heterogeneous, chronic **inflammatory** condition of the airways with a multifactorial etiology and varying presentations. The symptoms are due to bronchoconstriction, airway wall thickening, and increased mucus secretion. Patients can have intermittent, persistent, acute, or chronic manifestations. The primary manifestations of bronchoconstriction are recurrent episodes of wheezing, shortness of breath, chest tightness, and cough—that vary over time.

Asthma is usually reversible either spontaneously or with treatment. However, with chronic inflammation, fixed airway disease, which is irreversible, may develop.

Causes of Asthma

Asthma often develops early in life. However, the cause is often not discovered, especially in adult-onset asthma. Asthma appears to develop from complex interactions within and between 3 groups of factors:

- 1) Host factors
 - Atopy (IgE mediated)
 - Eczema
 - Allergic asthma
 - Allergic rhinitis
 - Aspirin-sensitive (or, more accurately, aspirin-exacerbated) asthma
- 2) Environmental factors
 - Airborne allergens and viral respiratory infections
 - Other environmental agents
 - Occupational causes (e.g., isocyanates)
- 3) Comorbid conditions

Host Factors

Genetic susceptibility is especially associated with the development of asthma, although the role of genes is complex and not well defined at this point. Some asthma cases are IgE mediated. **Atopic** (allergic) eczema dermatitis is the strongest identifiable predisposing factor for developing **IgE-mediated** asthma. Atopy is a predisposition toward developing certain allergic hypersensitivities. Many doctors use the term atopy for any IgE-mediated reaction. A person with atopy usually presents with ≥ 1 of the following:

- 1) Eczema (atopic dermatitis)
- 2) Allergic asthma
- 3) Allergic rhinitis (e.g., hay fever)

The term hay fever is a misnomer. Hay is not the usual cause of this problem, and it does not cause fever. The early description of sneezing, nasal congestion, and eye irritation while harvesting field hay promoted this popular term.

Allergic rhinitis and asthma are both systemic inflammatory conditions that affect the upper and lower airways and may reflect a spectrum of the same disease. Up to 80% of patients with asthma have rhinitis. The treatment of allergic rhinitis with intranasal glucocorticoids improves asthma symptoms and decreases emergency department visits and hospitalizations.

Patients with aspirin-exacerbated asthma often have the **asthma triad** (a.k.a. **Samter triad**): acetylsalicylic acid (ASA) sensitivity, asthma, and nasal polyposis. Patients are generally young- to middle-aged adults. Symptoms start with rhinitis or congestion and then progress to asthma,

polyposis, and ASA sensitivity. The asthma is typically ongoing and markedly worsened by aspirin or NSAIDs. The ASA sensitivity can be extreme and cause anaphylaxis. Patients with ASA-exacerbated asthma may also be sensitive to other NSAIDs and tartrazine dyes but **not** to **Na⁺** and **choline** salicylates.

Environmental Factors

The development of asthma is also associated with the exposure to certain **environmental agents** at critical points in immune development. **Triggers** are environmental factors that cause asthma, but they can also exacerbate symptoms in a person with asthma.

Triggers can be broadly categorized into 6 areas: allergens, irritants, chemicals, respiratory infections, physical stress, and emotional stress. Airborne **allergens** and respiratory viral **infections** play important roles in the **development** of asthma in susceptible individuals and have been studied the most.

Examples of environmental agents that contribute to the development of asthma are pollution, tobacco smoke, and airborne agents prevalent in certain occupations (causing “occupational” asthma). Occupational causes are limited to the workplace and are usually due to a **single** substance that is not found outside of the workplace. These factors include isocyanates found in paints, varnishes, and insulation material and are used in auto body repair shops. Isocyanates are primarily potent sensitizers, eliciting an inflammatory response, but they are also irritants to the mucous membranes of the eyes, the gastrointestinal tract, skin, and the respiratory tract.

Occupational asthma can be IgE dependent, which causes an early or biphasic reaction. It can also be IgE independent, which causes a late reaction. Both a history of smoking and atopy are important sensitizing factors for occupational asthma.

Asthma can be exacerbated by occupational exposures also. Common workplace respirable substances that worsen regular asthma: cotton dust, formaldehyde, volatile organic compounds, toluene diisocyanate, fluorocarbons, grain dust, wood dust (especially western cedar), and nitrogen oxide from unvented gas stoves.

Comorbid Conditions

Asthma is known to be exacerbated by certain comorbid conditions including, but not limited to:

- Allergic bronchopulmonary aspergillosis (ABPA)
- Obstructive sleep apnea-hypopnea syndrome (OSAHS)
- Stress
- Smoking and inhalation of tobacco, cocaine, or heroin
- Allergic rhinitis
- Gastroesophageal reflux disease (GERD)
- Obesity

Changes in the Lung with Asthma

The airway inflammation associated with asthma, whatever the etiology, causes a nonspecific airway hyperresponsiveness, leading to airway edema and bronchoconstriction. Persistent airway inflammation leads to remodeling of the airways with fibrosis and muscular hypertrophy, resulting in a continuous nonresponsive airflow obstruction as a component of the clinical picture.

Acute Exacerbation of Asthma

Early in an asthmatic attack, bronchospasm is the major factor. Later on, increased airway inflammation, airway edema, and airway secretions with possible mucous plugging dominate, especially in patients with status asthmaticus.

Asthmatics usually experience episodes of some combination of dyspnea, cough, chest tightness, and wheezing. However, on the initial presentation, the patient may complain only of a chronic cough. (Remember: Patients with GERD who do not have asthma can also present with cough that typically occurs when supine.)

Diagnosis of Asthma

The diagnosis of asthma is a clinical amalgam of history, symptoms, physical findings, and spirometric findings. The patient generally has evidence on spirometry of variable airflow limitation over time and/or airway obstruction reversibility postbronchodilator, as well as a compatible history and characteristic symptoms of wheezing, cough, shortness of breath, and/or chest tightness. In some cases, the spirometry does not capture bronchospasm at the time of testing. However, a compelling history and symptom improvement with inhaled bronchodilators or corticosteroids strongly suggest the diagnosis. Consider performing a challenge test to induce bronchospasm if these features are not demonstrated.

Measure the FEV₁, FVC, and FEV₁/FVC—before and after use of a bronchodilator—in all patients. Again, response to a short-acting bronchodilator is defined as an increase in the FEV₁ or FVC of $\geq 12\%$ and an increase of at least 200 mL.

Obtaining a fractional exhaled nitric oxide (FeNO) concentration helps in the diagnosis of eosinophilic-induced asthma with levels > 50 ppb in individuals who do not smoke to be considered inflamed. At present, optimal frequency of FeNO monitoring is not known.

Bronchoprovocation tests are done in a patient who has normal spirometry and ≥ 1 of the following characteristic symptoms of asthma:

- Chronic cough
- Intermittent symptoms of cough, wheeze, and/or chest tightness
- Exertional dyspnea without other cause

Methacholine, histamine, and thermal (cold air) challenges can be used to confirm the diagnosis of asthma. These work on the principle of nonspecific hyperirritability. For the diagnosis of asthma (which requires reversible bronchoconstriction), the patient's airways must both tighten up with the challenge and relax with the administration of a bronchodilator.

Exercise-induced bronchospasm (EIB) occurs after exercise after several minutes and causes chest tightness, dyspnea, or wheezing. It may be confirmed by a decrease in the FEV₁ of $\geq 10\%$ after graded exercise on a treadmill or a stationary bicycle. The shape of the flow-volume loop can be used to rule out other etiologies, such as extrathoracic obstruction. Patients who have EIB exclusively elicited by cold air can have false-negative exercise tests. Bronchoprovocation using methacholine, cold air, or eucapnic voluntary hyperventilation can be used to confirm a diagnosis of cold air-induced EIB. It is also useful in patients who might otherwise have a false-negative exercise test. The DLCO is normal.

The initial evaluation of an untreated patient determines the severity and, consequently, the treatment of the asthma. After the initial therapy is started, the focus is on asthma control and response to treatment, rather than the asthma's severity.

The 2020 Global Initiative for Asthma (GINA) guidelines stress assessment of control of asthma symptoms. 4 questions are asked to assess control over the 4 weeks preceding the clinical encounter. Patients are queried regarding:

- the presence of daytime symptoms more than 2 $\times$ /week,
- any nighttime awakening due to asthma,
- use of SABA reliever more than 2 $\times$ /week, and
- any activity limitation due to asthma.

The well-controlled asthmatic has none of these, while the partly controlled asthmatic has 1 to 2 of these and the patient with uncontrolled asthma has 3 to 4 of these.

Patients with asthma should also be assessed for risk factors for poor asthma outcomes, such as acute exacerbations, fixed airway obstructions, and medication side effects. The risk factors for these adverse outcomes are the presence of comorbidities such as obesity, GERD, chronic sinusitis, depression, anxiety, and food allergy; pregnancy; reduced FEV₁, especially if $< 60\%$; high SABA use; lack of ICS in the regimen; inhaled triggers (e.g., allergens, pollution, tobacco smoke); and adverse socioeconomic factors that interfere with asthma treatment and control.

Treatment recommendations follow a step system: Step up care if symptoms are not controlled; when controlled, attempt to decrease to a lower step. For Step 1 symptoms (mild intermittent) initiate therapy with ICA-LABA on an as-needed basis for symptoms occurring less than twice a month. Hint: Never prescribe an asthmatic a LABA or SABA without an ICS. The use of SABA without ICS has been associated with frequent exacerbations. If control is

not optimal, the asthma symptoms are then considered persistent, and treatment progresses to Step 2 (mild persistent) with the use of daily ICS with SABA or leukotriene inhibitor. If patients are not controlled with symptoms most days, they are treated with Step 3 (moderate persistent) medications: low-dose ICS-LABA or medium-dose ICS or ICS-leukotriene receptor antagonist. If control is still not sufficient, asthma is considered severe and requires Step 4 or 5 treatment modalities. Step 4 treatment consists of medium- or high-dose ICS-LABA, with or without added tiotropium or leukotriene inhibitor. Step 5 consists of medications with high-dose ICS-LABA and based on phenotype such as anti-IgE, anti-IL-5, anti-IL-4, and/or low-dose oral corticosteroids. Phenotypic medications are continued during pregnancy if risk of cessation results in worsening respiratory status (the FDA has not assigned pregnancy category with the caveat that the provider discuss potential unknown risks of therapy).

Asthma severity is retrospectively determined by what medication is needed to control the patient's symptoms. If patient exacerbates or presents in an elevated stage, once symptoms are under control, may be able to deescalate treatment to a lower stage of treatment. corticosteroids. See the **Severity** column under **Initial Evaluation** in [Table 6-5](#) and see [Table 6-6](#).

Treatment of Asthma

At patient visits, utilize the asthma control cycle: assess, adjust treatment, and review the response to treatment. The patient also needs to have a written action plan should symptoms worsen (i.e., when to use an oral corticosteroid (OCS), when to go to the emergency department).

The assessment should focus on:

- Diagnosis (ascertain if symptoms and signs are related to asthma and assess their severity)
- Symptom control and risk factors for poor outcomes
- Inhaler technique and adherence
- Patient preference

During the assessment, determine if the patient has characteristic asthma symptoms and/or needs to use the rescue (a.k.a. reliever) inhaler > 2×/week, has > 1 episode of nocturnal awakening due to asthma, or experiences any activity limitation. The well-controlled asthmatic has none of these findings, the partly controlled asthmatic has 1 or 2 of these, and the poorly controlled asthmatic has 3 or 4 of these findings.

Identify risk factors for poor outcomes, which include exacerbations: prior intubations for asthma, uncontrolled asthma symptoms, prior exacerbation in the last 12 months, low FEV₁, poor inhaler technique and/or adherence, smoking, obesity, pregnancy, blood eosinophilia, and delayed or insufficient ICS use. Fixed airflow is associated with lack of ICS use, smoking, occupational triggers, and eosinophilia.

Based on the level of control and/or the presence of risk factors for poor outcomes, adjust treatment (pharmacological and nonpharmacological) using stepwise management and ensure proper inhaler technique and adherence. In general, the guidelines for pregnant patients with asthma are the same; however, these patients need to be monitored closely because uncontrolled asthma increases the risk of preeclampsia, low birth weight, and preterm labor. The risk of poorly controlled asthma outweighs the risks of asthma

Table 6-5: Initial Tx and Maintenance Tx of Asthma for Patients ≥ 12 Years of Age

Clinical Features (with initial evaluation) and Control (while on treatment)					Initial Evaluation: Treatment Is Based on Clinical Features		Continuing Therapy: Treatment Is Based on Control	
Days with Sx	SABA Use (Control Only)	Nighttime Awakenings	FEV ₁ or PEF *	Impairment of Activity	Severity	Treat per Step Level	CONTROL Level	Changing Tx Based on CONTROL Level
≤ 2 days/ month	≤ 2 days/week	0	Usually ≥ 80%	None	Mild	Step 1	Well controlled	Maintain the current step
> 2 days/ month but not daily	> 2 days/week but not daily and not > 1× on any given day	3–4×/ month	≥ 80%	Minor limitation	Mild	Step 2	Well controlled	Maintain the current step
Daily	Daily	> 1×/week but not nightly	> 60%, < 80%	Some limitation	Moderate	Step 3 and 4	Not well controlled	Step up 1 step; reevaluate in 2–4 weeks
Throughout every day	Several times per day	Often 7×/ week	≤ 60%	Frequently limited	Severe	Step 5	Very poorly controlled	Add short course of OCS; step up 1–2 steps; reevaluate within 1 week

*Use only FEV₁ for the initial evaluation. Use either the FEV₁ or PEF for determining control and continuing therapy.

FEV₁ = forced expiratory volume in 1 second
OCS = oral corticosteroid

PEF = peak expiratory flow rate
SABA = short-acting β-agonist

Table 6-6: Treatment Steps Used in Asthma

Step	Preferred	Alternative
1	ICS-LABA prn	ICS with SABA prn
2	Low-dose ICS daily or ICS-LABA prn	LTRA, ICS with SABA prn
3	Low-dose ICS-LABA	Medium ICS or low-dose ICS + LTRA
4	Medium-dose ICS-LABA	High-dose ICS, add on LTRA or add on long-acting muscarinics
5	Refer for phenotypic add-on therapy with anti-IgE, anti-IL-5, anti-IL-4	Add low-dose OCSs, long-acting muscarinics

ICS = inhaled corticosteroid, LABA = long-acting β_2 -agonist, LTRA = leukotriene-receptor antagonist, OCS = oral corticosteroid, SABA = short-acting β_2 -agonist

medications during pregnancy. Asthma exacerbations usually start in the 2nd or 3rd trimester, and the rule of thirds applies during pregnancy: 1/3 get better, 1/3 get worse, and 1/3 stay the same. The asthmatic pattern established in the 1st pregnancy usually applies to subsequent pregnancies. For more on asthma during pregnancy, see the [Women's and Men's Health](#) section.

In the initial assessment, determine whether the patient should be prescribed an ICS with or without additional pharmacologic agents. If the patient has asthma symptoms > 2 $\times$ /week, experiences nocturnal awakening due to asthma > 1 $\times$ /month, or has asthma symptoms with risk factors for poor outcomes, prescribe an ICS, possibly with another agent, such as a long-acting β_2 -agonists (LABA) or SABA, depending on frequency and severity of symptoms.

Patients with persistent asthma symptoms should have their environment assessed for unidentified irritants and allergens. This includes looking for seasonal variation of symptoms, home and workplace evaluation, and skin testing.

The most effective intervention for most asthma is stopping the exposure to any **environmental agents** that are known to act as triggers for the patient. Advise patients who smoke or inhale asthma-exacerbating drugs to give up those habits. The goal is to remove the trigger entirely, but when unable, the patient should minimize the exposure. Inhaling a bronchodilator before the exposure—a common way to handle unavoidable triggers, such as visiting a house with a pet—is also helpful.

The GINA guidelines recommend **treatment of symptomatic gastroesophageal reflux disease (GERD)**, which is commonly done. Treating allergic rhinitis with nasal corticosteroids is associated with improved asthma status only in those not on an ICS.

Treat GERD with the following:

- Avoid consuming foods that lessen the lower esophageal sphincter tone (e.g., alcohol, caffeine, nicotine, peppermint).
- Avoid eating within 3 hours before bed.
- Elevate the head of the bed.
- Treat with proton pump inhibitors (PPIs).

Asthma symptoms improve with weight loss, especially after bariatric surgery.

Address comorbid ABPA, OSAHS, and stress.

Monitor the peak expiratory flow (PEF; a.k.a. peak expiratory flow rate [PEFR]) in patients with **moderate-to-severe** asthma and in patients who cannot reliably describe symptoms of an exacerbation. Note that **symptom-based** monitoring is as effective as PEF in **all other** groups.

Prescribe pharmacologic treatment when needed. These medications are categorized into quick relief and long-term control categories.

Quick relief (rescue therapy for acute exacerbations):

- Short-acting β_2 -agonists (SABAs)
- Systemic corticosteroids
- Anticholinergics

Long-term control:

- ICSs, which are the most potent and most effective
- LABA with ICS
- Long-acting muscarinic antagonists (i.e., tiotropium)
- Leukotriene modifiers (i.e., montelukast)
- Immunomodulators (e.g., omalizumab, mepolizumab, reslizumab)
- Methylxanthines (e.g., theophylline)

The following text is a review of these drugs followed by the recommended treatment regimens. Also refer to [Table 6-5](#) and see [Table 6-6](#) and [Table 6-7](#).

Table 6-7: Classification of Asthma Severity in Well-Controlled Patients

Step	Classification of Asthma Severity		
	Mild	Moderate	Severe
Step	1-2	3	4-5

Short-Acting β_2 -Agonists (SABAs)

The 1st choice for the rescue treatment of an acute exacerbation is the inhaled short-acting β_2 -agonist albuterol, even if the patient routinely uses it.

For chronic asthma treatment, albuterol is indicated for patients in the U.S. who have intermittent symptoms, though, as previously discussed under [Diagnosis of Asthma on page 6-13](#), the 2020 GINA guidelines recommend an ICS with albuterol or, alternatively, the use of budesonide/formoterol. Know that SABA use > 2 days/week indicates **poor control** of symptoms and treatment should be stepped up to include a controller, usually an inhaled steroid.

Inhaled Corticosteroids (ICSs)

An ICS is the preferred drug for the chronic treatment of persistent asthma when the symptoms are not controlled with a SABA. Some may require addition of a LABA. Why is this? Asthma is an inflammatory process and ICSs subdue the inflammation where it occurs—with minimal side effects. β_2 -agonists are merely bronchodilators and provide only symptomatic treatment.

The bid dosing of ICS is as effective as qid treatments in patients with mild-to-moderate asthma. The dose-response curve for ICS is flattened in the mildly affected patient group—more is not better, and low doses are best. However, in patients with severe asthma, the dose-response curve is not flattened, and this group benefits from increasing the ICS dose early in treatment.

A spacer greatly reduces the amount of metered dose inhaler (MDI) drug deposited in the oropharynx. Large particles are trapped in the spacer, thereby decreasing the systemic effects from swallowed drug. A spacer also increases the amount of drug reaching the lungs.

ICS and safety:

- There is little, if any, effect on the pituitary-adrenal axis.
- There is no increase in fractures.
- Long-term use of high doses over years can contribute to reduced bone mineral density.
- Cataracts and glaucoma are less of a problem with inhaled than with oral corticosteroids.
- Budesonide is the preferred ICS in pregnancy because it has been the most studied. However, if the mom is stable on another ICS, then she should continue that agent.
- ICS can cause easy bruising in elderly patients.
- ICS can cause initial slowing of growth in children, but there is a catch-up period that results in normal height.
- Higher doses can cause oral thrush and dysphonia and have been implicated in recurrent pulmonary infections.

Systemic Corticosteroids

An oral corticosteroid (OCS) is an effective, short-term treatment for acute asthma. It potentiates the effect of β_2 -agonists and has an antiinflammatory effect that decreases the frequency of return visits to the emergency department.

An OCS is indicated in the acute treatment of asthma when the peak flow is < 80% after 3 treatments of rescue SABA.

OCSs have near complete bioavailability and an onset of action within 1 hour. They can be used instead of IV or IM steroids if the patient is not vomiting.

Use IV steroids, at least initially, in respiratory failure.

Due to its side effects, the chronic administration of an OCS for asthma should be prescribed by highly trained asthma specialists and only under strict circumstances. The asthma algorithm does not include chronic OCS therapy until Step 5 (refer to [Table 6-6 on page 6-15](#))—after the institution of all other therapeutic options.

Anticholinergics

Anticholinergics cause a decrease in cyclic guanosine monophosphate (cGMP) that relaxes the contractions of the bronchial smooth muscle. Ipratropium bromide is a short-acting anticholinergic, and tiotropium is an example of a long-acting one. Ipratropium bromide is usually used in acute severe asthma treatment, while long-acting anticholinergics are used in the chronic management of asthma (especially when LABAs are contraindicated or ineffective).

For acute asthma, the use of ipratropium bromide with albuterol for treatment of severe exacerbations in the emergency department or intensive care unit (ICU) can reduce hospitalizations. This combination is also recommended in the 2020 GINA guidelines for use in acute exacerbations of asthma when admitted.

In 2015, the long-acting anticholinergic (a.k.a. long-acting muscarinic antagonist [LAMA]) tiotropium was approved by the FDA for the treatment of chronic asthma. It is typically added to a regimen that already includes the use of an ICS, a LABA, and prn SABA.

Oxygen

Oxygen is given during an asthma exacerbation with a goal of keeping a P_aO_2 of ≥ 60 mmHg or an $S_aO_2 \geq 90\%$.

Long-Acting β -Agonists (LABAs)

Like SABAs, LABAs (e.g., salmeterol, formoterol) induce an increase in cyclic adenosine monophosphate (cAMP), which results in the relaxation of bronchial smooth muscles. Unlike SABAs, however, LABAs cause a sustained effect. Still, LABAs do not address the inflammatory component of asthma, and as such, they are used only with ICS per treatment guidelines.

LABAs are indicated for the treatment of moderate-to-severe asthma with ICS and a SABA. LABAs alone are not recommended for asthma or acute rescue treatment. As noted previously (refer to [Diagnosis of Asthma on page 6-13](#)), GINA guidelines have recommended use of ICS-LABA starting with Step 1.

LABAs should **never** be used as monotherapy in asthma but should always be added to the current use of an ICS! LABA monotherapy correlates with more frequent exacerbations.

LABAs are recommended only in combination with ICS in an asthma regimen either as initial therapy or for patients who are uncontrolled on a SABA and an ICS.

LABAs with low-dose ICS is recommended by the GINA guidelines for EIB.

Leukotriene Modifiers

Leukotrienes are chemical mediators released from mast cells, basophils, and eosinophils. They are potent:

- Smooth muscle contractors
- Promoters of mucus production
- Causes of airway edema
- Vasoconstrictors
- Stimulators of more arachidonic acid release

Montelukast (Singulair) and **zafirlukast** (Accolate) are leukotriene-receptor antagonists (LTRAs), and **zileuton** (Zyflo) is a 5-lipoxygenase pathway inhibitor.

Leukotriene modifiers are less potent than ICSs and are not as effective as LABAs. They are more often used in children and are **not** the preferred treatment in adults.

Leukotriene modifiers also have some utility in the treatment of EIB, but they are effective in only ~ 50% of patients. Patients with an aspirin allergy are more likely to benefit.

Rarely, a patient treated with a leukotriene modifier has been diagnosed with eosinophilic granulomatosis with polyangiitis (EGPA). The agent does not cause EGPA. However, preexisting vasculitis may be unmasked when patients are weaned off corticosteroids and started on a leukotriene modifier. This is a vasculitis discussed in greater detail under **Eosinophilic Granulomatosis with Polyangiitis** on page 6-38.

Theophylline

Theophylline, a methylxanthine, is a less effective bronchodilator than the β_2 -agonists. Some mechanisms of action include bronchodilation and mild antiinflammatory activity brought about through the inhibition of phosphodiesterase. Unfortunately, theophylline has a narrow therapeutic index and an increased risk for toxicity.

Theophylline is **not** recommended for the **acute** treatment of any asthma exacerbation (including in-hospital management) because the benefit does not exceed the risks of toxicity and drug interactions.

For chronic treatment, theophylline is indicated as an adjunct or add-on to a regimen for difficult-to-control asthma. Know that theophylline with an ICS is inferior in efficacy to the combination of a LABA and an ICS. Other

add-on treatments should be used before theophylline such as leukotriene inhibitors, LABAs, and potentially biologic agents, such as omalizumab or dupilumab, if appropriate.

Ideally, give theophylline as a sustained-release preparation and maintain the serum concentration in the therapeutic range of 5–15 mcg/mL (27.75–83.25 μ mol/L). Adverse effects can occur even within the therapeutic range. Definitely know the symptoms of theophylline toxicity and drug interactions. Toxicity symptoms include nausea and vomiting (the first symptoms), headache, tremulousness, and palpitations. Toxic patients may die or suffer morbidity from seizures, hypotension, and cardiac arrhythmias.

The list of drug interactions with theophylline is long but important. Exam-relevant interactions to remember are listed in Table 6-8.

Table 6-8: Drug Interactions with Theophylline

Interaction	Agents
Increase theophylline levels (causing toxicity)	Ciprofloxacin, clarithromycin, zileuton, allopurinol, methotrexate, estrogens, propranolol, verapamil, cimetidine
Decrease theophylline levels (possibly exacerbating asthma)	Various antiseizure medications, rifampin, St. John's wort, and smoking (more of an issue when patients stop smoking and theophylline levels subsequently increase on the same dose)
Decrease levels of coadministered drugs	Phenytoin, lithium

See the **General Internal Medicine** section for an in-depth discussion on theophylline toxicity, including treatment.

Long-Term Control — Immunomodulators

Omalizumab (an anti-IgE agent) is a monoclonal antibody that blocks the IgE receptors on mast cells and basophils. It is indicated in patients who have allergies and severe, uncontrolled persistent asthma currently on high doses of an ICS and a LABA (Steps 5 on the asthma treatment algorithm; refer to Table 6-6 on page 6-15).

Monoclonal antibodies for eosinophilic asthma approved by the FDA: **mepolizumab**, **benralizumab**, and **reslizumab**, which are monoclonal antibodies that bind to and inactivate interleukin-5 (IL-5). **Dupilumab** is an anti-IL-4 receptor antagonist to treat asthma with or without eosinophilia, though it has greater effect with the former.

Long-Term Control — Bronchial Thermoplasty

Bronchial thermoplasty is a bronchoscopic procedure that delivers radiofrequency energy to the airway wall, thereby reducing airway smooth muscle. Purported benefits include improved asthma-related quality of life and reduced emergency department visits and hospitalizations. Long-term effects on lung function are not known.

This technique is not used for acute treatment. This is not commonly done but may be available in some centers for selected patients with severe or persistent asthma not controlled by a robust regimen of inhaled steroids, bronchodilators, and additional medications.

Management of Asthma

Notes on the Guidelines

As discussed under [Diagnosis of Asthma on page 6-13](#), the 2020 GINA recommendations classify asthma by control rather than severity. For chronic asthma management, think about asthma as 2 separate types of clinical encounters: **treatment initiation** and **continuing therapy** (rather intuitive). Refer to [Table 6-5 on page 6-14](#) during this discussion.

Treatment initiation occurs when a patient initially presents with the signs/symptoms of asthma and is not on chronic management. Assess disease severity based on a number of factors (including the FEV₁, but not the peak flow!), then prescribe a step level of treatment.

If your patient's risks include > 1 category, then classify according to the most severe category. Use the purple part of [Table 6-5 on page 6-14](#) to classify the patient, and find the patient's initial severity level by reading the green section of the table in the Severity column. The initial medications you start are based on the initial severity classification and are designated as Steps 1-5.

Continuing Therapy

After instituting the proper initial step level of treatment, reevaluate the patient again in 1 to 2 months to assess the level of **control** using the same set of factors (now you can use either FEV₁ or PEF).

At the initial follow-up visit and all future visits, determine the **control level** of asthma using the purple part of the table and reading the green section in the Control column to determine whether the asthma is well controlled, not well controlled, or very poorly controlled. Based on the level of control, modify the step level of treatment if needed (per [Table 6-6 on page 6-15](#)).

The 2020 GINA guidelines recommend the approach described in [Treatment of Asthma on page 6-14](#).

Once the patient is well controlled for 3 months, look at the regimen required to maintain control and assign the patient a category of severity that corresponds with that step level of treatment (refer to [Table 6-7 on page 6-15](#)). Note that it is only at this point, when the patient is well controlled, that you can define how severe the disease is because the severity of asthma is based on the steps needed to control it. The control aspect of care is dynamic. Every 3 months, step up if the patient is not controlled or step down if controlled. The goal is to maintain control on the fewest medications.

So, the initial assessment is based on the **severity** of the presenting symptoms. Determination of continuing therapy is

based on the **control** of symptoms with treatment. Lastly, the determination of the **severity of disease** is based on how much medication is required to maintain good control. Be careful that you do not confuse these 2 uses of **severity**.

The Treatment Steps

Again, refer to [Table 6-6 on page 6-15](#) for this discussion.

The stepwise approach to treatment relies on the assessments previously discussed (refer to [Continuing Therapy](#)). Patients who have asthma symptoms more than twice a month, who have nocturnal awakening due to asthma no more than once a month, and who do not have risk factors for poor outcomes are generally candidates for Step 1 therapy, ICS for mild intermittent asthma. If they exceed these symptom thresholds, they are considered persistent and treatment escalates to Step 2 therapy, ICS with LABA. An alternative is a leukotriene inhibitor or the next step up. Higher-dose ICSs can be used with more-difficult-to-control asthma, and subsequent add-on therapy includes leukotriene inhibitors, and tiotropium. For severe persistent asthma phenotypes, Step 5 treatment can include oral corticosteroids, anti-IgE (e.g., omalizumab) or anti-IL-5 therapy (e.g., mepolizumab, reslizumab) or anti-IL-4 therapy (i.e., dupilumab). Alternative agents at each step include medications from the next step up or an add-on agent.

The continuous use of oral prednisone is only recommended once other therapies have been exhausted and should be done with expert consultation. Give chronic OCS **only** for severe asthma (or for an acute asthma exacerbation) and, even then, **repeat** attempts to wean. Steroid-sparing drugs have been tried, including methotrexate, cyclosporine, and troleandomycin, but these are not recommended for acute or long-term treatment of asthma.

When an exacerbation occurs, chronic management can be stepped up 1 or 2 levels, then slowly stepped down until symptoms recur, and then stepped up 1 level. When treatment is initially started, it is usually started 1 or 2 levels above the presumed severity level and then gradually stepped down in the same way.

Use LABAs only in combination with an ICS for asthma. ICS is the cornerstone of asthma therapy.

Treat **acute exacerbations** at any level the **same way**: inhaled **SABAs** and oxygen as needed. Add an OCS if the patient's peak flow is < 80% after 3 treatments with an inhaled SABA or if inhaled therapy is unlikely to effectively treat the acute exacerbation due to its severity. Patients should have written action plans to address worsened symptoms and acute exacerbations.

Studies show that guideline-based treatment of asthma is superior to other methods.

Management of Exercise-Induced Bronchospasm (EIB)

Treat EIB with low dose ICS-SABA.

Management of Acute Exacerbations

Algorithms for managing acute asthma exist in the guidelines; the one you use depends upon whether you are treating patients at home, at the clinic, or in the emergency department.

Assess the **severity** based on clinical history, pulse, respiratory rate, PEF (initial contact can be by phone to initiate triage), and physical exam if able.

The 2020 GINA guidelines define mild-to-moderate exacerbations as those patients with the ability to talk in phrases, respiratory rate elevated but < 30 breaths/minute, no accessory muscle use, HR 100–120 bpm, O_2 saturation 90–95%, and PEF $> 50\%$ of predicted. These guidelines recommend that mild-to-moderate asthma exacerbations should be treated in primary care with SABA, supplementary O_2 , and oral corticosteroids. If there is significant objective improvement with initial treatment, the patient can be considered for discharge with a 5–7-day steroid taper and stepped-up controller therapy for 1–2 weeks with a follow-up visit within a week. Patients in exacerbation who are on chronic β -blockers may not respond as well to β -agonists, such as albuterol, and should receive ipratropium.

Severe asthma exacerbation is defined in the GINA guidelines as consisting of being able to talk only in words and not phrases, agitation, the inability to sit still, O_2 saturation $< 90\%$, respiratory rate > 30 breaths/minute, HR > 120 bpm, accessory muscle use, and PEF $< 50\%$. Life-threatening exacerbation is defined as patients who may be drowsy or confused or have a silent chest. They should be treated in an acute care facility with SABA, ipratropium bromide, oral or IV corticosteroids, supplemental O_2 , intravenous magnesium, and possibly high-dose ICS.

A patient who has a sustained PEF > 60 – 80% of predicted or personal best 1 hour after the last SABA treatment and who looks good can potentially be discharged home with a prescription for continued outpatient frequent SABA, OCS, and a close follow-up. However, risk factors for exacerbation, including nature and severity of past exacerbations, should be considered, as well as likelihood of being able to assiduously adhere to the stepped-up regimen for treatment of the acute exacerbation. Close follow-up within a week is recommended.

Consider a patient for hospitalization if despite treatment in the emergency department with repeated doses (usually 3) of inhaled bronchodilators the patient continues to maintain a PEF of 40–69% (e.g., severity of airflow obstruction). As well, consider admitting the patient to the hospital if there is a known severity of prior exacerbations (i.e., required intubation), poor support at home, or underlying psychiatric illness.

If there is deterioration in the emergency department with a drop in the PEF to $< 40\%$, or the patient continues to have signs of severe exacerbation, admit the patient to the ICU. Inpatient care consists of a SABA, oxygen prn, and systemic steroids. If the patient was on an ICS prior to the exacerbation, continue the ICS

during hospitalization. Some spontaneously breathing patients who are awake and can guard their airways may benefit from noninvasive ventilation with bilevel positive airway pressure (BiPAP), but they must be closely monitored as they may require intubation.

Intubation and the Asthma Patient

During a severe asthma attack, the patient initially hyperventilates and the pCO_2 is low. As the chest wall and the diaphragm muscles fatigue, the patient starts to breathe more and more slowly, normalizing the pCO_2 , and later becoming hypercapnic. Mild hypoxemia and **hypocapnia** are the norm with acute asthma attacks. **Normocapnia** or **hypercapnia** indicates impending respiratory failure and possible need for **intubation or noninvasive ventilatory support!**

If intubation is required, first sedate, but paralyze **only** if needed. Try to avoid use of neuromuscular-blocking drugs to avoid a prolonged blockade (this makes weaning more difficult). Avoid morphine because it can cause histamine release.

Once intubated, do not ventilate too quickly! These patients require a prolonged expiratory period, and ventilating at too high a rate causes progressive air trapping. This could happen particularly when assist-control/volume control is used, as every inspiratory effort triggers a full ventilator breath. Patients with severe airflow obstruction do not have enough time for a full exhalation, so as a result of the **dynamic hyperinflation** that happens when the next breath is taken above the functional residual capacity (FRC), breath stacking (a.k.a. auto-PEEP) develops. This causes decreased venous return and hypotension or can lead to barotrauma. Both tension pneumothorax and dynamic hyperinflation cause a decrease in venous return $\rightarrow$ decreased filling pressure $\rightarrow$ decreased cardiac output $\rightarrow$ hypotension and poor perfusion of vital organs and, potentially, cardiac arrest. In patients who succumb to a fatal asthma attack, the amount of auto-PEEP they experience predicts mortality. For patients with significant auto-PEEP, it is the high respiratory rate that causes the problem, and the rate must be reduced, often requiring sedation. This may cause some hypoventilation.

Permissive hypercapnia is a technique of controlled hypoventilation with small tidal volumes. It is no longer recommended to try to get the pCO_2 down to 40 mmHg to resolve the acute respiratory acidosis. This effort in just-intubated asthmatics has had bad outcomes (due to auto-PEEP)! Initially, the focus is maintaining an O_2 saturation of 90%. Do not worry about the pCO_2 —a reasonable level is 60–70 mmHg or even 80 mmHg with a serum pH of 7.20–7.25. The initial blood gas may have an even lower pH and higher pCO_2 , but this generally improves with mechanical ventilation on the next blood gas in 30–60 minutes, depending on these blood gas values.

Besides maintaining an adequate O_2 saturation, you must ensure enough time for the inspired air to get out! Listen with your stethoscope and check that the ventilator is not kicking in while the patient is still exhaling. Monitor the expiratory flow waveform on the ventilator to ensure a return to baseline flow prior to the next inspiratory cycle to look for risk for auto-PEEP. Some ventilators measure auto-PEEP during an expiratory hold maneuver.

When putting an asthmatic patient on a ventilator, use a **low respiratory frequency**, a **small tidal volume**, and **high inspiratory flow rate**. Be aware that with AC/VC mode, if the patient is breathing faster than the set respiratory rate, they will get full tidal volumes and can develop air trapping. These settings cause a prolonged expiratory phase and reduce peak inspiratory pressure. The **high flow** on inspiration allows for more time devoted to expiration. A high flow can result in a slightly higher circuit pressure, but this rarely affects our main concerns—the end-inspiratory plateau pressure and the avoidance of auto-PEEP.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

PREVIEW | REVIEW

- What is the specific definition of chronic obstructive pulmonary disorder (COPD)?
- What are the effects of COPD on the alveoli?
- What is the specific definition of chronic bronchitis?
- What is the significance of clubbing in a patient with COPD?
- What is a strong prognostic indicator in COPD?
- A COPD patient with evidence of right heart failure has a resting P_aO_2 of 58 mmHg. How many hours a day should he be on supplemental oxygen?
- What are the benefits of pulmonary rehabilitation?
- Describe the emergent workup of a patient with an apparent COPD exacerbation.

COPD is diagnosed when patients have symptoms of dyspnea, cough, and sputum production **with** evidence of **irreversible** airflow **obstruction** ($FEV_1/FVC < 0.70$ or less than the LLN provided by the PFT lab) without another explanation for disease. This common condition affects 6% of the population and is the 3rd leading cause of death in the U.S.

COPD results from chronic exposure to an inflammatory stimulus (e.g., cigarette smoke, pollution, dust). The lungs respond with inflammatory cell infiltrates and eventually develop structural changes due to the repeated repair attempts. These structural changes are

usually permanent, even after smoking cessation. Chronic exposure causes varying degrees of damage to the large airways, small airways, and lung parenchyma that evolves over time. In later stages, chronic hypoxic vasoconstriction of the small pulmonary arteries causes pulmonary hypertension. If pulmonary hypertension progresses, right heart failure ensues with cor pulmonale.

Although smoking is definitely a cause of COPD, not all cigarette smokers develop COPD. Disease expression is mediated by additional factors, such as genetics and environment. However, the number of pack years smoked contributes to severity.

Pathophysiology

Cigarette smoking damages both large and small airways, as well as the alveoli.

Large airway damage causes the cough and mucus production that are clinically diagnosed as **chronic bronchitis**.

Small airway damage causes **airflow obstruction** with hyperinflation. Airflow obstruction is caused by the narrowing of these small airways in response to smoke. Inflammatory cells are recruited and infiltrate the walls, secreting mucus. Fibrosis ultimately contributes to chronic airflow obstruction and intermittent bronchoconstriction.

Over time, the smallest airways and alveolar spaces increase in size to try to overcome the airway resistance instigated by the narrowing—a phenomenon called **hyperinflation**. As a compensatory maneuver, it works nicely at first and is expressed as a spirometric increase in the RV and even in TLC.

However, as the lungs lose elastic recoil, the stretched-out small airways and the alveolar sacs trap air, rather than forcing it out against the resistance. Clinically, you will see this as the development of a barrel chest and a prolonged expiratory phase, manifested as an increase in TLC.

Alveolar damage also leads to impaired **gas exchange**. Over time, the alveolar sacs become distended and perforated units full of an “inflammatory soup” of macrophages and other immune cells. Pathologically, these changes are described as emphysema. However, not all patients develop emphysema.

Emphysema can occur focally in the bronchioles (centriacinar) or it can occur evenly across the lung (panacinar). Centriacinar emphysema is seen most often in smokers, and it usually affects the upper lungs. Panacinar emphysema is seen most often in α_1 -antitrypsin deficiency, and it typically affects the lower lungs. Advanced COPD from cigarettes usually involves both types.

Small airway and alveolar disease are present in almost all people with COPD, but the damage does not universally correlate with a specific presentation. That is, the damage to these units causes symptoms that vary from person to person.

Diagnosis and Assessment of COPD

Suspect COPD in any patient who presents with dyspnea, chronic cough, and sputum production—whether they smoke or not. Know that, by definition, bronchitis without objective evidence of airway obstruction is **not** COPD.

Recognize that some patients do not complain of shortness of breath. Rather, they progressively restrict their exertion in order to avoid activities that make them short of breath. For example, they might start taking elevators instead of using the staircase, or they might give up riding a bicycle.

Chronic bronchitis is defined as cough with sputum production for at least 3 consecutive months within at least 2 consecutive years. Patients may have a bronchospastic component responsive to bronchodilators.

Physical exam classically shows an obvious prolonged expiratory phase, wheezing, barrel chest, and increased lung sizes to percussion. Late-stage patients or those in exacerbation often sit forward on their elbows in the tripod position in order to harness strength from their accessory muscles. These patients are often cyanotic in the nail beds and lips.

The traditional descriptions of pink puffers and blue bloaters have fallen out of favor because COPD is **always** a mixed pathologic picture of chronic bronchitis and emphysema. Differentiation between the 2 clinical presentations is artificial because the overwhelming majority of patients do not present that way and treatment is the same.

Know: COPD, as an isolated disease process, does not cause clubbing. If you see clubbing in a patient with COPD, look for other lung pathology, such as IPF or lung cancer.

The Global Initiative for Chronic Obstructive Lung Disease (**GOLD**) is a worldwide association that sets the criteria for the diagnosis, severity grading, and management of COPD.

The GOLD criteria categorize COPD into 4 levels of severity based on the reduction of the FEV₁ compared to the predicted value. All 4 groups require spirometric diagnosis of irreversible obstruction as defined by an FEV₁/FVC < 0.70. The COPD levels are:

- GOLD 1 = mild (FEV₁ ≥ 80% of predicted)
- GOLD 2 = moderate (FEV₁ = 50–79%)
- GOLD 3 = severe (FEV₁ = 30–49%)
- GOLD 4 = very severe (FEV₁ < 30%)

The GOLD spirometric diagnostic criteria are controversial because they overdiagnose COPD in the elderly and underdiagnose it in patients < 45 years of age with mild disease. An alternative criterion for COPD, is a FEV₁/FVC below the LLN provided by the PFT lab.

The GOLD guidelines are updated regularly, including in 2020. Recent updates have emphasized that spirometry

alone does not capture COPD's full impact on individual patients. Therefore, it is recommended to assess COPD addressing:

- the GOLD **spirometry** criteria (1–4),
- the assessment of symptoms with the COPD Assessment Test (CAT) or the modified Medical Research Council (mMRC) Dyspnea Scale,
- the risk of **exacerbations** (based on history of previously treated exacerbations), and
- the presence of other **comorbidities**.

In this revised combined assessment, patients are divided into 4 groups based on symptoms using the CAT score and their exacerbation history:

- A = fewer symptoms (CAT < 10 or mMRC 0–1) and low exacerbation history
- B = more symptoms (CAT ≥ 10 or mMRC < 2) and low exacerbation history
- C = fewer symptoms (CAT < 10 or mMRC 0–1) and high exacerbation history
- D = more symptoms (CAT ≥ 10 or mMRC < 2) and high exacerbation history

For example, examining the assessments, a GOLD 4 with low exacerbation history and minimal symptoms would be assessed as GOLD 4A, but a GOLD 4 with high exacerbation history and more symptoms would be GOLD 4D. Together this approach assesses the level of airflow obstruction and ranks the severity of symptoms and frequency of exacerbations (A–D).

The **BODE** index (body mass index, airflow obstruction, dyspnea, and exercise capacity) adds a little to the GOLD severity criteria by considering how outcomes are affected by some extrapulmonary manifestations. Patients get points according to body mass index, FEV₁, dyspnea, and a 6-minute walk test. The result helps to prognosticate 4-year survival and assess response to treatment changes. Higher BODE scores correspond to an increased risk of death.

Again: COPD pathology results in airflow obstruction, hyperinflation, and problems with gas exchange.

Some must-know items and useful clinical pearls:

- Diagnosis is based on FEV₁/FVC < 0.70 by GOLD criteria or alternatively by a FEV₁/FVC less than the LLN.
- BODE index and exercise tests, such as a 6-minute walk test, are strong prognostic indicators in COPD. Low FEV₁ also can correlate with mortality.
- **Pack years** of cigarette smoking is the best predictor of FEV₁. The normal age-related decrease in FEV₁ is ~ 15–30 mL/year. COPD patients can lose 60–120 mL/year of lung function.
- Cessation of smoking is most beneficial to the lungs when accomplished at a **younger** age and before there is any loss of pulmonary function.
- P_aO₂ does not usually fall until late in the disease, when the FEV₁ is < 50% of predicted (or even lower in many patients).

- Chronic **retention** of CO_2 does not generally occur until very late in the disease, usually when the FEV_1 is < 1 liter.
- Cor pulmonale (right ventricular [RV] dysfunction due to chronic lung disease) occurs only after prolonged, marked reductions in the FEV_1 (usually $< 25\%$ of predicted) with severe chronic hypoxemia.
- Hypoxemia in COPD is almost exclusively due to V/Q mismatching. Therefore, COPD exacerbations **are** responsive to low-flow oxygen (2–3 L/minute). If a patient with an apparent COPD exacerbation is not responsive to moderate amounts of oxygen, consider another cause for the decompensation, such as a shunt process.

Let's review the lung mechanics of emphysema. Decreased elastic recoil means increased compliance and an increased TLC. Although there is an increase in TLC, there is an even greater increase in RV from air trapping, so VC (or FVC) is decreased! This air trapping leads to the process of dynamic hyperinflation and can result in a large amount of auto-PEEP (intrinsic PEEP). DLCO is reduced in patients who have a great amount of emphysema. [Figure 6-7](#), [Figure 6-8](#), and [Figure 6-9](#) show classic COPD changes on CT and on chest x-rays.

Treatment of COPD

General Treatment Principles

Management is based on the 2020 GOLD updates:

- Educate each COPD patient; encourage smokers to quit. Effective nicotine replacement therapy comes in many forms (i.e., gum, nasal spray, patch, tablet, lozenge, inhaler). Other pharmaceutical options include varenicline, bupropion, and nortriptyline. Review inhaler technique regularly.
- Use SABAs as needed in all patients.
- Use **long-acting bronchodilators** when SABAs fail to control symptoms. These drugs **reduce exacerbations and hospitalizations**.
- Long-acting anticholinergics (e.g., tiotropium) improve the efficacy of pulmonary rehab if the patient is enrolled and decrease exacerbations and hospitalizations.
- ICSs are no longer routinely recommended. They should be considered in Group D patients with asthma overlap, eosinophilia > 300 cells/ μL , or as trial in some cases. ICSs may cause an increased risk for pneumonia in severe COPD. ICSs are not recommended as long-term monotherapy for COPD.
- Patients already on LABA/LAMA with or without ICS who continue to have frequent exacerbations, may benefit from roflumilast, a phosphodiesterase-4 inhibitor, or azithromycin to reduce acute exacerbations. Roflumilast does not have any direct bronchodilator activity and is primarily directed at patients with predominant bronchitis, not emphysema.

Figure 6-7: CT—bullous emphysema
Source: Vinay Maheshwari, MD

Figure 6-8: Emphysematous COPD
James Heilman, MD

Figure 6-9: Chest x-ray showing emphysema bulla

- Patients with frequent exacerbations may benefit from azithromycin 3x/week, but they may infrequently experience hearing loss and harbor resistant bacteria. There can be a small risk of arrhythmias. A discussion with the patient of the risk/benefits of azithromycin should occur.
- Reserve theophylline for use in those who are on maximum therapy. It adds a slight bronchodilator effect to salmeterol, and this relieves breathlessness and reduces exacerbations. It may also have salutatory effects on the diaphragmatic function and the hypoxic drive to breathe in higher doses, but there is a narrow therapeutic index.
- Do not use leukotriene modifiers unless there is clearly asthma overlap syndrome. These agents are ineffective in pure COPD.
- Give pneumococcal (PCV13 and PPSV23) and influenza vaccines.
- Use oxygen as needed when patients meet the criteria (see below).
- Screen for α_1 -antitrypsin deficiency in all patients < 45 years of age who get COPD and in those who have a lower lobe prominence of bullae. The WHO 1997 guidelines recommend screening all COPD patients once at some point, especially in areas of high prevalence.
- Consider a referral for pulmonary rehabilitation.

Oxygen therapy for patients with COPD: The focus of O₂ therapy in patients with COPD (or in any other patient in respiratory distress, for that matter) is to give them enough O₂ to achieve a 90% O₂ saturation (S_aO₂)—or as close to that as possible. The 2016 Long-Term Oxygen Treatment Trial (LOTT) via the National Institutes of Health (NIH) Centers for Medicare and Medicaid Services (CMS) showed that there was no survival benefit to prescribing supplemental O₂ to those with moderate resting desaturation (S_pO₂ 89–93%). While CMS guidelines for supplemental oxygen prescription have not been revised as a result of this 2016 study, it appears that long-term oxygen therapy to prolong survival among patients with COPD would benefit those who have chronic (> 3 weeks) severe resting P_aO₂ of $\leq$ 55 mmHg or S_pO₂ of < 88% on room air. The LOTT study would also move the threshold for prescribing oxygen for ambulation to $\leq$ 89% or for those hypoxemic individuals whose dyspnea is significantly relieved by oxygen. However, these findings have not been officially incorporated into current U.S. oxygen-prescribing guidelines at this time. Not treating hypoxia causes further end-organ damage, worsens pulmonary vasoconstriction, and leads to the downward spiral to death.

The CMS criteria for starting continuous O₂ are:

- a resting P_aO₂ $\leq$ 55 mmHg or an S_aO₂ $\leq$ 88% or
- a resting P_aO₂ $\leq$ 59 mmHg or an S_aO₂ $\leq$ 89% in a patient with evidence of cor pulmonale.

The criteria of cor pulmonale include:

- Clinical evidence of right heart failure
- P pulmonale on ECG (a > 2.5 mm P-wave height in leads II, III, and aVF)
- Hct > 56% (Cor pulmonale causes chronic hypoxia leading to polycythemia.)

Continuous O₂ use, if needed for resting hypoxemia, increases the life span. Keep these patients on supplemental oxygen 24 hours/day (if not possible, at least 15 hours/day).

Intermittent O₂ use: Some patients have similar findings of hypoxia and desaturation during low-level exercise or sleep. Giving these patients supplemental O₂ during these activities can improve the exercise capacity and the quality of life, but it does not improve survival.

After 2 months of a stable drug regimen, reassess COPD patients placed on oxygen during an exacerbation—oxygen can be discontinued in up to 40% of these patients!

Pulmonary rehabilitation: A pulmonary rehabilitation exercise regimen results in a small but significant improvement in overall strength and endurance and is encouraged for those with high CAT scores and frequent exacerbations. Unfortunately, pulmonary rehabilitation does not improve PFT or ABG parameters. Know: Pulmonary rehabilitation improves symptoms and the quality of life and reduces the number of hospitalizations and days in the hospital. The 2020 GOLD update states that pulmonary rehab improves dyspnea, health status, and exercise tolerance in stable patients. Many of the immediate benefits of pulmonary rehabilitation are lost without subsequent maintenance exercise.

Lung volume reduction surgery (LVRS): LVRS can be useful for emphysematous patients with upper lobe disease and low exercise capacity. Those with diffuse emphysema are not likely to benefit. The 2003 National Emphysema Treatment Trial (NETT) was a large, randomized trial of LVRS for emphysema that showed an improved exercise capacity but no overall mortality benefit in patients with severe emphysema. There was benefit for a subset of study participants with predominantly upper lobe emphysema and low exercise capacity who showed improvement in exercise, quality of life, and mortality. LVRS can be done in such patients who are symptomatic despite the use of optimal bronchodilator therapy and pulmonary rehabilitation. However, those in the most severe group (those with an FEV₁ < 20% or a DLCO < 20%) should not undergo LVRS due to high mortality. Lung volume reduction via endoscopic bronchial valves or lung coils in select cases of hyperinflation refractory to medical therapy may be considered, but evidence of benefit is not as robust.

Know: No medication prevents the decline of FEV₁ in COPD! The only interventions that affect long-term COPD outcomes are smoking cessation, oxygen therapy in hypoxemic patients, and LVRS or lung transplantation in appropriately selected patients.

Treatment of Stable COPD

As discussed previously under [Diagnosis and Assessment of COPD on page 6-21](#), the GOLD COPD assessment classifies patients into Groups A, B, C, and D. Note: In the following treatment guidelines, **bronchodilator** means either an anticholinergic or a β -agonist. Thus, a short-acting bronchodilator can refer to either a short-acting anticholinergic or a SABA. A long-acting bronchodilator can refer to either a long-acting anticholinergic or a LABA.

The following treatments are based on the 2020 GOLD COPD guidelines:

- Group **A** patients: A short- or long-acting bronchodilator is used to improve breathlessness.
- Group **B** patients: A **long-acting bronchodilator** is used, but for patients with persistent breathlessness, long-acting bronchodilators can be combined.
- Group **C** patients: The first choice is a LAMA. Second choice is LAMA + LABA. Third choice is LABA + ICS (if there is asthma-COPD overlap or eosinophilia of at least 300 cells/ μ l, but this may increase risk of pneumonia).
- Group **D** patients: First choice is LAMA + LABA. Second choice is either LABA + LAMA + ICS or LABA + ICS. Adding an ICS is useful in asthma-COPD overlap (see [Asthma-COPD Overlap \(ACO\)](#)) patients or if there is eosinophilia of at least 300 cells/ μ l. If there are frequent exacerbations, azithromycin may be given 3 $\times$ /week (i.e., MWF) or roflumilast may be used if FEV₁ < 50% and chronic bronchitis is present.

Treatment of COPD Exacerbations

An exacerbation is a worsening of respiratory symptoms beyond the normal variation requiring a change in medication. Patients frequently present with worsening shortness of breath, coughing, wheezing, sputum production, and hypoxemia.

The **assessment** of COPD exacerbations depends upon the nature and severity of the symptoms:

- Consider obtaining a **chest x-ray**. This can help diagnose or rule out pneumonia, pulmonary edema, or pneumothorax. Up to 23% of presenting patients show new infiltrates that can change the chosen therapy.
- Consider obtaining an **ECG**. Pay attention to the history for clues suggesting pulmonary embolism, such as S₁Q₃T₃, anterior T-wave inversions, new right bundle branch block (RBBB), or reactive airway disease. Pulmonary emboli are often an unsuspected trigger of COPD exacerbations. Remember that the most common ECG abnormality in a pulmonary embolism is sinus tachycardia.
- Assess the S_aO₂ and draw an **arterial blood gas** if respiratory failure is suspected. Hypoxia not improving on oxygen, elevated pCO₂ above baseline, or acute respiratory acidosis indicate life-threatening respiratory failure.

- Do **not** use spirometry or peak flows to diagnose or to assess the severity of a COPD exacerbation.
- COPD exacerbations contribute to advancement of disease.

For the **treatment** of COPD exacerbations:

- Start treatment with a **SABA** and add an anticholinergic agent if the patient does not quickly improve.
- Give low-flow oxygen (1–2 L/minute) with close observation to keep the saturation > 90%. Note that patients with initial abnormal blood gases are at risk for hypercarbia and subsequent respiratory failure with supplemental O₂ administration.
- Begin **systemic corticosteroids**. These drugs shorten recovery time, reduce the risk of early relapse, and decrease the length of hospital stays. Treatment with 40 mg of oral prednisone for 5 days generally is as good as a 14-day taper for most patients with acute exacerbations. In some instances, additional steroids are required, up to a 14-day course. Patients with severe exacerbations, such as those admitted to the ICU or with a history of requiring a repeated or an extended course of steroids, often require a more individualized approach, including the use of IV steroids.
- Start antibiotics with increased sputum production, dyspnea, and purulent secretions. The recommended 5- to 7-day course of broad-spectrum antibiotics should be guided by local bacterial resistance patterns; consider **amoxicillin/clavulanic acid**, **azithromycin**, or tetracyclines. If the patient has underlying severe GOLD with high CAT and exacerbation scores, cover for *Pseudomonas* or resistant organisms with addition of **respiratory quinolones**.
- Noninvasive positive pressure ventilation (**NiPPV**), generally with BiPAP, is used to treat patients who are awake and spontaneously breathing but have labored breathing or hypercapnia. NiPPV reduces hospital stays, intubations, and mortalities in exacerbations. However, for patients with contraindications to BiPAP or for those rapidly progressing to respiratory failure, endotracheal intubation with mechanical ventilation is recommended. Remember, these patients are at risk for development of dynamic hyperinflation with increase in auto-PEEP, resulting in venous collapse and pneumothorax. Prolonging expiratory time and increasing inspiratory flow rates is protective.
- For patients who experience frequent exacerbations, consider prescribing azithromycin 3 $\times$ /week or roflumilast (if FEV₁ < 50% and chronic bronchitis is present).

Asthma-COPD Overlap (ACO)

ACO is a category (estimated to be 15–32%) defined by GINA 2020 as comprised of patients with both COPD and asthma features. ACO can stem from various underlying

mechanisms. Like COPD, it usually occurs after 40 years of age. The outcomes tend to be worse than in COPD or asthma alone, with more frequent exacerbations, more rapid decline in lung function, decreased quality of life, and higher mortality. Use ICS along with other controller medications. Evidence-based therapy for this category is lacking. However, patients may be treated with both asthma and COPD medications on an individual basis.

α_1 -ANTITRYPSIN DEFICIENCY

PREVIEW | REVIEW

- A 30-year-old smoker presents with COPD and emphysematous bullae in the bases. Which factors make you suspect α_1 -antitrypsin deficiency?
- What is the single environmental agent or exposure that worsens lung disease in all types of α_1 -antitrypsin deficiency?

α_1 -Antitrypsin deficiency causes 1–2% of COPD cases, so it is rather **rare**. Consider it in **young** smokers with bullous emphysematous COPD in the lung bases and in patients with family histories of both liver and lung disease.

The alleles responsible for α_1 -antitrypsin deficiency occur on a locus called *Pi*. The most common allele is *Pi^M*. The *M* means it moves moderately fast on an electrophoretic strip. There are other variants of *Pi*—some move faster (*Pi^F*) and some slower (*Pi^Z*). Null alleles do not code for any α_1 -antitrypsin. Patients homozygous for the slower allele (*Pi^{ZZ}*) or heterozygotes for *Z* and null alleles (both groups are referred to as *Pi^Z*) have severely decreased levels of α_1 -antitrypsin. Levels of α_1 -antitrypsin in heterozygotes (*Pi^{MZ}*) are ~ 60% of normal.

Disease severity is variable. For example, some *Pi^Z* individuals do **not** get COPD, and airflow obstruction among *Pi^{MZ}* individuals is unpredictable. Contrary to previous teachings, some studies show that heterozygote (*Pi^{MZ}*) nonsmokers have more airflow obstruction than patients with normal α_1 -antitrypsin levels (*Pi^{MM}*). One unifying factor in disease progression is cigarette smoking. Smoking **worsens lung disease in both groups**. Genetic factors, other than *Pi* locus alleles, likely account for the variability in disease expression.

Do not forget! Patients with α_1 -antitrypsin deficiency can also develop progressive **liver fibrosis** and **cirrhosis**. Expression of the genetic defect in the liver is variable and, as with the lung disease, *Pi^Z* patients are most affected. With cirrhosis of any cause, there is an increased incidence of hepatocellular carcinoma.

α_1 -Antitrypsin deficiency presents as airflow obstruction in a young person with unusual bullous formation in the lung bases. Chest x-ray often shows hyperinflation and bullae. There may also be elevated serum aminotransferase levels. In severe *Pi^Z* cases, liver disease can progress to cirrhosis in childhood.

Diagnosis of α_1 -Antitrypsin Deficiency

Diagnose α_1 -antitrypsin deficiency by measuring the serum level of α_1 -antitrypsin followed by the genetic testing of the *Pi* locus. Once you know the phenotype and the genotype, you can better counsel the patient and the patient's family members. The 2020 GOLD guidelines suggest a screening serum level in all patients who develop COPD at some point as well as in family members with α_1 -antitrypsin deficiency.

Treatment of α_1 -Antitrypsin Deficiency

α_1 -Antiprotease (pooled human α_1 -antitrypsin) can be given in weekly IV infusions in patients with severe disease. These infusions are expensive!

Selection criteria for IV augmentation:

- *Pi^Z* genotype
- Serum α_1 -antitrypsin level < 11 μ mol/L (equal to 50–80 mg/dL, depending on the assay)
- Abnormal chest CT
- Abnormal spirometry
- Nonsmoking or ex-smoking patient

Some experts advocate treating all individuals who have α_1 -antitrypsin deficiency with low levels of α_1 -antitrypsin to help maintain the current lung function. However, the expense of this intervention is hard to justify in COPD patients with end-stage lung damage.

In addition to the IV infusion, continue to treat patients with bronchodilators, antibiotics, oxygen as needed, and yearly vaccines. Please do not forget the vigorous anti-smoking message!

When the COPD is severe, the only treatment is lung transplantation. Note that IV infusion has no effect on liver disease and the only treatment for cirrhosis is liver transplantation.

BRONCHIECTASIS

PREVIEW | REVIEW

- What is the classic presentation in a patient with bronchiectasis?
- Which organism is particularly contagious in cystic fibrosis (CF)?
- What is the next test to perform in a patient with new diagnosis of CF?
- What are the inhaled treatments for CF?

Bronchiectasis is a persistent, pathologic, permanent dilatation of the bronchi caused by inflammation and destruction of the airway walls. The bronchi fill with mucus and pus and then become fibrotic. The infectious

or inflammatory insult is sometimes primary (e.g., adenoviral infection), or it can be secondary due to an underlying lung disease that prevents adequate clearance of organisms from the respiratory tree (e.g., *Cystic Fibrosis* (CF)).

Consider bronchiectasis in an older or middle-aged individual with a **chronic** productive cough with copious **purulent** sputum, with or without hemoptysis, that either arose insidiously over years or followed a dramatic lung event (e.g., chemical inhalation, severe pneumonia).

Specific causes of bronchiectasis include:

- Severe infections, such as viral pneumonia (from adenovirus or influenza), staphylococcal or gram-negative pneumonia (severe, untreated, or poorly treated), *Bordetella pertussis*, and mycobacteria (especially if there is a focal area of involvement). It is often difficult to tell whether the organisms growing in the patient's lungs initiated the bronchiectasis or are just colonizers. (For example, *Mycobacterium avium* complex is sometimes a colonizer of bronchiectatic lungs, but it can also cause bronchiectasis.)
- Focal lung obstructions (e.g., endobronchial tumors, lymph nodes, foreign bodies)
- Systemic diseases that reduce mucociliary clearance or prevent an adequate immune response (e.g., CF, primary ciliary dyskinesia, HIV/AIDS, immunoglobulin deficiency). These allow the colonization of destructive bacteria.
- Inhalation of a toxin (e.g., chemical fumes); aspiration of gastric contents
- ABPA (a favorite test question)
- α_1 -Antitrypsin deficiency (rare)
- Gastroesophageal reflux (increasingly implicated as a potential cause)
- Collagen vascular diseases, such as rheumatoid arthritis
- Anatomic defects of trachea or bronchi; enlargement of either can decrease mucus clearance (i.e., Mounier-Kuhn syndrome)

Diagnosis

Diagnose bronchiectasis with an HRCT of the chest, although many cases of bronchiectasis may be evident on standard CT of the chest as well (Figure 6-10). A bronchiectatic airway will be wider than the accompanying blood vessel. Chest x-ray findings are usually nonspecific but may show surrounding infiltrates. Sometimes classic "tram tracks" can be seen. Treatment decisions are not only driven by symptoms, marked changes in sputum color, consistency, and volume, but also by Gram stains with bacterial sputum culture and acid-fast bacteria (AFB) smears with cultures. Based on the clinical history and physical exam, consider testing for HIV and rheumatoid arthritis, measuring quantitative immunoglobulins, performing the prick test for ABPA, and ordering a sweat chloride measurement.

Figure 6-10: HRCT—bronchiectasis

Source: Thomas Roy, MD

Treatment

Clearance of respiratory secretions is a mainstay in the management of bronchiectasis. This includes coughing, chest physiotherapy, postural drainage, and eliciting sputum, often with the use of an expectorant such as guaifenesin as well as adequate hydration. An oscillating positive expiratory pressure (PEP) device such as a flutter valve or chest percussion can help mobilize mucus by oscillating the air column within the trachea and bronchi. The evidence base for these interventions is not solid, but they are commonly employed and generally afford some symptom relief.

Bronchiectasis exacerbations are generally treated with a 14-day course of antibiotics (though the evidence base is inconclusive) to reduce the burden of pathogenic organisms in the small airways (or treat ABPA if that is the underlying cause).

Microbiologic data from sputum drives the antibiotic choice. An organism of concern is *Pseudomonas*. However, patients with exacerbations frequently respond to antibiotics that do not treat *Pseudomonas*. In this case, there may be a colonization of *Pseudomonas* and also a proliferation of other organisms causing the exacerbation.

Chronic antibacterial **prophylaxis** for bronchiectasis is usually reserved for those with frequent exacerbations who are not able to take prophylactic macrolides. Inhaled alternating monthly tobramycin is also used in those with frequent exacerbations and *Pseudomonas* in sputum. **Macrolides** can provide antiinflammatory and antibiotic effects. The European Respiratory Society 2017 guidelines on bronchiectasis recommend, based on several studies, treating patients with several exacerbations with extended macrolide preventive therapy, such as MWF azithromycin, in non-CF bronchiectasis. If long-term macrolides

are considered, obtain sputum culture first to assess for atypical mycobacterial or pseudomonal presence; if present, do not use.

Massive hemoptysis or unresolving focal infections require vascular embolization by interventional radiology or even surgical resection for localized bronchiectasis.

Do **not** treat bronchiectasis with aerosolized recombinant DNase (because it can cause harm), except in patients who have underlying CF.

Cystic Fibrosis (CF)

Cystic fibrosis, an autosomal recessive disease, occurs as a result of a mutation in the CF transmembrane conductance regulator (*CFTR*) gene on chromosome 7. This protein normally controls Na^+/Cl^- transport on the epithelial membranes of the lung, GI tract, sweat glands, and the urogenital system. The gene mutation results in decreased Na^+ absorption and Cl^- secretion. Lung mucus is dehydrated, sticky, and low in oxygen. This contributes to bacterial superinfection with particularly virulent and refractory organisms.

Diagnosis

Only 5% of patients with CF initially present in adulthood, and the median survival is 29 years.

Initial diagnosis: Consider adult CF in a patient with a history of recurrent sinusitis, nasal polyps (found in 25%), weight loss, chronic cough productive of thick, purulent sputum, and recurrent febrile respiratory infections requiring antibiotics. Sputum Gram stain often reveals gram-negative rods (GNRs), and cultures often grow *Staphylococcus*, *Haemophilus influenzae*, *Pseudomonas*, or enteric GNRs (e.g., *Proteus*, *E. coli*, *Klebsiella*). Growth of less common organisms such as *Alcaligenes xylosoxidans*, *Burkholderia gladioli*, or *Burkholderia cepacia* raises the suspicion for CF. *Aspergillus* and nontuberculous mycobacteria are also commonly found. CF patients tend to go through a progression of colonization and infection with gram-positive organisms and then gram-negative bacteria, the most concerning of which is *Burkholderia*. This particular organism is highly contagious among CF patients, causes further decline in the lung function, and can lead to death.

Most **male** patients with CF are **infertile**, providing an additional historical clue. Females may not be infertile.

Clubbing and the signs and symptoms of cor pulmonale occur in late-stage disease.

Chest x-ray changes are nonspecific (hyperinflation and bronchial cuffing), but **bronchiectasis**, which can become extensive, is common. Pneumothorax occurs in 10%. Spirometry shows reductions in the FEV_1/FVC ratio and the FEV_1 , some of which are reversible until late in the disease process.

Screen for CF by performing the **sweat chloride** test. Approximately 1–2% of patients with CF have normal

sweat chloride tests, so pursue further testing if the patient has a strong clinical history and a negative sweat chloride test. The nasal potential difference (NPD) test and a **genetic analysis** are confirmatory tests of CF. If CF is confirmed, then proceed to *CFTR* genotyping.

Management

Manage CF with aggressive pulmonary toilet (percussion and exercises preserve lung function), oral pancreatic enzymes, ADEK fat-soluble vitamin supplementation, and culture- and susceptibility-guided antibiotics for exacerbations. Inhaled bronchodilators may help with obstructive lung disease and mucus clearance. Routine use of inhaled steroids is not recommended as benefit has not been shown and it may increase infections.

Two inhaled medications for CF management are recombinant human **DNase** and inhaled **hypertonic saline**. DNase degrades accumulated DNA in the airways and provides for better airflow. Hypertonic saline improves airway clearance.

IV antibiotics are used for more severe pulmonary exacerbations or resistant organisms. All gram-negative organisms get 2 antipseudomonal antibiotics to cover mucoid and nonmucoid strains until you obtain the identification and susceptibilities. In **CF patients**, *Pseudomonas* is often multidrug resistant. The empiric treatment for exacerbations related to *Pseudomonas* is a combination of piperacillin-tazobactam, ceftazidime, imipenem-cilastatin, or meropenem plus an aminoglycoside or a fluoroquinolone. Treatment is adjusted according to drug susceptibility results.

For the **chronic** management of CF, **antibiotic prophylaxis** using drug rotations helps to prevent exacerbations by reducing microbial colonization. Inhaled aminoglycosides, inhaled aztreonam, and oral azithromycin are commonly used. Azithromycin is used as an antiinflammatory medication, and it reduces the adherence of *Pseudomonas* to the pulmonary epithelial cells, thereby preventing its growth within biofilm.

Bilateral lung transplantation is a treatment option in patients with end-stage lung disease secondary to cystic fibrosis, with a 65% 5-year survival rate.

Complications of CF include respiratory failure, pulmonary hypertension with cor pulmonale, pneumothorax, and hemoptysis.

CFTR modulator therapies are designed to correct the function of the defective *CFTR* protein. The correction allows Na^+ and Cl^- to move properly in and out of the cells lining the lungs and other organs. In 2012, the FDA approved ivacaftor (Kalydeco) for patients over age 6, and in 2019 approved use for infants, with a certain mutation of CF. The combination drug lumacaftor/ivacaftor (Orkambi) was approved in 2015 to treat CF in patients ≥ 12 years of age and in 2018 approved for CF patients ≥ 2 years of age. The combination drug tezacaftor/ivacaftor (Symdeko) was approved in 2018 for

homogenous F508 deletions and residual function mutations. Elexacaftor/ivacaftor/tezacaftor (Trikafta) was approved in 2019 for patients ≥ 12 years of age who have at least one *F508del* mutation, the most common CF gene mutation.

INTERSTITIAL LUNG DISEASES (ILDs)

PREVIEW | REVIEW

- Name the common clinical features of all interstitial lung diseases.
- Which disease do you think of when a patient presents with recurrent pneumonia each time she cleans her birdcage?
- Characterize the chest x-ray abnormalities in patients with a history of significant asbestos exposure.
- Smoking and asbestos exposure increase the risk of which types of lung cancer?
- Which type of CT scan assists with the diagnosis of idiopathic pulmonary fibrosis (IPF)? Which findings are seen in early IPF?
- What is the typical presentation of a patient with IPF?
- Lung cancer is associated with what nail finding?
- How do you evaluate patients with IPF?
- Characterize the differences in presentation between IPF and cryptogenic organizing pneumonia.
- Which findings in a pleural effusion can be helpful in distinguishing rheumatoid arthritis as an etiology?
- In which autoimmune diseases is pulmonary hypertension a prevalent clinical presentation (sometimes out of proportion to the amount of pulmonary disease)?
- Which pulmonary function test results are seen with sarcoidosis?
- What are the indications for the treatment of sarcoidosis with corticosteroids?
- What is a potential lung complication of lymphangioleiomyomatosis?
- Which vasculitis is cytoplasmic-antineutrophil cytoplasmic antibody positive (c-ANCA+) and anti-proteinase-3 antibody positive (anti-PR3+)?
- Characterize the typical presentation of a patient with granulomatosis with polyangiitis.
- An asthma patient with worsening symptoms and peripheral eosinophilia makes you think of which diseases?

- Eosinophilic granulomatosis with polyangiitis is associated with which medications?
- Describe the differences in the presentations of Löffler syndrome, acute eosinophilic pneumonia, and chronic eosinophilic pneumonia.
- What is the workup of the uncontrolled asthmatic that you suspect has allergic bronchopulmonary aspergillosis?

OVERVIEW

ILDs are a diverse (> 100!) group of disorders that affect the supporting tissue of the lung, including the structural portions of the alveolar walls, often with diffuse airway and alveolar involvement.

The interstitium is usually a potential space between the capillaries and the alveoli. In ILDs, specifically fibrotic ILDs, primary or secondary collagen deposition in the interstitium creates fibrosis and changes the architecture of the alveoli and surrounding airways.

ILDs have **common** factors in their clinical presentation: dyspnea, diffuse disease on chest x-ray, restrictive PFTs with a decreased DLCO, and an elevated A-a gradient (Figure 6-11 and Figure 6-12 on page 6-30).

ILDs are grouped into those that have a **known** cause and those that are **idiopathic**. Those with a known cause are usually due to **dust** (organic or inorganic) from occupational or environmental exposures. We will discuss the groups of ILDs as follows:

- Occupational and environmental ILDs
- Idiopathic interstitial pneumonias
- ILDs with other causes

DIAGNOSIS OF ILDs

PFTs in ILD patients may show a classic **restrictive** pattern. This means normal airway flow rates but decreased lung volumes. With decreased compliance, there is increased lung stiffness from increased elastic recoil caused by pulmonary fibrosis (this recoil is decreased in emphysema). A chest x-ray with diffuse interstitial infiltrates is often the 1st suggestion of disease, but it correlates poorly with the severity of disease. High-resolution CT (HRCT) is integral to the workup of ILD.

Chest x-ray clues suggesting the cause of ILD:

- Asbestosis: lower lung field predominance of infiltrates (+/- pleural calcifications and plaques)
- Silicosis: hilar eggshell calcifications; nodular lesions
- Sarcoidosis: bilateral symmetrical hilar and paratracheal lymphadenopathy. See the **Dermatology** section for more on sarcoidosis.
- Lymphangioleiomyomatosis (LAM): ILD with a pneumothorax in a premenopausal woman; there can also be chylous effusions and characteristic diffuse, thin walled cysts on CT.

Figure 6-11: PA chest—diffuse interstitial fibrosis
Source: Thomas Roy, MD

Bronchoscopy with transbronchial biopsy is limited by the small tissue specimens acquired. However, this technique (when combined with bronchoalveolar lavage) can be helpful in diagnosing and ruling out infections, lymphangitic spread of carcinoma (though this may not be indicated in some cases), cryptogenic organizing pneumonia (COP), sarcoidosis, and airway centered ILDs like respiratory bronchiolitis-ILD.

Video-assisted thoracoscopic surgical (VATS) biopsy (minimally invasive thoracoscope through the chest wall) and open lung biopsy generally give the best yield for diagnosing interstitial pneumonitis.

Remember that the DLCO is the 1st test to become abnormal in ILD, so follow this parameter in patients receiving potentially lung-toxic drugs (e.g., amiodarone, chemotherapy).

OCCUPATIONAL AND ENVIRONMENTAL ILDs

The 2 categories of occupational and environmental ILDs are:

- 1) Organic dust-induced ILD: hypersensitivity pneumonitis and byssinosis
- 2) Inorganic dust-induced ILDs: asbestosis, silicosis, coal worker's pneumoconiosis, and berylliosis

Organic Dusts that Cause ILD

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis is an **immune-mediated** granulomatous reaction to organic antigens. Not many people get it—just those who are susceptible to it. Poorly formed granulomas are typical. (The granulomas in sarcoidosis are more dense and better organized.)

Hypersensitivity pneumonitis has a wide range of causes. An occupational history can be highly revealing; for example:

- Moldy hay—farmer's lung (thermophilic actinomycetes)
- Pet birds—bird fancier's or bird-breeder's lung (feathers and bird droppings)
- Grain dust—miller's lung (grain elevators)
- Isocyanates—chemical worker's lung (paints, resins, and polyurethane foam)
- Air conditioning systems (organic dusts, fungi, and molds)

Hypersensitivity pneumonitis has acute, subacute, and chronic forms. Usually, the onset is insidious. Consider this diagnosis in a patient with recurrent or persistent pneumonias who gives you a history of exposure to 1 of the above. Symptoms tend to wax and wane with exposure. In occupational lung diseases, symptoms occur during workdays and abate during days off.

Diagnose by history. Chest x-rays reveal recurrent infiltrates, but these are **transient**. Serum precipitins are **nonspecific** for hypersensitivity pneumonitis because they only indicate exposure. Most people exposed to these antigens have no immune reaction. Eosinophilia is **not** a feature of acute hypersensitivity pneumonitis.

Subacute hypersensitivity pneumonitis eventually evolves into chronic hypersensitivity with irreversible, parenchymal, fibrotic changes that are typically localized to the upper lobes.

The differential diagnosis of acute hypersensitivity pneumonitis includes other causes of recurrent or persistent pneumonias, including **eosinophilic pneumonia** and cryptogenic organizing pneumonia (COP; an idiopathic form of organizing pneumonia, formerly called bronchiolitis obliterans with organizing pneumonia [BOOP]). Note that bronchoalveolar lavage (BAL) may show an increased number or percentage of lymphocytes, with a CD4/CD8 helper/suppressor ratio of < 1 (while sarcoidosis has a ratio of > 4:1).

The best treatment is to **remove** the patient from the offending antigen or site of exposure. Corticosteroids appear to be beneficial in acute disease.

Byssinosis

Byssinosis is caused by the inhalation of cotton, flax, or hemp dust. It is **not immune** mediated, so no sensitization is needed. Early-stage disease occasionally presents with chest tightness. Late-stage disease can present with **Monday chest tightness** (regular chest tightness towards the end of the 1st day of the work week). The frequency of symptoms increases with continued exposure. Chest x-ray is normal. Flock worker's lung occurs from inhalation of ultra-fine nylon fabrics, and HRCT shows diffuse micronodules and ground-glass opacities.

Inorganic Dusts that Cause ILD

ILDs caused by inorganic dusts are asbestosis, silicosis, coal worker's pneumoconiosis, and berylliosis.

Asbestos

Asbestos causes some conditions that can occur independently of asbestosis, the ILD. Asbestos exposure causes bilateral, midthoracic pleural thickening, plaques, and calcification. The pleural thickening usually involves the midthorax (posterolateral) and spares both the costophrenic angles and the apices. Remember that pleural plaques and pleural thickening are **benign**, but when they are extensive, they can cause pulmonary restriction. Asbestos-related pleural plaques (Figure 6-12) are often erroneously called asbestosis.

Figure 6-12: PA lateral chest—*asbestos pleural plaques*

Rounded atelectasis is most commonly due to asbestos and occurs when fibrosis on the visceral pleural surface invaginates and may trap lung tissue, causing localized atelectasis. These may appear classically as a “comet tail” but are sometimes masslike.

Benign asbestos pleural effusions (BAPE) are a common manifestation of asbestos exposure in the first 10 years after exposure. These vary from serous to bloody and tend to occur early in the exposure history (within 5–10 years). About 1/3 of patients have eosinophils in the pleural fluid.

Asbestosis is pulmonary parenchymal fibrosis caused by asbestos exposure. This fibrosis develops mostly in the bases and is subpleural, but often there are longer fibrotic streaks. Other radiologic manifestations of asbestos exposure may or may not be present. Asbestosis generally occurs with > 10 years of moderate exposure, although the latency period can be > 30 years! There is no specific treatment for asbestosis.

Smoking has a synergistic effect with asbestosis in the development of lung cancer. The associated lung cancers are **squamous cell** and **adenocarcinoma** (not small cell cancer).

Malignant mesotheliomas are tumors arising from the mesothelial cell of the pleura, often where there was preceding asbestos-related pleural disease. 80% of mesothelioma patients have prior asbestos exposure. Pleural plaques do not necessarily progress to mesothelioma and in fact rarely do. The latency period is on the order of decades and can be > 40 years. Mesothelioma is **not** due to smoking. It is usually a rapidly fatal disease. A keypoint: If you have a patient who was exposed to asbestos with progressive dyspnea, pleuritic chest pain, and a bloody pleural effusion, think mesothelioma!

Silica

Silicosis is one of the most common occupational ILDs in the world. It generally requires years of exposure to crystalline silica in order for it to develop. Exposure comes from occupations such as mining, glassmaking, ceramic manufacturing, sandblasting, metal casting, and brick making. There is a demonstrable trend in construction workers who cut natural stone (quartz, marble, granite) for home renovations. The latency is 20–30 years.

Silicosis is characterized by **silicotic nodules** and **hilar lymph node involvement** (hilar eggshell calcifications). There is an increased susceptibility to **TB disease**. See Figure 6-13 and Figure 6-14. Silica ingested by alveolar macrophages renders them ineffective.

Figure 6-13: PA chest showing simple nodular silicosis with diffuse 1–3 mm nodules

There is no specific treatment for silicosis—but if symptoms such as cough rapidly worsen, or the patient presents with hemoptysis, consider a concurrent TB or other infection. A positive interferon- γ release assay (IGRA) is preferable to a positive purified protein derivative (PPD) and is diagnostic for TB in these patients. Patients with silicosis are at high risk of concurrent mycobacterial infection and should be evaluated for latent and active tuberculosis in the context of constitutional symptoms, hemoptysis, or lung cavitation on radiograph.

Figure 6-14: PA chest—hilar eggshell calcifications in silicosis
Source: Vinay Maheshwari, MD

Since it usually involves the **upper lung**, the differential diagnosis includes TB, coal worker's pneumoconiosis, and berylliosis.

Silica is also a human carcinogen. Patients with silicosis have an increased risk for malignancy development. Silicosis is also associated with scleroderma and rheumatoid arthritis.

Simple nodular silicosis presents with small lung nodules and is also called fibrocalcific.

Complicated nodular silicosis presents with big lung nodules and is also called progressive massive fibrosis. It has nodules > 1 cm that tend to coalesce in the upper lobes.

Silicoproteinosis may develop from overwhelming exposure in ~ 5 years. This results in the alveoli filling with eosinophilic material similar to that found in pulmonary alveolar proteinosis (discussed under **Alveolar Proteinosis** on page 6-39). These patients present with symptoms easily mistaken for pulmonary edema.

Corticosteroids are thought to be beneficial in acute silicosis but not in chronic disease. Consider lung transplant for those with severe disease.

Note: Asbestosis involves the **lower lung**, while silicosis involves the **upper lung**.

Coal

Coal worker's pneumoconiosis (CWP) also has simple and progressive forms. The chest x-ray shows **upper lung** field nodules (similar to that of silicosis and berylliosis). Progression of simple CWP correlates with the amount of coal dust deposited in the lungs, whereas complicated CWP does not. Complicated CWP is a progressive massive fibrosis defined by lung nodules > 2 cm without hilar involvement. With large depositions of coal dust, patients can have melanoptysis. As expected, cigarette smoking accelerates the deterioration of pulmonary function. There is no association with TB, and there is no specific treatment.

Caplan syndrome is a seropositive rheumatoid arthritis associated with pneumoconiosis related to inorganic occupational dust (coal, asbestosis, silica). This syndrome is heralded by the development of peripheral basilar lung nodules (in addition to the upper lung field nodules seen in pneumoconiosis related progressive massive fibrosis).

Beryllium

Berylliosis (a.k.a. chronic beryllium disease [CBD]) is caused by a cell-mediated immune response that can occur from ≥ 2 years of exposure to even slight amounts of beryllium. This is especially suspected in persons who have worked with high-tech electronics, alloys, or ceramics or in the aerospace industry, the nuclear industry, or pre-1950 fluorescent light manufacturing.

It usually causes a **chronic interstitial pneumonitis** that tends to affect the **upper lobes** (similar to silicosis, TB, and CWP). Patients often have hilar lymphadenopathy that looks identical on chest x-ray to that caused by **sarcoidosis**—a key point.

Diagnosis of CBD:

- History of beryllium exposure
- Positive beryllium lymphocyte proliferation test (BeLPT)
- Characteristic radiologic changes
- Lung biopsy showing interstitial cell infiltrates (with mononuclear cells) and/or noncaseating granulomas

This ILD can be responsive to ongoing corticosteroids. Methotrexate (MTX) or azathioprine can be tried if steroids fail or a steroid-sparing agent is desired, but no data supports this.

IDIOPATHIC INTERSTITIAL PNEUMONIAS

We will now discuss the second category of ILDs—**idiopathic** interstitial pneumonias (IIPs). Here is a list of IIPs:

- 1) Idiopathic pulmonary fibrosis (IPF; usual interstitial pneumonitis [UIP] is the prototype)
- 2) Nonspecific interstitial pneumonia (NSIP)
- 3) Cryptogenic organizing pneumonia (COP, an idiopathic form of organizing pneumonia)
- 4) Acute interstitial pneumonia (AIP)
- 5) Respiratory bronchiolitis-associated ILD (RB-ILD)
- 6) Desquamative interstitial pneumonia (DIP)
- 7) Lymphocytic interstitial pneumonia (LIP)
- 8) Pleuroparenchymal fibroelastosis
- 9) Unclassifiable IIPs

Each of these entities has specific histopathologic findings. IPF also has typical clinical and radiologic findings. We will discuss 2 of the most frequently encountered IIPs: **IPF** and **COP**.

Idiopathic Pulmonary Fibrosis

As its name implies, idiopathic pulmonary fibrosis (IPF) has uncertain etiology. It is a diagnosis of exclusion that remains when known causes of pulmonary fibrosis have been excluded. There are **limited extrapulmonary** manifestations in IPF, although **clubbing** is seen in up to 50–60% of patients and tends to occur more frequently in men. The typical presentation is a male > 60, prior smoker, who presents with an insidious dry cough and dyspnea on exertion in the setting of bibasilar predominant fibrotic changes on HRCT without apparent cause. However, it may occur in middle aged populations as well. As before, smoking exacerbates the disease. ~ 10% of patients have low titers of ANA or RF, which are acute-phase reactions to lung inflammation.

IPF, by definition, has the specific histopathologic findings of UIP, including varying degrees of fibrosis, bronchiectasis, honeycombing, and mild interstitial inflammation interspersed with normal lung tissue. IPF ranges from an early stage—with radiographic findings of early fibrotic interstitial changes—to a late, lower lobe predominant fibrotic stage, with severe restrictive disease, pulmonary hypertension, and cor pulmonale (with diffuse, fibrotic-appearing parenchymal infiltrates on HRCT).

HRCT in early IPF shows a subpleural reticulation and traction bronchiectasis (Figure 6-15).

Figure 6-15: HRCT of idiopathic pulmonary fibrosis

Early IPF is characterized by leakiness of the capillaries and alveolar walls (from damage to the capillary endothelial cells and the adjacent Type I alveolar epithelial cells). This leads to interstitial and alveolar edema, which ultimately causes intraalveolar collagen deposition.

Late IPF leads to fibroblast-mediated collagen deposition in the interstitial space at the interface between abnormal lung adjacent to normal lung. HRCT shows fibrosis with **bibasilar honeycomb** pattern and traction bronchiectasis.

In IPF, the fluid in the alveoli and the interstitial edema increases the number of alveolar macrophages. They release profibrotic cytokines and proinflammatory mediators which mediate fibrinogenesis and inflammatory cascades (tumor necrosis factor [TNF], interleukin 8,

and leukotriene B₄)—some of which attract neutrophils. This is reflected in the BAL results of increased macrophages, neutrophils (PMNs > 5%), and eosinophils (> 2%) and increased BAL neutrophilia has been associated with worse prognosis. Importantly, the BAL is typically lymphopenic in IPF.

Consider IPF in a patient who presents with dyspnea; non-productive cough; mid-inspiratory, Velcro-like crackles; and a diffuse interstitial process on chest x-ray or HRCT. Patients often report a progressive decline in exercise tolerance. Velcro crackles are loud and coarse. They mimic the sound made when a Velcro patch is opened and sound different from the fine crackles made when hair is rubbed together. **Clubbing** of the nails is common, and is secondary to enlargement of the soft tissue of the distal nail, with subsequent exaggerated curvature of the nails. A widening of the angle between the proximal nail fold and the nail bed is observed (> 180°). Clubbing may be acquired or congenital, and 80% of cases are due to a pulmonary disorder like advanced pulmonary fibrosis, infections, or lung cancer.

Like many ILDs, PFTs show a restrictive intrathoracic disease (i.e., low TLC, normal FEV₁/FVC, low DLCO). Know that in IPF, a low DLCO out of proportion to restriction may correlate with the presence of pulmonary arterial hypertension (and thus, a poor prognosis).

Diagnosis

The diagnostic workup of IPF includes chest x-ray; HRCT showing characteristic features of subpleural reticulation, traction bronchiectasis, and bibasilar honeycomb formation; PFTs; ABG; and a functional assessment and oxygen requirements with exercise (e.g., 6-minute walk test). The diagnosis of IPF needs to be established by ruling out other progressive fibrotic lung diseases including NSIP and chronic HP.

When the diagnosis is in question because of an **atypical presentation**, consider a lung biopsy to characterize the pathology of the HRCT abnormalities and to exclude inflammatory-mediated disease, cancer, and infections. This is important because empiric treatment with steroids can cause harm in IPF patients and treatment should be targeted at the antifibrotic pathway.

Definitely avoid lung biopsy in a patient who has a negative environmental and rheumatologic history (corroborated by negative serologic workup), significant medical comorbidities, significant pulmonary hypertension, significant debility, and/or FVC or DLCO < 40% predicted—which suggests advanced disease that would not tolerate such a procedure. In these cases, empiric therapy can be trialed.

Once a diagnosis of IPF is established, patients are followed with serial evaluations with PFTs (including spirometry lung volumes), DLCO, and a 6-minute walk with oximetry and symptoms. Abnormalities in the above may prompt further workup with radiologic testing or bronchoscopy.

IPF has a relentless progression, but the severity and time course vary.

Treatment

In 2014, 2 drugs—**nintedanib** (a tyrosine-kinase inhibitor) and **pirfenidone** (an antifibrotic agent)—were approved by the FDA for patients with mild-to-moderate UIP (who meet specific criteria) to **slow the progression of disease**. They are frequently used in severe UIP, but data is less robust regarding proven efficacy. There is insufficient evidence to recommend a choice between nintedanib and pirfenidone. Consider patient preference, side effect profile, and tolerances.

Nintedanib is taken by mouth 2×/day. Patients with known liver disease are not candidates for nintedanib. Diarrhea, nausea, vomiting, and liver function test elevation are the common side effects of nintedanib. Nintedanib is also associated with a slightly increased risk of bleeding.

Pirfenidone is taken by mouth 3×/day. Rash, photosensitivity, nausea, diarrhea, and abdominal discomfort are the common side effects.

Studies taking both nintedanib and pirfenidone have shown overall tolerability, but further evaluation is needed to determine if they add benefit.

Routine maintenance care for patients with IPF/UIP **no longer** includes systemic glucocorticoid monotherapy; combination therapy with azathioprine, prednisone, and *N*-acetylcysteine; or monotherapy with *N*-acetylcysteine. There has been no demonstrated efficacy, and these treatments may be potentially harmful. Therapy to prevent acid reflux, such as a PPI, may be beneficial in patients with IPF. For patients who seem to have a condition other than UIP, such as NSIP, a trial of steroids may be considered. Lung transplantation is an option for patients with progressive disease and minimal comorbidities. 60% of all lung transplants result from progressive ILD.

Steroids are utilized for IPF patients with an **acute exacerbation of IPF** (i.e., a sudden acceleration of the disease with a significant decline in lung function), typically administered as high-dose IV glucocorticoids. Broad-spectrum antibiotics are typically initiated until infection can be excluded.

Cor pulmonale is treated symptomatically. Lung transplantation is an option for some end-stage IPF patients with single organ failure. Give IPF patients **pneumococcal** and **influenza** vaccines, evaluation for oxygen, palliative care consultation, and enroll in pulmonary rehab.

Organizing Pneumonias

Causes of Organizing Pneumonias

There are various types of organizing pneumonias that have the common finding of a chronic alveolitis. 50% of

organizing pneumonia cases are idiopathic. The other 50% are caused by the following:

- Inhalation of toxic fumes (e.g., smoke, paint aerosols, nylon flock fibers)
- Exposure to drugs (e.g., amiodarone, bleomycin, carbamazepine, minocycline, nitrofurantoin, phenytoin, penicillamine, sulfasalazine)
- Immunodeficiencies
- Infections (e.g., respiratory viruses, *Mycoplasma*, *Pneumocystis*, GNRs, fungi)
- Connective tissue disorders (e.g., rheumatoid arthritis)
- Myelodysplasia
- Radiation

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia (COP) is an idiopathic form of organizing pneumonia. COP is a **bronchiolitis** (inflammation of the small airways) and a chronic **alveolitis** (the organizing pneumonia). The bronchiolitis causes a proliferation of granulation tissue within the small airways and alveolar ducts.

Consider COP in a patient with an insidious onset (weeks to 1–2 months) of cough, fever, dyspnea, malaise, and myalgias. Often, patients have had multiple courses of antibiotics without effect. Rales are common. Chest x-ray shows some interstitial disease, bronchial thickening, and patchy bilateral alveolar infiltrates. Chest CT shows bilateral, peripheral-based infiltrates, but these can become confluent. PFTs demonstrate a restrictive pattern with a reduced diffusion capacity.

You must differentiate COP from IPF because, contrary to IPF, COP has a **good** prognosis and a good response to steroids. To differentiate IPF from COP, know that IPF is **even more** insidious in onset (> 6 months) and the patients do **not** have fever (Table 6-9). Radiographically, the consolidative infiltrates of COP differ from the subpleural reticulations and fibrosis with traction bronchiectasis and honeycombing of UIP. Bronchoscopic lung biopsy is the definitive means of diagnosing COP.

Table 6-9: Comparison of COP and IPF

	COP	IPF
Signs	Acutely ill appearing Fever	Not acutely ill No fever
Onset of Symptoms	Days to weeks	Very slow —at least 6 months
HRCT	Patchy peripheral based infiltrates	Honeycombing, peripheral reticulation, traction bronchiectasis

Corticosteroids are the **treatment of choice** for COP. COP does not respond to antibiotics. **Slowly** taper corticosteroids over 6–12 months because exacerbations can occur with rapid tapering. Corticosteroid-sparing treatment can be used if relapses occur with steroid weaning.

OTHER CAUSES OF INTERSTITIAL LUNG DISEASE

Other causes of ILD and diffuse lung disease are:

- Drug-induced interstitial lung disease
- Collagen vascular diseases
- Sarcoidosis
- Langerhans cell histiocytosis
- Lymphangioleiomyomatosis
- Vasculitides causing ILD: granulomatosis with polyangiitis (GPA), lymphomatoid granulomatosis
- Eosinophilic ILDs: acute and chronic eosinophilic pneumonia, ABPA, EGPA
- Autoimmune-associated ILDs: systemic sclerosis, rheumatoid arthritis, Sjogren syndrome, SLE, polymyositis/dermatomyositis, MCTD, interstitial pneumonia with autoimmune features
- Pulmonary alveolar proteinosis

Drug-Induced Interstitial Lung Disease

There are hundreds of drugs that have reported pulmonary toxicities. These include antibiotics that may cause hypersensitivity and/or eosinophilic responses and chemotherapeutic agents that may cause a variety of findings. Drugs may cause pulmonary toxicity in an idiosyncratic manner—usually an acute exposure and illness—or it may be dose-related, where the cumulative dose may lead to chronic toxicity.

Mechanisms of pulmonary injury include direct toxic effects such as generation of free radicals, immune-mediated reactions, fibrotic reactions, vascular injury, and others. A broad array of findings can be seen with different medications, including:

- Hypersensitivity reactions
- Eosinophilic pneumonia (i.e., gemcitabine, cocaine, heroin, nitrofurantoin)
- Nonspecific interstitial pneumonitis
- Other ILDs
- Pulmonary edema
 - Cardiogenic (i.e., cocaine, heroin, amphetamines, rituximab)
 - Noncardiogenic (i.e., cocaine, MDMA, heroin, interferons, MTX)
- Diffuse alveolar damage (i.e., amiodarone, bleomycin, cocaine, cyclophosphamide, MTX, radiation)
- Pulmonary hemorrhage (i.e., penicillamine, tumor necrosis factor- α (TNF- α), propylthiouracil)
- COP (i.e., amiodarone, bleomycin, cocaine, MTX)
- Granulomatous interstitial disease (i.e., MTX, interferons, rituximab, TNF- α)
- Pulmonary nodules (i.e., amiodarone, MTX)
- Lipoid pneumonia (e.g., aspiration)

- Pulmonary alveolar proteinosis (i.e., sirolimus)
- Pleural effusions (i.e., penicillamine, nitrofurantoin, MTX)
- Other histopathologic findings

Airway disease can also result from drug-induced pulmonary toxicity and includes bronchospasm, hoarseness, cough, and bronchiolitis obliterans. Pulmonary vascular disease manifestations potentially include thromboembolism, alveolar hemorrhage, vasculitis, and pulmonary vascular disease. Crack lung (from inhalation of cocaine) can present with acute dyspnea with hemoptysis due to diffuse alveolar damage as well as with a pneumothorax. Consider obtaining a urine drug screen. Electronic vaping-associated lung injury can also present with diffuse alveolar hemorrhage, COP, hypersensitivity pneumonitis, and acute eosinophilic pneumonia.

Epidemiology

Prescription drug-induced pulmonary toxicity is generally an uncommon side effect. Older patients appear to be more susceptible, as well as those with prior lung injury such as from radiation or chemotherapy. In some cases, hyperoxia with prior exposure to certain medications may precipitate pulmonary toxicity.

Diagnosis

Drug-induced lung disease is a diagnosis of exclusion. Generally, infection, collagen vascular disease-associated ILD, vasculitis, and other etiologies need to be excluded. In some cases, the absence of fever, absence of purulent sputum, negative serologies, and negative cultures help exclude these etiologies. A temporal relationship and exposure should be compatible, and discontinuation of the offending or suspected agent leads to the disappearance of the manifestations. Rechallenge to establish the diagnosis is not usually done in pulmonary toxicity. Physical findings are nonspecific and can include clear lungs, crackles, or wheezes.

Radiologic findings are generally nonspecific, but other diagnoses such as COP and sarcoidosis may be suggested by their classic findings, discussed earlier.

Testing

There are no specific tests for drug-induced lung disease. Index of suspicion must be high (always consider iatrogenesis). Sputum culture and BAL with cultures, direct fluorescent antibody for *Pneumocystis*, differential cell count, and CD4/CD8 ratio may also be helpful in excluding diagnoses. Lung biopsy, whether transbronchial or open, cannot provide any specific histopathologic pathognomic finding of drug-induced lung toxicity. Biopsy is done when other etiologies are strongly suspected and there is a need to differentiate from other non-drug-related etiologies.

Treatment

Any potential offending agents should be discontinued, particularly when more acute or severe pulmonary toxicity occurs. This is also the case with known or suspected hypersensitivity or eosinophilic reactions, pulmonary edema, diffuse alveolar damage, alveolar hemorrhage, and other more severe and acute reactions. Steroids may be useful in immune-mediated reactions, some pulmonary hemorrhage situations, vasculitis, and in other situations where the etiology is not clear but the acuteness of the situation calls for a trial of steroids.

Connective Tissue Collagen Vascular Diseases and ILD

Rheumatoid arthritis (RA): > 1/3 of patients with RA get ILD! The most common lung problem in RA is pleurisy (with or without pleural effusion). Pleural effusions are **exudative** and can have uniquely very **low** glucose levels with pseudochylous findings. See **Exudative Effusions** on page 6-50. Occasionally, these patients have **necrobiotic nodules**—usually in the **upper** lung zones. ILD can also be due to a complication of gold and MTX treatment in RA patients. COP rarely results from penicillamine treatment but may occur in association with RA itself. Pleuropulmonary manifestations can occur before the articular manifestations of RA appear. The most common form of chronic ILD in RA patients is histologically UIP.

Systemic lupus erythematosus (SLE) can cause painful pleuritis (+/- effusion). It additionally causes diffuse atelectasis and sometimes diaphragmatic weakness—and, therefore, orthopneic dyspnea that is **out of proportion** to the chest x-ray findings. The chest x-ray may show elevated diaphragms. The uncommon “shrinking lung syndrome” consists of unexplained dyspnea, an elevated diaphragm, and restriction on PFTs. SLE diffuse alveolar hemorrhage (similar to that seen in idiopathic pulmonary hemosiderosis) may or may not manifest as hemoptysis. SLE affects both the lung and pleura more frequently than any other collagen vascular disease (60%). Other manifestations include acute lupus pneumonitis, pulmonary vasculitis, pulmonary hypertension, and pulmonary embolism (associated with APLA).

Systemic sclerosis (scleroderma) affects the lung 100% of the time—but there are no pleural changes! Nintedanib was FDA approved for systemic sclerosis ILD in 2019 to decrease rate of decline in lung function. Patients are treated with immunosuppression and, depending on the severity of their disease, can be considered for autologous hematopoietic stem cell transplant.

Patients with systemic sclerosis are more susceptible to pneumonia. Chronic aspiration and gastroesophageal reflux are common, and possibly related to the development and/or progression of pulmonary fibrosis.

Systemic sclerosis, rheumatoid arthritis, and systemic lupus erythematosus.

Isolated pulmonary hypertension (**without** ILD) occurs more often in patients with limited cutaneous systemic sclerosis (previously CREST syndrome) than in patients with diffuse cutaneous systemic sclerosis.

Both RA and systemic sclerosis can be associated with exposure to silica, and both have an increased incidence of bronchogenic carcinoma!

Sjögren syndrome causes desiccation of the airways and is also associated with lymphocytic interstitial pneumonia (LIP) and interstitial lung disease.

Sarcoidosis

Sarcoidosis is a multisystem disease that can affect any organ. This commonly comes to medical attention with complaints of fever, joint pains, and constitutional symptoms. ~ 50% of patients have dyspnea, chest pain, cough, and/or hemoptysis (more with established disease). A subset of patients may present with acute fever, hilar lymphadenopathy, polyarthralgia, and/or erythema nodosum, a.k.a. Löfgren syndrome. This type of presentation has a good prognosis as it is highly likely to resolve spontaneously, but NSAIDs can be used. Another syndrome is uveoparotid fever (a.k.a. Heerfordt syndrome), which is anterior uveitis, parotitis, cranial nerve 7 paralysis, and fever. It may also spontaneously resolve, but some need treatment. A significant number are asymptomatic and come to attention with an incidental abnormal chest x-ray demonstrating hilar/mediastinal adenopathy with or without parenchymal changes.

Findings

Physical examination may be normal, but findings can include uveitis, parotid tenderness, lymphadenopathy (including epitrochlear), rashes (e.g., erythema nodosum; plaquelike lesions; subcutaneous nodules; maculopapular rash; raised, indurated, purplish skin lesions on the nose known as lupus pernio), crackles on lung exam, and an array of neurologic manifestations, from neuropathy to optic nerve dysfunction, meningeal findings, myelopathic findings, and other changes.

Sarcoidosis is characterized by noncaseating granulomas in affected organs, and its cause is unknown. The granulomas are an inflammatory collection of cells that have a typical appearance on biopsy of lymphocytes around multinucleated giant cells. Skin involvement is common and may be the presenting manifestation. Cardiac involvement is variable and can cause life-threatening arrhythmias. Uveitis is a frequent ocular manifestation. Sarcoidosis affects a bimodal distribution of patients, first in the 20–30s and again in 50–60s, and is more common in females and in African Americans in the United States.

Pulmonary involvement can be an incidental finding on chest x-ray. Usually, there is bilateral hilar and/or mediastinal adenopathy (+/- reticulonodular or alveolar infiltrates). PFTs can either be normal or show **restrictive** (+/- **obstructive**) mechanics. The radiographic staging of

sarcoidosis (Table 6-10) illustrates the interesting point that hilar adenopathy disappears in advanced stages of the disease (see Figure 6-16 and Figure 6-17).

Serum angiotensin-converting enzyme (ACE) level is **nonspecific** in diagnosing sarcoidosis, but it **is sometimes** useful in the correct clinical context. However, its utility in practice has been modest, at best. Hypercalcemia (due to hydroxylation of vitamin D in granulomas and elevated 1,25 (OH)-vitamin D₃), hypercalciuria, and hypergammaglobulinemia are common.

Table 6-10: Sarcoidosis Staging

Stage	Chest X-Ray Findings
0	Clear
1	Bilateral hilar adenopathy
2	Adenopathy + parenchymal infiltrates
3	Diffuse parenchymal infiltrates
4	Fibrosis, bullae, cavities, architectural destruction (primarily upper lobe)

Figure 6-16: PA chest—Stage 1 sarcoidosis
Source: Vinay Maheshwari, MD

Diagnosis

Sarcoidosis is a diagnosis of exclusion. It is **imperative** to exclude the other granulomatous diseases, including hypersensitivity pneumonitis, berylliosis, and infectious diseases caused by mycobacteria and fungi. A positive BAL shows an increased number of lymphocytes, with a CD4/CD8 helper/suppressor ratio of $> 4:1$. (Hypersensitivity pneumonitis has a ratio of < 1 .) Material for histological exam should be cultured and examined for organisms.

While ensuring the absence of organisms and negative cultures, flexible bronchoscopy with transbronchial biopsy

Figure 6-17: PA chest—Stage 2 sarcoidosis
Source: Vinay Maheshwari, MD

of lung parenchyma or endobronchial ultrasound (EBUS) biopsy of lymph nodes showing **noncaseating granulomas** is the best method for diagnosing sarcoidosis.

Erythema nodosum is an associated skin lesion that denotes a **good prognosis**! This form of sarcoidosis is called **Löfgren syndrome**. When sarcoid presents in a classic form such as Löfgren's, biopsy confirmation is not necessary.

Treatment

Overall, 75% of sarcoid patients recover without treatment. It rarely progresses to pulmonary fibrosis or pulmonary hypertension. Treat only severe or symptomatic disease. Patients without pulmonary physiologic compromise do not need treatment unless they meet conditions below. There is no set regimen. Corticosteroids have **not been proven to induce remissions** in sarcoidosis, although they do decrease the symptoms and improve PFTs. Inhaled corticosteroids decrease the respiratory symptoms and can be used instead of systemic corticosteroids if the disease is primarily in the bronchi but not for parenchymal lung disease.

Corticosteroids are indicated for persistent hypercalcemia and evidence of other organ involvement:

- Eyes (e.g., conjunctivitis, uveitis)
- Heart (conduction abnormalities)
- CNS (signs of optic nerve or optic chiasm involvement)
- Lungs (in the presence of significant pulmonary symptoms)
- Skin (severe skin lesions)

If the case is refractory to steroids, or treatment is expected to be long term (with the goal of minimizing steroid related side effects), consider leflunomide, mycophenolate, infliximab (Remicade), adalimumab (Humira), MTX, and azathioprine. Occasionally MTX or azathioprine are combined with leflunomide.

Lung transplantation remains an option for advanced disease and associated pulmonary hypertension. Sarcoidosis can recur after transplant, but does not necessitate retransplantation.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) causes characteristic lytic bone lesions (eosinophilic granulomas). Langerhans cells are the predominant cell form. LCH sometimes involves the posterior pituitary—leading to **diabetes insipidus**.

In the lung, it causes nodules which can cavitate and small, thick-walled cystic spaces in the upper lung fields, both of which are visible on chest x-ray and HRCT.

Virtually all affected patients are **smokers**, and males are affected more than females. Patients have ILD with normal or **increased** lung volumes. (Most ILDs have decreased lung volumes.)

Pneumothorax is a major feature, accounting for 10% of the initial presentations. Up to 50% of these patients have a pneumothorax sometime in the course of their illness. Cysts and nodules are evident on HRCT scan.

Diagnose LCH with suggestive CT findings or by Langerhans cells on lung biopsy or BAL. Electron microscopy demonstrates the presence of Birbeck granules (remember tennis rackets), and histopathologic markers for S-100 antigen, CD1a, and CD207 are positive in this disease.

Treatment: Stop smoking! Many do a trial of steroids, although drugs generally do not help. Occasionally there is spontaneous resolution.

Again: Think about LCH in a young, male smoker with recurrent pneumothoraces.

Lymphangioleiomyomatosis

Lymphangioleiomyomatosis (LAM) is the result of immature smooth muscle proliferation in the lymphatic, vascular, alveolar, and peribronchial structures. This proliferation results in the formation of constrictions and cysts in the affected structures. There is a genetic relationship to tuberous sclerosis.

LAM occurs almost exclusively in premenopausal women. Symptoms and signs included worsening shortness of breath, fatigue, and often spontaneous pneumothorax.

Chest x-ray in LAM is nonspecific. See **Figure 6-18**. HRCT can identify the characteristic multilobar, thin-walled cysts.

Thoracic and abdominal lymphatics are often involved, resulting in **chylous** pleural effusions—with triglycerides > 110 mg/dL (1.24 mmol/L; +/- chylomicrons in the fluid). Pneumothorax can occur in up to 36%.

First-line treatment for those with symptoms is inhibiting the rapamycin target (mTOR) with sirolimus (mTOR kinase inhibitor) and avoiding exogenous estrogen. Lung transplant remains an option.

Again: LAM = premenopausal, pneumothorax, chylous effusion (TG > 110 mg/dL [1.24 mmol/L; +/- chylomicrons]), and seen in tuberous sclerosis.

Figure 6-18: Lymphangioleiomyomatosis

Vasculitides that Cause ILD

Granulomatosis with Polyangiitis

Granulomatosis with polyangiitis (GPA) is a vasculitis that involves all of the following:

- **Upper respiratory** tract and paranasal sinus involvement
- **Granulomatous** pulmonary vasculitis with large (sometimes cavitory) nodules
- Necrotizing **glomerulonephritis**

Sometimes, it is limited to just the lungs or the upper airway (limited GPA).

Manifestations of GPA overlap with microscopic polyangiitis, another ANCA-associated vasculitis. The latter does not have granulomatous but rather neutrophilic inflammation, and it does not involve the upper airway.

The **ANCA test** (antineutrophil cytoplasmic antibody—an autoantibody that unleashes a locally destructive immunologic process) is often used as a diagnostic test. It is ~ 90% sensitive and 90% specific. When positive in a patient with GPA, the ANCA test is virtually always **cytoplasmic**, or **c-ANCA** (96%).

ELISA is used to quantitate anti-PR3, the major ANCA autoantibody. In the correct clinical context, a positive ANCA and/or anti-PR3 is often sufficient for diagnosis.

The diagnosis may be confirmed from a biopsy of the involved organ. The nasal membrane has variable sensitivity for diagnosis and the skin is often nonspecific. Biopsy of the kidney usually reveals a pauciimmune glomerulonephritis, and granulomatous infiltration is diagnostic.

The treatment of systemic GPA is **aggressive** because, without treatment, most patients die within 2 years, while

limited forms of the disease may have a more benign prognosis and do not require as aggressive treatment. For patients with active but not severe GPA, MTX and glucocorticoids induce and maintain remission. For those with severe disease, use glucocorticoids combined with cyclophosphamide, MTX, or rituximab. Plasmapheresis is another option. In less severe disease, start with MTX. Prophylaxis against *Pneumocystis pneumonia* is with trimethoprim/sulfamethoxazole (TMP/SMX) until prednisone dose is tapered to ≤ 10 mg per day. Treatment to induce remission is usually for a minimum of 3–6 months.

MTX, rituximab, mycophenolate, or azathioprine are typically used for maintenance therapy.

Again: kidneys, lungs, and sinuses. Consider GPA in any patient who presents with a purulent nasal discharge, epistaxis, and signs of a glomerulonephritis with hematuria. Neuropathy may also be present. The patient is not usually dyspneic and may not have a cough or hemoptysis. They may have thick walled cavitary lung lesions. If you see a similar presentation that is ANCA-negative, think antglomerular basement membrane disease (a.k.a. Goodpasture syndrome).

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare EBV-associated, systemic, angi-destructive lymphoproliferative disease. Although characterized by prominent pulmonary involvement, it can also involve extrapulmonary sites. 50% progress to **histiocytic lymphoma**. It is similar to GPA but has **no** upper respiratory lesions and only rarely affects the kidney. Although the principal site is the lung, lymphomatoid granulomatosis less often has **skin**, **CNS**, and peripheral nerve involvement. Biopsy shows a mononuclear angiocentric necrotic vasculitis.

Treatment of affected patients (who are immunocompetent) is with corticosteroids and biologic or chemotherapeutic agents, by experienced practitioners. In patients who are already immunocompromised, reducing immunosuppression can induce remission.

Eosinophilic Granulomatosis with Polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA) is a **necrotizing, small- to medium-vessel vasculitis** with **eosinophil** infiltration. It can affect multiple systems but most commonly affects the lungs. It does not affect the sinuses.

Patients typically present with preexisting **asthma** (for about 8–10 years) before vasculitic symptoms appear and have eosinophilia ($> 1,500$ cells/ μ L [1.5×10^9 /L]) and a neuropathy. Biopsy will show perivascular eosinophils. Think about EGPA (and ABPA) when assessing a progressively worsening asthmatic.

EGPA can be unmasked by treating an asthmatic patient with a **leukotriene-receptor modifier** while weaning oral corticosteroids.

The treatment of EGPA is mainly with systemic corticosteroids. Refractory cases are treated with cyclophosphamide,

azathioprine, rituximab, high-dose IV immunoglobulin, and/or plasmapheresis. Once in remission, maintenance is with azathioprine or mepolizumab. Reslizumab and benralizumab are in clinical trials.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis is a destructive granulomatous lesion of the bronchi and bronchioles that is generally believed to represent a nonspecific response to a variety of airway injuries. ~ 50% of all the cases are related to either asthma or ABPA. Because of the lack of a clear clinical syndrome, consider the lesion a nonspecific manifestation of lung disease.

Eosinophilic ILDs

The eosinophilic ILDs are **eosinophilic pneumonia**, **ABPA**, and **EGPA** (discussed earlier). Remember that asthma, hypereosinophilic syndrome, certain parasite infections, and some drugs are non-ILD causes of **peripheral eosinophilia**.

A **hypereosinophilic syndrome** is defined as a persistently elevated eosinophil count in the blood for at least 6 months without any recognizable cause with involvement of either the heart, nervous system, bone marrow, or the lungs.

Eosinophilic Pneumonias

In all types of eosinophilic pneumonia, you must **rule out drugs and parasites** as the cause. Eosinophilic pneumonia consists of 3 types:

- 1) **Löffler syndrome** is typically self-limited and was originally described as a result of the transpulmonary passage of helminthic larvae early in their life cycle. *Ascaris*, *Strongyloides*, and hookworms have all been reported as common causes. However, Löffler syndrome has been reported to occur with fungal infections or as a hypersensitivity response to various medications, such as NSAIDs or sulfonamides. This syndrome describes an acute pulmonary eosinophilia that is transient (usually < 30 days in duration) with blood-tinged sputum containing narrow, elongated Charcot-Leyden crystals from the eosinophil-derived lysophospholipase. It is generally found incidentally, and patients have migratory peripheral infiltrates on chest x-ray. Eosinophils are found in the blood and sputum. Typically, no specific lung treatment is necessary, but if severe, corticosteroids may be prescribed. Anthelmintic therapy (albendazole, mebendazole, or pyrantel pamoate) may also be appropriate.
- 2) **Acute eosinophilic pneumonia** is an acute, febrile pulmonary illness with hypoxemic respiratory failure resembling ARDS. The condition can be idiopathic or caused by inhalational exposures. Rule out infection. BAL shows a large number of eosinophils. This is treated with ventilatory support and systemic glucocorticoids.

- 3) **Chronic eosinophilic pneumonia** is the **most common** eosinophilic pneumonia in the U.S. It usually occurs in middle-aged women. The illness is subacute with cough, wheeze, night sweats, and a low-grade fever. An asthma history is identified in 50% of the patients. The chest x-ray classically shows bilateral, very peripheral infiltrates in a pattern that is the photographic negative of pulmonary edema. However, this pattern is not always present. There is an increased number or percentage of eosinophils in the BAL, but > 1/3 have no peripheral eosinophilia. BAL is often done to exclude infection. A very high ESR is typical. Treat with long-term steroids. The response is usually rapid, with improvement in 24–72 hours. Relapses are common, especially if steroids are tapered too early.

Allergic Bronchopulmonary Aspergillosis

As the term suggests, allergic bronchopulmonary aspergillosis (ABPA) is caused by an **allergic** reaction to *Aspergillus* that results in chronic cough, mucous plugging, and recurrent pulmonary infiltrates with eosinophilia in patients with asthma or CF.

Diagnosis: Think about ABPA in patients with either **asthma** or **CF** who have uncontrolled disease. Look for eosinophilia and *Aspergillus* in the sputum culture. In **asthmatics**, the clinical history is one of recurrent exacerbations that improve with prednisone, with return of wheezing, coughing, and dyspnea shortly after stopping steroids.

Test for ABPA with serum IgG *Aspergillus* precipitins, elevated eosinophils (> 500 cells/ μ L [0.5×10^9 /L]), and/or total IgE (usually > 1,000 IU/mL). Also check an HRCT. Central mucus impaction and bronchiectasis result in a central infiltrate on chest x-ray and HRCT known as the **finger-in-glove** sign. Mucous plugging is common, and sputum can show branching hyphae (nonspecific). If the only finding is lung eosinophilia with peripheral eosinophilia, consider a chronic eosinophilic pneumonia instead.

These antibody levels, plus the clinical history and other lab and x-ray data, can be reviewed in consideration of the major and minor criteria for ABPA (which you do not need to know for the exam).

Treat active ABPA with itraconazole (if not able to tolerate, then voriconazole) and oral steroids. In most patients, the addition of itraconazole reduces the duration of steroids, thus reducing long-term side effects. Treatment with IgE monoclonal antibody (e.g., omalizumab) shows evidence of efficacy. See *Aspergillus* on page 6-74 for additional information.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis (IPH) clinically manifests as a triad of:

- 1) hemoptysis,
- 2) diffuse parenchymal infiltrates, and
- 3) iron deficiency anemia.

Patients can have repeated episodes of intraalveolar bleeding that lead to an abnormal accumulation of iron in the form of hemosiderin-laden alveolar macrophages. Subsequently, pulmonary fibrosis from iron deposition and severe anemia can develop. The DLCO can be elevated on PFTs. Remember that pulmonary hemorrhage also occurs in other diseases, such as small-vessel vasculitis and SLE.

One type of IPH has antibasement membrane antibodies. Anti-GBM disease (Goodpasture syndrome) is a similar disease with anti-BM antibodies to the lung and the kidney. Unlike Goodpasture's, IPH does **not** affect the kidneys.

IPH has a chronic course in adults. In children, IPH is extremely rare but more acute and more severe. Treatment is with chronic steroids; immunomodulators have shown limited success.

NONINTERSTITIAL DIFFUSE LUNG DISEASES

ALVEOLAR PROTEINOSIS

PREVIEW | REVIEW

- Which organisms cause chronic pneumonia in patients with pulmonary alveolar proteinosis?

Alveolar proteinosis is usually more alveolar than interstitial. There are defective alveolar macrophages causing a buildup of surfactant phospholipids. It can occur as a primary disease or secondary to dust exposure, granulocyte macrophage colony-stimulating factor (GM-CSF) deficiency, or myeloid dyscrasias.

Chest x-ray looks like pulmonary edema. Consider this with gradual dyspnea, fatigue, low-grade fevers, and occasional productive, gelatinous sputum production. Patients may be hypoxemic from a large right-to-left shunt with secondary polycythemia.

HRCT shows a **ground-glass** appearance with interspersed, thickened, interlobular structures—a pattern called “crazy paving.”

Diagnose with positive GM-CSF antibodies and bronchoscopy with BAL and biopsy showing copious periodic acid-Schiff (PAS) material filling terminal bronchioles with milky effluent. If GM-CSF is negative and BAL evidence is not revealing, perform surgical lung biopsy.

Treatment: If severe, do a whole-lung lavage under general anesthesia with double-lumen endotracheal tube (very experienced specialists only). If the disease is refractory to repeated whole-lung lavage, a trial of inhaled or subcutaneous GM-CSF or rituximab can attempt to restore proper function to the alveolar macrophages. Know that nonresolving pneumonias in these patients are most likely to be caused by *Nocardia*, mycobacteria, *Pneumocystis*, or endemic fungi. If the patient smokes, counsel them to stop. *Nocardia* can also present as a brain abscess from dissemination of pulmonary infection.

ANTI-GBM DISEASE

Anti-GBM disease can present as a pulmonary-renal disease, and a certain subset presents with diffuse pulmonary hemorrhage (Goodpasture syndrome). This is discussed in the [Nephrology](#) section.

HEMOPTYSIS

PREVIEW | REVIEW

- Which autoimmune diseases are associated with pulmonary hemorrhage? Which cardiopulmonary diseases?

Immunologic lung diseases that cause pulmonary hemorrhage:

- Goodpasture syndrome
- SLE
- Granulomatosis with polyangiitis
- Microscopic polyarteritis
- IPH
- Rarely, other vasculitides such as Behçet disease and Takayasu arteritis

Cardiopulmonary diseases that cause pulmonary hemorrhage:

- Pulmonary embolism (infarct usually needed)
- Pulmonary AV malformations
- Aortic aneurysm
- Pulmonary hypertension
- Septic emboli
- Mitral stenosis
- Heart failure

Other causes of hemoptysis, diffuse alveolar hemorrhage, and pulmonary hemorrhage:

- Acute bronchitis (most common cause)
- Bronchiectasis
- Aspergilloma
- Tuberculosis
- Lung abscess
- Severe thrombocytopenia or coagulopathy
- Aspergillosis, mucormycosis, and other acute fungal infections
- Lung cancer
- Bronchial adenoma
- Pulmonary carcinoid
- Endobronchial metastases
- Chemotherapy and bone marrow transplantation
- Drugs (e.g., cocaine)
- Coagulopathy (often with additional pathology present)
- Trauma or instrumentation within lung

Massive hemoptysis is usually defined as > 200 mL of blood coughed up in 24 hours or a rate of bleeding that is sufficient to potentially compromise the airway. Massive hemoptysis is most commonly caused by bleeding from the bronchial (arterial) circulation. Hemoptysis while on an anticoagulant in most cases is still associated with airway or pulmonary pathology.

Assurance of a patent airway and protection of the unaffected lung is important, in some cases requiring intubation and/or selective intubation of the unaffected lung.

Locate the site of bleeding by chest x-ray or CT scan and bronchoscopy—this is important. A temporary balloon can infrequently be used to tamponade an airway, allow clotting in the atelectatic area, and avoid spillover to the unaffected lung. However, more commonly, interventional radiologic embolization is used early to control bleeding once the anatomical location is suggested by imaging and bronchoscopy.

VENOUS THROMBOEMBOLIC DISEASE

PREVIEW | REVIEW

- What is the usual cause of pulmonary embolism (PE) in hospitalized patients?
- Which symptoms and physical exam findings are seen with submassive PE?
- Characterize the clinical findings seen with massive PE.
- What is the 1st step in evaluating a patient with possible PE?
- What happens to the A-a gradient in most patients with a large PE?
- What is the imaging of choice to diagnose PE in the nonpregnant patient with normal renal function and no dye allergy?
- In a low clinical probability scenario, what does a normal ventilation/perfusion (V/Q) scan imply with regard to the probability of PE?
- In a patient with a low clinical probability of venous thromboembolism, what is the significance of a negative D-dimer? A positive one?
- Know perfectly the 3 items under [Putting It All Together – How to Diagnose PE on page 6-43](#).
- In which situations can you use direct oral anticoagulants (DOACs) to treat thromboembolism?
- In which situations do you not use DOACs for treating thromboembolism?
- In which situations do you use low molecular weight heparin (LMWH) to treat thromboembolism? Unfractionated heparin?

- Should aPTT be monitored in patients on LMWH? How are Factor 10a levels used?
- What are the major complications with heparin-induced thrombocytopenia (HIT) Type II? Describe the treatment.
- In which patients is warfarin contraindicated?
- When are thrombolytics used to treat PE?
- What are the indications for a vena cava filter?
- Make sure you thoroughly understand the treatment points under [Putting It All Together – How to Treat PE on page 6-46](#).
- Which medications are the 1st choice for venous thromboembolism prophylaxis in the hospitalized at-risk patient?

OVERVIEW

Venous thromboembolic (VTE) disease is the term that includes both deep venous thrombosis (DVT) and pulmonary embolus (PE). The majority of medically significant PEs originate as DVTs in the lower extremities or pelvic veins. Virtually all are from DVTs above the knee (iliofemoral area). Most calf vein thromboses do not embolize. Remember postoperative surgical risk factors for VTE are higher for orthopedic, colorectal, trauma, and spinal cord injury.

Other sources of PEs are upper extremity, internal jugular, and subclavian thrombi. Typically, the source for the **upper body** thrombi are **IV catheters**, especially PICC lines.

PE is the 3rd most common **cardiovascular** cause of death (after ischemic heart disease and stroke); 11% die within 1 hour of onset of symptoms. Despite medical knowledge of the cause and effect of PE, the **incidence** has **not** declined. In hospitalized patients, inadequate VTE prophylaxis is the usual cause of PE.

This is the sequence of events in medically significant PE:

- 1) Embolic obstruction of a pulmonary artery
- 2) Increased alveolar dead space (ventilated but not perfused)
- 3) Vascular constriction
- 4) Loss of alveolar surfactant with atelectasis (V/Q mismatch + shunt areas)

These events result in an increased resistance to blood flow → increased pulmonary artery pressure → increased right ventricular (RV) work. The pulmonary circulatory system is highly compliant and therefore inherently has high **capacitance**. Consequently, up to **50%** of the lung vasculature can be blocked before the increased workload on the RV becomes significant in a normal individual. Massive PE usually occurs when > 2/3 of the functioning lung pulmonary arterial circulation is compromised.

Note that lung-tissue infarction is rare (< 10% of cases) because the tissue is perfused by **multiple sources**, including both the **bronchial and pulmonary arterial circulations** and **back diffusion** through the pulmonary venous system.

DIAGNOSIS OF PE

We will go over the clinical findings of PE first, then go over all the diagnostic tests, and then have a brief (whew!) discussion on working up PE that brings it all together.

Presentation

Clinical findings are varied and usually nonspecific, but there is a suggestive **set** of signs and symptoms. Sudden onset of dyspnea, pleuritic chest pain, and tachypnea are the most common. Hemoptysis and pleuritic pain, when due to PE, indicate an associated lung **infarction**.

Massive PE is defined by sustained hemodynamic instability (bradycardia, SVT, hypotension) requiring vasoactive support that is attributable to the PE.

PE is divided into risk stratified groups based on hemodynamic stability and sPESI, FAST, and BOVA severity scores. The definitions are important for determining prognosis and for ascertaining treatment strategies for patients:

- 1) **High-risk PE** is defined as cardiac arrest, obstructive shock, or persistent hypotension (systolic BP < 90 mmHg) not attributable to sepsis, hypovolemia, or arrhythmia (ERS 2019 guidelines).
- 2) **Intermediate-risk PE** is usually a patient with hemodynamic stability who has clinical/radiologic/laboratory severity scores that are considered intermediate risk, based on hemodynamics, troponin leak, and RV dysfunction notable on TTE.
- 3) **Low-risk PE** is defined as a hemodynamically stable PE with no clinical, radiologic, or laboratory features that are concerning for RV dysfunction.

The Wells prediction rules or revised Geneva criteria determine the **pretest** probability of PE based on clinical findings and medical history. As discussed later, assessing these (or similar verified pretest probability rules) is the **1st** step of the diagnostic workup of PE ([Table 6-11 on page 6-44](#) and [Table 6-12 on page 6-44](#)).

Malignancy, one of the Wells DVT criteria, is present in 50% of patients with **phlegmasia cerulea dolens** (an unusual type of DVT resulting in additional thrombosis of collateral veins, which causes massive edema, pain, and blue discoloration from arterial insufficiency). Malignancy is also suggested by superficial migratory thrombophlebitis, DVT resistant to anticoagulants, and thrombophlebitis in unusual places, such as the arms and trunk.

Review of Lab and Radiological Tests for PE

Here we discuss 12 tests and how they are used to diagnose PE and determine the patient's prognosis. In the

next topic we put it all together and cover how PE is actually diagnosed.

These are the 12 tests. Know all of them:

- 1) ABGs
- 2) Chest x-ray
- 3) ECG
- 4) CTPA
- 5) Venous ultrasound of lower extremities
- 6) V/Q scan
- 7) Venous studies
- 8) D-dimer
- 9) Pulmonary angiography
- 10) Echocardiography
- 11) Serum troponins
- 12) Serum BNP

Use **ABGs** to look for V/Q mismatch. Hypoxemia and increased A-a gradient are key indicators for V/Q mismatch that occur with large PEs. The V/Q mismatch is initially from decreased perfusion of ventilated areas (dead space). Shunting, from perfusion of poorly ventilated areas, occurs later as a side effect of PE (secondary to bronchoconstrictive mediators and atelectasis). Secondary RV failure can also contribute to the V/Q mismatch.

Chest x-ray helps exclude other causes in the differential (e.g., **pneumonia**, **pneumothorax**). Chest x-rays in patients with PE are most commonly either normal (12%) or nonspecific (e.g., infiltrate, effusion, atelectasis). Even so, PE is suggested by:

- Pulmonary infiltrate with a normal or elevated WBC count on peripheral smear
- Pulmonary consolidation in conjunction with an elevated ipsilateral hemidiaphragm (from atelectasis)
- Hampton hump—a pleural-based, wedge-shaped defect from infarction just above the diaphragm
- Oligemia (Westermarck sign; infrequently seen)—a lack of vascular markings in the area downstream of the embolus
- Large right descending pulmonary artery (Palla sign)

ECG is highly suggestive but **not** sensitive. ECG changes seen with PE are tachycardia and RV strain from acute cor pulmonale. On ECG, acute right heart strain = S1Q3T3. That is, the S wave is large in lead I, the Q wave is large in lead III, and the T wave is inverted in lead III. This is not seen often, but it tends to appear frequently on exams! The most common EKG finding in PE is sinus tachycardia. ECG also helps rule out MI.

CT pulmonary angiography (CTPA; more under **Computed Tomography (CT)** Chest on page 6-1) is as accurate and is less invasive than pulmonary angiography. CTPA is the **gold standard** for primary, noninvasive imaging to diagnose **acute** PE with high sensitivity and specificity. It is

especially helpful when the patient has cardiopulmonary problems that might obscure the results of the V/Q scan.

When assessing for **chronic** pulmonary thromboembolism, the V/Q scan is more sensitive than CTPA.

Ventilation/Perfusion lung scan remains useful in obese patients, in those with **iodine allergy**, and in patients with **chronic kidney disease (CKD)** for whom contrast dye is undesirable. The V/Q scan is the test of choice for the diagnosis of recurrent PEs due to chronic venous thromboembolic disease.

Normal: A normal chest x-ray plus a normal V/Q scan has a **very low risk of PE**. When coupled with a low clinical probability, a normal V/Q scan essentially eliminates the diagnosis of PE.

Low-probability and **moderate-probability** scans are considered indeterminate because these patients have a 14–40% chance of PE.

Moderate-probability scans consist of subsegmental perfusion defects or matched ventilation and perfusion defects. A chest x-ray finding of an infiltrate in the area of perfusion defect indicates the same risk. If clinical suspicion of PE is low, no further testing is necessary. If it is high, consider CTPA, selective pulmonary arteriogram, ultrasound (U/S) of the lower extremities, or empiric anticoagulation.

High-probability scans occur in 2 situations:

- 1) ≥ 2 segmental or larger perfusion defects are present with a normal ventilation study.
- 2) The perfusion defect is much larger than the ventilation defect.

The trouble with V/Q scans is that large numbers come back as low-probability/indeterminate. You greatly improve accuracy of the above scans by factoring in pretest probability of a PE. For instance:

- ~ 30% of patients with a low-probability scan have a PE, but with a low pretest probability, this rate drops to 2%! With a high pretest probability, it jumps to 40%.
- ~ 85% of patients with a high-probability scan have a PE, but with a high clinical probability, this rate jumps to 96%! With a low pretest probability, it plummets to 6%.

Determining the probability for PE (by means of verified criteria such as Wells or revised Geneva) is included as the 1st step of the diagnostic workup.

Venous studies: Determining the existence of DVT of the lower extremities is important in diagnosing and preventing PE.

Treatment of isolated venous thrombosis in the calf with no involvement of the popliteal vein is controversial because the incidence of embolization is 50% less than with proximal thromboses. Some centers use anticoagulation, and some follow with serial ultrasounds if there are no risk factors (i.e., immobility, prior DVT, inpatient status, cancer, elevated D-dimer $> 500 \mu\text{g/L}$ [$0.5 \mu\text{g/mL}$]).

Duplex ultrasonography combines real-time, B-mode ultrasonography, which visualizes the vessel with Doppler flow detection, with looking for **compressibility** of the vessel and **flow**. This test is reliable only in **symptomatic** patients being evaluated for their 1st DVT by an **experienced** operator (operator-dependent). In these patients, the sensitivity is 93% while the specificity is 98%. It is poor for detecting distal DVT (because the vessels are hard to visualize) and abdominopelvic thrombi (from which most cases of PE arise).

D-dimer testing is sensitive and useful. Used with any 1 of the above noninvasive tests, it increases the **negative** predictive value of the test. A **negative** D-dimer in a **low-risk** patient **excludes** DVT/PE as a diagnosis.

Because of the **poor specificity**, the D-dimer has a poor positive predictive value, so do **not** use it to screen for DVT or PE. A positive D-dimer in a low risk individual is not diagnostic of PE.

Pulmonary angiography was the gold standard for the diagnosis of PE. Because pulmonary angiography is an invasive test, it is reserved for cases with inconclusive results from CTPA and/or V/Q scan. It is used in patients who have a high clinical probability of disease but negative results from other studies, such as CTPA and Doppler U/S.

Pulmonary angiography, especially if selective (guided by V/Q or HRCT scan findings), is a relatively safe procedure. Mortality is < 0.1%, although in patients with marked pulmonary hypertension mortality may be higher. Morbidity = 1-2%.

Echocardiography has poor sensitivity and specificity. However, it can be used at the bedside to determine if right heart strain is present in a patient who has a presentation consistent with massive PE. In such fluid-refractory hypotensive cases, when there is acute RV strain, relatively normal LV function, and a clinical picture consistent with PE, urgent thrombolytic therapy can be considered. A transesophageal echocardiogram can sometimes identify a central pulmonary embolus or a clot in transit through the heart.

Echo is also useful for making a prognosis in acute PE. Increased mortality is seen in patients who have normal BP and evidence of RV dysfunction or presence of an RV thrombus.

Troponins I and T are elevated in 30-50% of submassive to massive PEs and are probably the result of right heart failure. They are mainly used to determine the prognosis but are often drawn for cardiac evaluation in the midst of the acute presentation. Elevated levels correlate with increased severity of PE and increased short-term mortality.

BNP elevation can also be used as a marker of increased morbidity and mortality.

Putting It All Together — How to Diagnose PE

So, how is the diagnosis of PE made using these tests?

Know! It is really quite simple:

- 1) Use clinical prediction rules (Wells or revised Geneva are the most commonly cited) to determine probability of DVT and then pretest probability of PE (refer to [Table 6-11 on page 6-44](#) and [Table 6-12 on page 6-44](#)). In patients with low pretest probability, a negative D-dimer indicates a low likelihood of PE and essentially excludes the diagnosis.
- 2) U/S of lower extremities is recommended for patients with intermediate-to-high pretest probability for PE. If there is a high pretest probability for PE and proximal (iliofemoral or higher) thrombi, treat for PE.
- 3) CTPA, V/Q scan, or standard pulmonary angiography is recommended in patients with intermediate or high pretest probability if the lower extremity U/S does not show clotting.

Once the diagnosis of a PE is made, utilizing the Simplified Pulmonary Embolism Severity Index to risk stratify patients by their mortality risk is the next step in triaging their care.

TREATMENT OF PE

Treatment options for PE include:

- Adjunctive treatment (i.e., O₂, hemodynamic support with vasopressors, extracorporeal membrane oxygenation [ECMO])
- Anticoagulants (i.e., heparins, DOACs, warfarin)
- Thrombolytics (i.e., tPA [tissue plasminogen activator])
- Surgery (i.e., vena cava filters, thromboembolectomy)

Adjunctive Treatment for PE

Give oxygen for hypoxia. Many use IVF boluses to treat hypovolemia and raise preload or filling pressure in a dilated, strained RV. If in shock, norepinephrine is the vasopressor of choice. Mechanical ventilation is used in the setting of respiratory failure.

Anticoagulants for PE

The main anticoagulants are **heparins**, **fondaparinux** (Arixtra), **direct oral anticoagulants** (DOACs), and **warfarin**. Achieve adequate anticoagulation ASAP with a heparin or fondaparinux! It is indicated in hemodynamically stable patients in whom PE is **suspected** or confirmed unless there are contraindications.

Table 6-11: Wells Criteria for DVT

Criteria	Score
Active cancer (current Tx or palliation, or Tx within last 6 months)	1
Recent immobilization of lower extremities (e.g., plaster cast, paralysis, paresis)	1
Recently bedridden > 3 days or major surgery with general/regional anesthesia	1
Localized tenderness along the distribution of deep venous system	1
Entire leg swollen	1
Calf swelling 3 cm larger than asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral nonvaricose superficial veins	1
Alternative diagnosis is at least as likely as DVT.	-2
Score: ≥ 3 = high probability of DVT 1-2 = moderate probability 0 = low probability	
Note: If symptoms are in both legs, use the more symptomatic one.	

Table 6-12: Geneva Criteria for PE

Criteria	Score under Original Version	Score under Simplified Version
Previous DVT/PE	3	1
Heart rate 75-94 beats/minute	3	1
Heart rate ≥ 95 beats/minute	5	2
Surgery or fracture in the previous 4 weeks	2	1
> 65 years of age	1	1
Hemoptysis	2	1
Active cancer	2	1
Unilateral lower-limb pain	3	1
Pain on lower-limb deep venous palpation and unilateral edema	4	1
Three-level score under original version: ≥ 11 = high probability of DVT 4-10 = intermediate probability 0-3 = low probability		
Three-level score under simplified version: ≥ 5 = high probability of DVT 2-4 = intermediate probability 0-1 = low probability		
Two-level score under original version: ≥ 6 likely DVT 0-5 unlikely DVT		
Two-level score under simplified version: ≥ 3 likely DVT 0-2 unlikely DVT		

Anticoagulants are relatively contraindicated in the following:

- Uncorrected major bleeding disorder (e.g., thrombocytopenia, hemophilias, liver failure, renal failure)
- Uncontrolled severe hypertension (systolic BP > 200 mmHg, diastolic BP > 140 mmHg)
- Potential bleeding lesions (e.g., active peptic ulcer, esophageal varices, aneurysm, recent trauma/surgery to the head/orbit/spine, recent stroke, intracranial or intraspinal bleed)
- NSAIDs (increases risk of GI bleeding; if able, stop NSAIDs)
- Repeated falls or unstable gait

Remember warfarin is teratogenic and increases risk of fetal bleeding, so low molecular weight heparin is the preferred agent in pulmonary embolism treatment during pregnancy. (For more information on pulmonary embolism in pregnancy, see the [Women's and Men's Health](#) section.) Contraindications require consideration of an IVC filter or thrombectomy/embolectomy.

Heparins

There are 2 types of heparin, low molecular weight heparin (LMWH) and unfractionated heparin (UFH). LMWH is preferred over UFH for PE.

LMWH: Use subcutaneous full-dose LMWH (dalteparin or enoxaparin) whenever possible to treat PE (inpatients and outpatients) because of the lower risk of major bleeding compared to UFH. Either LMWH or UFH can be used for the initial treatment of PE. Most prefer LMWH, especially if the patient is hemodynamically stable, because LMWH reaches the therapeutic state faster. UFH is used in the setting of dynamic renal dysfunction or when there is need for rapid reversal.

LMWH is made from the depolymerization of heparin, which produces some molecular fragments with 30-50% the weight and more anticoagulant activity. LMWH has no effect on thrombin like UFH does. Rather, it solely inactivates Factor 10a (so aPTT is not sensitive to LMWH anticoagulant effect). Factor 10a levels can be used to monitor therapeutic effect. LMWH causes fewer instances of major bleeding than UFH in DVT, and in any VTE situation anticoagulation is established more quickly than with UFH. LMWH can still cause heparin-induced thrombocytopenia (although less often than UFH), so monitor the platelet count.

LMWH is preferred for treating VTE in pregnant women, cancer patients, and anybody who is treated for an extended period because the risk of osteoporosis is much lower than with UFH. You can monitor activity by assessing activated Factor 10a levels in outpatient settings, but this is usually not necessary as dosing is weight based.

Do not use LMWH in patients with a creatinine clearance < 30 mL/minute. Instead, use UFH because it can be titrated.

For both UFH and LMWH, protamine is the antidote for bleeding, but it is less effective against LMWH.

UFH binds with antithrombin (AT) to make it 1,000–4,000× more effective in inactivating thrombin and Factor 10a. To inactivate thrombin, heparin binds to both AT and thrombin.

UFH is **no longer** the drug of choice for DVT, but it is still used for the initial treatment of PE—especially if the patient is unstable and might require rescue thrombolysis. UFH dosage is determined by means of a **weight-based nomogram** to achieve adequate anticoagulation. Check aPTT levels every 6–8 hours after dosage change to allow time to achieve a steady state.

UFH is more often given to unstable PE patients because subcutaneous LMWH requires good blood pressure and tissue perfusion for optimal delivery, and this situation is not reliable in unstable patients. (Thrombolytics are also used in hypotensive patients with PE; know that you do **not** give tPA to **stable** patients with PE.)

Adjust the dose of IV UFH to keep the **aPTT** at least 1.5× control for 7–10 days. Greater increases than this result in an increased incidence of bleeding. Then continue anticoagulant treatment (minimum **3–6 months**), preferably with either LMWH, DOAC, or warfarin.

Complications: The major problem with UFH use is hemorrhage. Before giving it, be sure the patient has no major bleeding syndromes, no evidence of recent bleeding, and no significant thrombocytopenia.

Patients who are at high risk for bleeding should be given UFH in an infusion so it can be turned off and the effect reversed quickly with protamine if needed.

Heparin antidote: Again, for both UFH and LMWH, **protamine** is the antidote for bleeding. However, it is less effective against LMWH.

Heparin-induced thrombocytopenia (HIT):

- HIT Type **I** develops within 1–2 days of initiating heparins. HIT-I is common and of **no** clinical consequence.
- HIT Type **II** is an immune response where **antibodies** develop against the complex of heparin and platelet Factor 4. The antibodies are named anti-H-PF4. HIT-II starts **4–10** days after initiation of treatment. It occurs in 1–3% of patients receiving UFH and in about 0.5% of patients receiving LMWH. Arterial and venous thromboemboli are the major life-threatening complications.

Always monitor the **platelet count** in patients on heparin; if it drops > 50% and/or thromboembolic symptoms develop, stop using heparin—even heparin flushes. Use the 4 Ts score to determine the likelihood of HIT (see more in the **Hematology** section). Then, start treatment with a direct thrombin inhibitor, such as argatroban. Start DOAC or warfarin when the platelet count recovers to $\geq 100,000/\mu\text{L}$ ($100 \times 10^9/\text{L}$; and continue the thrombin inhibitor) because there is a long-term risk of clots as long as the antibodies are present.

Factor 10a and Direct Thrombin Inhibitors

There are 2 groups of direct oral anticoagulants (DOACs):

- 1) Factor 10a inhibitors: apixaban (Eliquis), rivaroxaban (Xarelto), edoxaban (Savaysa, Lixiana), betrixaban (Bevyxxa)
- 2) Direct thrombin inhibitor (dabigatran [Pradaxa])

They are fixed-dose oral agents that, compared to warfarin, do not require routine laboratory monitoring and have fewer drug-drug interactions. These agents usually reach their peak efficacy within a few hours after ingestion, so bridging therapy with unfractionated or LMWH is not required. Previously, the major disadvantage with these oral agents was the lack of a reversal agent, but in 2018 the FDA approved a reversal agent to dabigatran: idarucizumab (Praxbind), a monoclonal antibody that binds to dabigatran and rapidly neutralizes the anticoagulant effect. There is no safety profile on the use of DOACs in pregnancy. Andexanet alpha (activated factor 10) was approved by the FDA in 2018 for reversal of rivaroxaban and apixaban. In massive bleeding in the presence of direct thrombin or factor 10a inhibitors, also consider 4-factor prothrombin complex concentrate or tranexamic acid.

In 2013, multiple large Phase III trials demonstrated the noninferiority of DOACs compared to UFH or LMWH + vitamin K antagonists (VKA) such as warfarin in acute symptomatic VTE and fatal VTE recurrence with reduced rates of major bleeding. Most of these trials were performed in stable patients and designed as noninferiority trials. Do not use these agents for the initial treatment of a hemodynamically unstable pulmonary embolus since their use can interfere with potential thrombolytic therapy or pulmonary embolectomy if clinically indicated.

Fondaparinux

Fondaparinux is a **Factor 10a inhibitor**. Give it subcutaneously, once daily. It is approved for **DVT prophylaxis** in surgical patients and for treatment of both **DVT** and **PE** as an alternative to UFH and LMWH. Fondaparinux does not cause heparin induced thrombocytopenia (HIT), so it is a useful drug for patients who need anticoagulation or prophylaxis and who have a history of HIT.

Fondaparinux is cleared exclusively by the **kidneys**. Therefore, it is contraindicated in patients with creatinine clearance < 30 mL/minute and probably should be used cautiously when the clearance is between 30 and 80 mL/minute because it accumulates. It does not require Factor 10a level monitoring, and there is **no antidote**. Rate of bleeding is similar to heparins. Fondaparinux and enoxaparin are preferred over UFH in patients receiving parenteral/subcutaneous therapy without hemodynamic stability.

Warfarin

International normalized ratio (INR) is a product of the $PT_{\text{patient}}/PT_{\text{control}}$ ratio multiplied by an international sensitivity index (ISI). The ISI accounts for the sensitivity of the thromboplastin used by the lab, which varies from batch to batch. The formula is $INR = (PT_{\text{patient}}/PT_{\text{control}}) \times ISI$. INR is used to determine proper dosages of warfarin.

Warfarin is adjusted to maintain INR at a goal range of 2.0–3.0 (target 2.5). Initial dosing is usually 5 mg/day, and this is often titrated to patient specific parameters based on things like diet or drug-drug interactions. Note: Warfarin is a vitamin K antagonist that prevents activation of Factors 2, 7, 9, and 10.

Remember: After starting warfarin, Factor 7 is the most rapidly decreasing procoagulant, but protein C (an anticoagulant) also decreases rapidly—so you can (rarely) see an initial net procoagulant effect. This can occur only until the slower-clearing Factor 2 decreases enough to result in a net anticoagulant state. This usually takes ~ 4 days. This potential problem is addressed by starting the warfarin right after heparin is started (within 8 hours) and keeping patients on heparin for at least 4 days. Alternatively, using enoxaparin or fondaparinux (rather than UFH) can decrease hospital stays.

Warfarin necrosis is an idiosyncratic side effect that causes full-thickness skin necrosis requiring skin grafts.

Any decrease in the minimum level of dietary vitamin K results in an increase in the INR. Monitor the INR more frequently if the diet is changed or if the patient is treated with an antibiotic that might kill the gut flora required for proper vitamin K absorption.

Warfarin interacts with many drugs. For a detailed review of warfarin interactions, see the [General Internal Medicine](#) section.

Note: Warfarin can be started at the same time or any time after heparin or fondaparinux is started. The overlap period should be at least 4–5 days (10 days with massive PE) with the INR at a therapeutic level for 2 days before discontinuing the heparin and continuing the warfarin.

Warfarin in pregnancy can cause congenital deformities, especially if given in the 1st trimester. Use LMWH or adjusted-dose UFH instead. For more information on pulmonary embolism in pregnancy, see the [Women's and Men's Health](#) section.

Treat patients who have cancer (with venous thromboembolisms) with LMWH for the entire duration of therapy.

Thrombolytics for PE

tPA is indicated for patients with massive PE with hemodynamic compromise who have “acceptable” risks of bleeding and do not have absolute contraindications.

PE patients with intermediate risk factors for increased mortality can also benefit if they develop hemodynamic instability. Consider the patient's bleeding risk. A multidisciplinary pulmonary embolus response team (PERT) team is recommended in high (and some intermediate) risk cases.

Thrombolytics are not indicated for treatment of low-risk PE.

Vena Cava Filters for PE / VTE

Indications for vena cava filters include recurring VTE with adequate anticoagulation or recurring VTE when anticoagulant treatment is contraindicated.

Retrievable vena cava filters are used when only short-term protection is required and can be removed when the risk for PE has subsided or when anticoagulation can be resumed.

So, what can be used if TPA is not an option?

Surgical thrombectomy/embolectomy is a potential option but has high operative mortality.

Devices allow for mechanical thrombectomy (i.e., catheter extraction, rheolytic thrombectomy using high velocity saline jets) or mechanical disruption (i.e., pigtail catheters, intravascular U/S), but results vary by institutional expertise.

Putting It All Together — How to Treat PE

Know!

First, stabilize the patient: Put on O₂ and give hemodynamic support as needed with IV fluids and vasopressors.

Then, determine which anticoagulant to start. It is usually subcutaneous LMWH—especially if the patient is pregnant, has cancer, or is bedridden with normal renal function. If there is a history of HIT, fondaparinux is a good choice unless the patient has a creatinine clearance < 80 cc/min. In this case, argatroban, a direct thrombin inhibitor, is your only choice. If the patient is unstable without a history of HIT, IV UFH is given (aPTT = 1.5× control) to allow for rescue thrombolytics in the setting of decompensation. If massive PE, consider thrombolytics.

Home treatment with LMWH, DOAC, or warfarin is continued for:

- 3 months for PE due to transient risk factors
- At least 3 months and long term for PE without identifiable risk factors for those with low-to-moderate bleeding risk
- Indefinitely for recurrent PEs or thrombotic tendencies without significant bleeding risk

Periodically evaluate the risk/benefit of long-term anticoagulation.

Some DOACs can be started immediately after UFH is stopped, or they can be started 6–12 hours following the last dose of LMWH. Warfarin alone can be used after UFH when INR is 2.0–3.0 for 2 days.

TREATMENT OF DVT WITHOUT PE

Know that if the patient has a high probability of DVT with a low probability of PE (or if these diagnoses have been confirmed), the treatment is **exactly the same as that for PE** (more under [Treatment of PE on page 6-43](#)).

A patient that has extensive DVT with swelling (resulting in insufficient arterial blood flow in the limb causing pain, cyanosis and paresthesias) would be diagnosed with phlegmasia cerulea dolens and would be considered a surgical emergency, requiring thrombolytics or thrombectomy.

Although few **calf vein thromboses** migrate above the knee, the ones that do are usually **painful**! So, treatment depends on present risk factors or pain. If risk factors or pain exist, treat; if not, perform serial U/S.

RISK AND PROPHYLAXIS OF VTE

Pulmonary embolism is the most common preventable cause of death in hospitalized patients. Prophylaxis for DVT (and therefore PE) is cost effective. Despite the existence of numerous evidence-based guidelines, adequate prophylaxis is still not being offered to many at-risk patients (which makes this topic ripe for exam questions).

VTE Prophylaxis

The American College of Hematology (ACH) issued guidelines in 2018 for VTE prophylaxis, and the recommendations have somewhat simplified things.

Know that the use of either pharmacological prophylaxis **or** mechanical prophylaxis is favored over combined pharmacological and mechanical prophylaxis.

Unless patients are very high risk for bleeding, a drug for VTE prophylaxis is recommended. Types include subcutaneous LMWH, fondaparinux, and UFH. LMWH is preferred over DOACs for acutely ill, hospitalized patients. The ACH does not recommend extended duration post-hospitalization prophylaxis with DOAC over in-hospital prophylaxis. DOACs are typically used in patients who refuse injections or after orthopedic procedures.

For patients at the highest risk for bleeding, use pneumatic compression instead of drugs for VTE prophylaxis (or instead of no VTE prophylaxis).

FAT EMBOLI

Fat emboli cause the triad of **dyspnea**, **confusion**, and **petechiae**—usually in the neck, axilla, and/or conjunctiva. Fat emboli can occur within 72 hours after a **fracture** of

a **large bone** (e.g., femur) or operative manipulation of a large bone, sometimes **after CPR**, and with **sickle cell** bone-occlusive crisis.

Treatment is supportive; corticosteroids have **not** been proven to be helpful.

PULMONARY HYPERTENSION (PH)

PREVIEW | REVIEW

- Which common physical exam findings are seen in pulmonary hypertension (PH)?
- What are the 1st tests you order in the workup of PH? Which follow-up test is done if the 1st tests are suggestive?
- Which test of lung function, when low, indicates a poor prognosis in PH?

OVERVIEW

Definition of PH by the 2019 World Symposium on Pulmonary Hypertension: The **mean** pulmonary artery pressure is ≥ 20 mmHg on a right heart catheterization. Left heart failure as a cause is excluded by demonstrating the pulmonary capillary wedge pressure (PCWP) to be ≤ 15 mmHg and the pulmonary vascular resistance (PVR) to be > 3 Wood units (WU).

The World Health Organization (WHO) categorizes PH into 5 groups based on the **etiology**:

- **Group 1 PAH** (pulmonary **arterial** hypertension) is composed of familial PAH (heterozygous *BMPT2* mutations), idiopathic PAH (IPAH; previously known as primary pulmonary hypertension), **and** associated PAH caused by diseases or toxins that damage small muscular pulmonary arterioles. Examples include collagen vascular diseases, intracardiac shunts, portal hypertension, HIV, appetite suppressants/stimulants, toxic rapeseed oil, pulmonary veno-occlusive disease (PVOD), and pulmonary capillary hemangiomatosis (PCH).
- **Group 2 PH** is due to **left-sided heart** disease (i.e., atrium, ventricle, valve).
- **Group 3 PH** is seen in disorders of the **respiratory system** (e.g., ILD, COPD) or chronic hypoxemia (e.g., OSAHA).
- **Group 4 PH** is caused by **chronic venous thromboembolic** disease.
- **Group 5 PH** has unclear and/or multifactorial causes (i.e., myeloproliferative disorders, metabolic disorders, fibrosing mediastinitis).

Note that Group 1 is pulmonary **arterial** hypertension (PAH). PAH affects the entire vasculature of the lung, including the endothelium, smooth muscle, and even the extracellular matrix. However, it affects the arterioles of the pulmonary vasculature the most. This results in an **obliterative** process in which the pulmonary

vessels become more tortuous and close off with resultant increased resistance. Group 4 definitive treatment is surgery, often with high morbidity, and lifelong anticoagulation. Riociguat (an oral soluble guanylate cyclase stimulant) can be used in inoperable patients.

PHYSICAL FINDINGS OF PH

Symptoms include dyspnea on exertion and fatigue and can be nonspecific, making early diagnosis difficult. Physical exam reveals a loud 2nd heart sound (P_2 component is accentuated), tricuspid regurgitation, and RV heave.

Tricuspid regurgitation is common with PH and is due to the dilation of the RV (holosystolic murmur along the LLSB that increases with inspiration and a parasternal heave). The tricuspid regurgitation and RV failure present as jugular venous distention (JVD) with large v waves, liver pulsations, and lower extremity edema.

DIAGNOSIS OF PH

The chest x-ray can provide clues in an undiagnosed case. Significant PH manifests on the chest x-ray as enlargement of the central pulmonary arteries with attenuation of the peripheral vessels, resulting in oligemic, darker lung fields ("pruning" on chest x-ray). Use V/Q scan to evaluate for chronic thromboembolic disease as a cause of PH; this can be missed on a CT chest with contrast.

The ECG shows a right axis deviation (from right ventricular hypertrophy). The 1st tests to order when you suspect PH are an ECG and an echocardiogram.

The echocardiogram is useful in the workup of PH to evaluate for:

- Elevated pulmonary artery pressure (and to estimate RV systolic pressure)
- Right ventricular hypertrophy and RV dilation/dysfunction
- Right atrial enlargement (RAE) and right atrial size
- Shift of interventricular septum toward the left during systole

It can also rule out congenital cardiac pathology and evaluate for anatomical shunting through a cardiac defect.

If the echocardiogram is suggestive of pulmonary hypertension, right heart catheterization is the next best step. For a positive diagnosis, the mean pulmonary artery pressure is ≥ 20 mmHg and PCWP ≤ 15 mmHg.

An additional finding in the diagnosis of Group 1 PAH is pulmonary vascular resistance > 3 WU.

Remember that most pulmonary function parameters are normal in PH, but the DLCO decreases. Know that a very low DLCO indicates a poor prognosis in patients with PH.

TREATMENT OF PH

Exercise, Diuretics, and Oxygen

Exercise is encouraged based on the individual's symptom limitations and improves quality of life and functional capacity.

Diuretics are recommended for fluid overload.

Oxygen helps symptoms in any WHO group when the patient is hypoxemic. Give oxygen to all who meet the criteria as discussed under [Treatment of Stable COPD on page 6-24](#).

Balloon atrial septostomy, double-lung transplantation, and heart-lung transplantation are considered when symptoms remain Class 3 or 4 despite maximal combined medical therapy for Group 1.

Vasodilators in PH

Note

The recommendations of the 2015 Joint Task Force of the European Society of Cardiology (ESC) and European Respiratory Society are as follows: Pharmacologic agents for reducing PH are intended for Group 1 PAH.

Calcium Channel Blockers

Calcium channel blockers (CCBs) can be used in the small number of patients who have positive vasoreactivity testing.

Vasoactive reactivity testing looks for a response to a CCB during right heart catheterization for a specific subset of Group 1 PAH (idiopathic, hereditary, toxins, and drugs). Amlodipine, nifedipine (for relative bradycardia), and diltiazem (for relative tachycardia) are used, and selection is guided by underlying heart rate. Vasoreactivity is confirmed by a reduction in mean pulmonary artery pressure (mPAP) ≥ 10 mmHg to reach an mPAP of ≤ 40 mmHg, with the same or increased cardiac output, and minimal change in systemic blood pressure. Commonly used agents include inhaled nitric oxide (the preferred agent), epoprostenol, adenosine, and iloprost. Patients without documented vasoreactivity should not be started on a CCB due to risk of syncope and RV failure.

Endothelin Receptor Antagonists

Bosentan (Tracleer), ambrisentan (Letairis) and macitentan (Opsumit) are oral endothelin receptor antagonists. Endothelins are vasoconstricting polypeptides released by an injured endothelium and are elevated in patients with PH and heart failure. Medications in this category tend to be very well tolerated.

Prostanoids

Continuous IV (pump) infusion of epoprostenol (Flolan, Veletri) and treprostinil has been approved and is recommended as 1st line therapy for NYHA Class IV disease.

These medications have been shown to yield good results for functional Class III also, but there are many other agents from which to choose for Class III disease.

Know that patients getting IV epoprostenol or treprostinil exhibit tachyphylaxis and require a slow ramp-up of the dosage over time.

Inhaled vasodilators iloprost (Ventavis) and treprostinil can help reduce the side effects of IV prostanoids, but improvement in survival has not been demonstrated.

Oral medications in this group are selexipag (Uptravi), a prostacyclin receptor agonist, and treprostinil (Orenitram), a prostacyclin analogue.

PDE-5 Inhibitors

Sildenafil (Revatio, Viagra), tadalafil (Adcirca, Cialis), and vardenafil inhibit cyclic guanosine monophosphate (cGMP) phosphodiesterase Type 5 (PDE-5) in smooth muscle of the pulmonary vasculature, where PDE-5 is responsible for the degradation of cGMP. Increased cGMP concentration results in pulmonary vasculature relaxation and vasodilation in the pulmonary bed.

Guanylate Cyclase Stimulators

Guanylate cyclase stimulators are used for chronic thromboembolic pulmonary hypertension (CTEPH) and portopulmonary hypertension. Do not combine this with PDE-5 inhibitors. The 1 drug available so far is riociguat (Adempas).

Prostacyclin Oral Agents

Selexipag is a nonprostanoid, selective oral prostacyclin receptor agonist for the long-term treatment of PAH in adults. Treprostinil is an oral prostacyclin analogue used for long-term treatment of PAH.

Caution: Many of these medications have significant drug interactions. For example, ritonavir, amiodarone, and fluconazole can increase bosentan levels, and bosentan can decrease amiodarone levels. Expert guidance is suggested.

- Which specific tests for *M. tuberculosis* are available to diagnose tuberculosis (TB) using pleural fluid?
- Which diagnostic tests are done for suspected pleural TB?
- What is the definition of hemothorax?
- Define chylous effusion. What causes it?

EXUDATIVE vs. TRANSUDATIVE

Pleural effusions (Figure 6-19) are either transudative or exudative. They are distinguished by comparing total protein and LDH in the effusion to that in the serum. Also, LDH level (in units/L) in the effusion is an independent indicator. One can send labs in 2 stages or, as is more commonly done, send all at once, particularly if the etiology is not clear or if there is concern for infection (i.e. empyema and/or parapneumonic effusion).

Figure 6-19: PA chest—right-side pleural effusion
Source: Vinay Maheshwari, MD

A **transudative effusion** is secondary to **systemic** changes that affect the accumulation and absorption of pleural fluid. The most common causes are LV failure, hypoalbuminemia, cirrhosis, and nephrotic syndrome.

An **exudative effusion** is due to a **local** cause, and the 2 most common are bacterial pneumonia and cancer—but remember PE, even though it is not as common. [Table 6-13 on page 6-50](#) details the results of fluid studies that help determine whether a pleural effusion is a transudate or an exudate. These biochemical measurements and ratios are called Light's criteria. Note that **all 3** conditions must be met for an effusion to be called a transudate—failing any 1 criterion makes it an exudate.

Put another way, only 1 Light's criterion is needed to qualify as exudative effusion.

PLEURAL EFFUSIONS

PREVIEW | REVIEW

- Name the most common causes of transudative pleural effusions.
- Which 3 conditions must be met for an effusion to be called a transudate?
- Which clinical and laboratory features make a pleural effusion complicated?
- What is the definition of empyema?

Table 6-13: Light's Criteria for Pleural Effusions

	Eff:Serum Protein Ratio		LDH in Effusion		Eff:Serum LDH Ratio
Transudative	≤ 0.5	and	≤ 200 U/L (3.34 μkat/L)	and	≤ 0.6
Exudative	> 0.5	or	> 200 U/L (3.34 μkat/L)	or	> 0.6

Concern over using LDH as a parameter twice in Light's criteria has given rise to alternate diagnostic criteria for exudates:

- The 2-test rule: pleural cholesterol > 45 mg/dL (1.17 mmol/L) or pleural LDH > 0.45× the upper limit of your lab's normal for LDH
- The 3-test rule: pleural protein > 2.9 g/dL (29.00 g/L), pleural cholesterol > 45 mg/dL (1.17 mmol/L), or pleural LDH > 0.45× the upper limit of your lab's normal for LDH

Transudative effusions and/or the underlying causes are usually treated with diuresis and sometimes with albumin.

Exudative effusions require further tests of the fluid to establish the cause. For this reason, you want to send several tubes of pleural fluid to the lab. Evaluate the 1st tube, then tell the lab to save the rest. Once you know the type of effusion, you can then decide on the other tests, if your lab will do such 2-stage testing. If not, the tests discussed below can be sent all at once. If there is concern for a parapneumonic effusion, the pertinent labs should be sent at once, including pleural fluid pH, cell count, glucose, LDH, cholesterol, and protein.

Transudative Effusions

Transudative effusions do not need further evaluation.

Know that **LV failure** is the #1 cause, and it is not unusual to see an isolated right-sided effusion. Transudative effusions are common after abdominal surgery and are typically benign.

In patients without obvious heart failure, perform a thoracentesis on unilateral, asymmetric, or diuretic-nonresponsive effusions of significant size.

Generally, do **not** tap bilateral effusions that are equal in size and responsive to diuretics occurring in patients with well-established LV failure, cirrhosis, hypoalbuminemia, or nephrotic. The overwhelming majority of these are transudates.

Relief of dyspnea after therapeutic thoracentesis for an effusion is due to a **decrease** in the intrathoracic volume! This is because most of the volume occupied by a pleural effusion distends or displaces the diaphragm, causing the dyspnea. Only ~ 20% of the volume results from compression of the lung. Know that the

removal of a large amount of pleural fluid can actually be accompanied by a transient fall in the pO₂ during the first 12 hours, until atelectatic alveoli can reexpand and participate in gas exchange. In some cases, with removal of at least 1.4–2 L, reexpansion pulmonary edema may develop.

Exudative Effusions

Once you determine that your fluid is an exudate, tell the lab to do the following studies on the remaining fluid you sent (or, with high suspicion for exudate, malignancy, or infection, obtain all labs at once):

- Glucose and amylase; consider triglyceride level
- Cholesterol
- Cell count with differential
- Gram stain and bacterial culture
- Cytology
- pH
- Marker for tuberculosis (e.g., adenosine deaminase level) if available and if there is suggestive clinical information
- Analyze the serum/pleural fluid albumin ratio.
- If the above studies do not help you with diagnosis, consider CTPA to evaluate for PE.

These studies, plus the clinical history and exam, help you determine the most likely cause, which we will discuss in the next topic. In general, when there is high suspicion for infection (i.e., empyema, parapneumonic effusion), the pleural fluid should be promptly sampled and labs sent all at once to avoid delaying any necessary intervention.

Bacterial pneumonia is the most common cause of an exudative effusion in the U.S. The effusion develops in association with **bacterial** pneumonia or lung abscess. Consider the possibility of effusion every time you consider bacterial pneumonia as a diagnosis for a dense infiltrate on chest x-ray. If clinical evidence of effusion is present in the setting of pneumonia, quantify the size using imaging (decubitus chest x-ray, CT, or U/S). The key is **10 mm**! If there is > 10 mm of fluid from the lung surface to the chest wall, the patient may need a thoracentesis to determine if there is an empyema or complicated parapneumonic effusion.

A **complicated** effusion is diagnosed if any of the following are found on analysis of the therapeutic thoracentesis fluid:

- Loculations on imaging
- pH < 7.20
- Glucose < 60 mg/dL (3.33 mmol/L)
- Positive Gram stain or culture

The treatment of a complicated effusion generally requires chest tube drainage. This removes the bulk of the inflammatory material and organisms to give the

patient the best chance to heal. In some cases, this type of effusion may progress to empyema, which requires tube thoracostomy drainage or, in some cases, surgery.

Transudative effusions can be misclassified as exudates using Light's criteria when a patient with heart failure has been receiving diuretics.

Empyema is the diagnosis when visible frank pus is found in pleural space. Treatment options include tube thoracostomy with IV antibiotics and, if not successful, a brief trial of intrapleural tPA and DNase for persistent loculations to avoid decortication. Otherwise proceed to VATS or open thoracostomy with decortication.

Malignancy is the 2nd most common cause of an exudative effusion. The most common malignant pleural effusions are **lung** cancer (1/3), **breast** cancer (1/4), and **lymphoma** (1/5). (Lung, breast, lymphoma... 1/3, 1/4, 1/5.)

In a pleural-based malignancy, repeated cytologic examination of the effusion fluid has as high a yield as pleural biopsy! 3 effusion samples have a combined yield of > 90%. Larger volumes sent for cytology have greater yield than relatively small samples. Thoracoscopy is done if the repeat cytologies are negative. Closed pleural biopsies are rarely needed anymore to diagnose cancer. The main use for a closed pleural biopsy is to diagnose pleural TB.

Less common (but important!) causes of exudative pleural effusions are mesothelioma, PE, viral infections, and TB.

Mesothelioma: Think about mesothelioma (most often related to asbestos exposure) in patients with dyspnea, chest pain, and a grossly **hemorrhagic** pleural effusion with pleural thickening or mass, most commonly with an occupational history of asbestos exposure.

Pulmonary embolism: Consider this in the dyspneic patient with an exudative effusion showing normal fluid amylase, glucose > 60 mg/dL (3.33 mmol/L), normal or slightly increased cell count and differential, and a Gram stain showing no organisms. These effusions may be hemorrhagic. Pleural effusion caused by PE is often missed clinically! There may be more compelling clinical reasons in the initial evaluation of such a patient that may suggest a PE.

Viral infection: Many viruses cause **self-resolving** pleural effusions. Think of a probable viral cause in someone who improves quickly without intervention.

Tuberculosis: Think of tuberculous effusion in the patient with risk factors for **primary** TB and additional history of fevers and wasting. Pleural fluid cell count is usually **lymphocytic**. AFB smear and culture of the pleural fluid have a low yield (20–30% in HIV negative), so the strategy incorporates mycobacteria-specific tests. For suspected pleural TB, order pleural adenosine deaminase (ADA; if available), serum interferon-γ release assay (IGRA), nucleic acid amplification (NAA) *Mycobacterium tuberculosis* direct (MTD), Xpert MTB/

RIF, or MTBDRplus (detection of TB and determination of rifampin or INH resistance).

If you do not have these special tests available, or the above testing is negative despite a high clinical suspicion, a **pleural biopsy may be done**. Send your tissue for routine pathology with AFB stains and send a sample for AFB smears and culture. Aside from the special mycobacteria-specific tests described above, obtaining pathology + cultures of pleura is the approach with the highest diagnostic yield for TB (between 65 and 90%; higher than any single approach).

In clinical practice, closed pleural biopsies are rarely performed in the U.S. Most of the pleural sampling procedures are done with VATS, which has a high diagnostic yield and can be used for both pleural fluid sampling and pleural biopsy.

Again: To diagnose cancer, use repeated taps and cytology. To diagnose TB on a pleural effusion, use special tests and pleural or VATS biopsy.

And a weird one: Think about **yellow nail syndrome** if the patient has a history of chronic peripheral edema and chronic exudative pleural effusions (often chylothorax). Patients with this genetically transmitted syndrome also have yellow, dystrophic nails.

Some Key Effusion Findings

Some clues to help you remember cell count and differential findings:

- WBCs > 1,000/μL ($1 \times 10^9/L$): Think exudate.
- WBCs > 10,000/μL ($10 \times 10^9/L$): Think complicated parapneumonic effusion.
- WBCs > 100,000/μL ($100 \times 10^9/L$): Think empyema or pus.
- Mesothelial cells normally line the cavity and are occasionally confused with malignant cells. There is a consistent finding that there are very few mesothelial cells with a tuberculous pleural effusion. So, if a high **mesothelial** cell count is reported in the fluid, then TB is highly **unlikely** to be the cause.
- Eosinophils > 10%: Think of pneumothorax, hemothorax, drug reaction, postthoracotomy, TB, paragonimiasis (trematode—fluke) or other parasites, fungal infection, and benign asbestos-related pleural disease.
- Lymphocyte predominance: Think of TB, malignancy, chronic inflammatory (i.e., rheumatoid, sarcoid), yellow nail syndrome, or chylothorax.
- Neutrophil predominance: Think of acute pneumonia, pancreatitis, PE, and peritonitis.
- Know the specific definition of hemothorax: grossly bloody pleural effusion with a hematocrit > 50% of the hematocrit of the peripheral blood. Think of trauma!

For fluid chemistry findings:

- Glucose ~ 80 mg/dL (4.44 mmol/L): Think TB.
- Glucose ~ 60 mg/dL (3.33 mmol/L): Think cancer or empyema.

- Glucose < 30 mg/dL (1.67 mmol/L): Think rheumatoid arthritis or empyema.
- Amylase is increased in pancreatic fistula and esophageal rupture (salivary amylase).
- Adenosine deaminase (ADA) concentrations (especially isoenzyme ADA-2) are elevated in tuberculous pleural effusions. (Conversely, ADA level < 40 U/L [666.68 nkat/L] is rarely TB.) This test is used as a diagnostic aid when a TB effusion is suspected but other tests are negative. Other tests include the IGRA and low-sensitivity, high-specificity PCR to identify TB DNA.

What if the pleural fluid is milky white, but not pus? Chylous effusions are white-colored, exudative effusions with a triglyceride level > 110 mg/dL (1.24 mmol/L; due to fat globules; i.e., chylomicrons). The chylous effusions are due to leakage of thoracic duct lymph. Think **trauma** and **cancer (especially lymphoma)**. Imaging studies of the mediastinum will help define the etiology.

Pseudochylous pleural effusions are caused by chronic inflammatory processes, especially TB and rheumatoid arthritis lung disease. Triglycerides in pseudochylous effusions are < 50 mg/dL (0.56 mmol/L). Total cholesterol is > 65 mg/dL (1.68 mmol/L) because the white color is due to cholesterol, not chylomicrons. Neither the chylous nor pseudochylous specimens clear with centrifugation.

PNEUMOTHORAX

PREVIEW | REVIEW

- Which conditions can result in secondary pneumothorax?

Classically, primary spontaneous pneumothorax (PSP) was thought to most commonly affect tall, slender, often smoking men 20–40 years of age. With high-resolution CT, we know that many of these patients have subpleural emphysematous blebs that rupture, causing spontaneous pneumothorax.

Secondary spontaneous pneumothorax (SSP) can be caused by:

- COPD/Emphysema (the most common cause)
- *Pneumocystis* pneumonia in AIDS patients
- Cystic fibrosis
- Langerhans cell histiocytosis (LCH)—smoking males
- Lymphangioleiomyomatosis (LAM)—exclusively premenopausal women
- Barotrauma—In the past, up to 10–15% of patients on mechanical ventilators developed barotrauma, including pneumothorax, though this has been reduced by the use of lung protective ventilation strategies (i.e., low tidal volumes of 6–8 mL/kg predicted body weight [PBW]).

Presenting symptoms of PSP and SSP are similar and include dyspnea and chest pain. SSP symptoms may be more severe due to underlying lung disease. Physical exam can show decreased breath sounds but often may not be helpful with underlying lung disease. Chest x-ray is the 1st and often only test needed for diagnosis. CT is useful if the diagnosis is still in question. In the ER or ICU, the most rapid and sensitive test for pneumothorax on a ventilator is bedside ultrasound. The ultrasound will also guide the placement of a chest tube, if needed.

Initial treatment: If the pneumothorax is small (< 15–20% or < 2 cm) and the patient is stable, observe and give the patient high-flow O₂. Giving high-flow O₂ may increase the rate of reabsorption (vs. inhalation of room air).

If the pneumothorax is larger (> 2 cm) or the patient is symptomatic or hypoxic, consider placement of a small anterior chest tube. In an emergent setting, this can consist of an IV catheter inserted in the 2nd intercostal space, aspirated, and either put on water seal or connected to low suction. A chest tube is mandatory in pneumothorax patients receiving positive pressure ventilation, regardless of the size of the pneumothorax, due to the risk of tension pneumothorax!

Here's a review of the chest tube drainage system components (Figure 6-20).

Figure 6-20: Chest tube drainage system

1st chamber (nearest the patient) = **collection chamber**—this is where effluent from the pleural cavity is collected.

2nd chamber (the middle) = **water seal chamber**—this allows air to bubble out from the pleural cavity but does not allow air into the chest. Bubbles in this chamber indicate air is in (or still entering) the pleural space. Or consider a leak in the chest tube itself!

3rd chamber (attached to suction) = **suction regulator**—the height of water determines the amount of suction on the chest tube (when vacuum is applied to the chamber and there is bubbling in the water of the chamber).

A persistent air leak for > 7 days suggests a leak in the chest tube, an alveolar-pleural fistula, or a broncho-pleural fistula, which requires surgical intervention and pleurodesis to prevent recurrences.

Recurrence rate for PSP is 28%, while that for SSP is 43%. Risk of mortality is 1–4% for PSP and up to 17% for SSP.

Recurrence prevention: Pleurodesis decreases the recurrence rate significantly. Pleurodesis is **not** usually done with the 1st episode of SSP, but there is more evidence suggesting that you should do pleurodesis for even the 1st occurrence of PSP due to the recurrence rates. Adjacent parenchymal blebs may influence this decision. Talc is the best and cheapest agent for pleurodesis. Doxycycline and minocycline are next. Often pleural abrasion with gauze accomplishes the pleurodesis effectively.

PNEUMONIAS

OVERVIEW

Pneumonia is categorized in 1 of 3 ways:

- 1) Community-acquired pneumonia (CAP)
- 2) Hospital-acquired pneumonia (HAP)
- 3) Ventilator-associated pneumonia (VAP)

In the 2016 Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS) guidelines, the concept of health care-associated pneumonia (HCAP) was removed in favor of HAP and VAP.

COMMUNITY-ACQUIRED PNEUMONIA (CAP)

PREVIEW | REVIEW

- Identify the organisms that cause typical and atypical community-acquired pneumonia (CAP).
- Detail the characteristics that a sputum sample must have to be considered an adequate specimen.
- List the tests that you need to order for patients with severe or unresponsive CAP.
- A patient who works on an animal farm develops pneumonia. Which organism should you think about?
- Which organism should you consider if pneumonia develops in a patient who spent an afternoon in a bat cave in Mississippi?
- Which organism should you think about if pneumonia develops in a patient who drove through an Arizona dust storm?
- Which organism should you consider if a chronic, cavitating pneumonia develops in a male logger from Arkansas?
- Name 2 drugs recommended to treat CAP in outpatients without risk factors for drug-resistant *S. pneumoniae* (DRSP).

- Name 3 regimens recommended to treat inpatient CAP in the non-ICU patient.
- Which antibiotics do you use for empiric treatment of the ICU patient with cavitary pneumonia and risk factors for *P. aeruginosa*?
- What are the diagnostic possibilities for the unresponsive patient with apparent pneumonia?

CAP can be organized into 2 groups based on the organisms that cause disease:

- 1) **Typical** CAPs are due to organisms such as pneumococcus, *H. influenzae*, *Staphylococcus aureus*, gram-negative rods (GNRs), and *Moraxella catarrhalis*.
- 2) **Atypical** CAPs are due to bacteria (i.e., *Mycoplasma*, *Chlamydophila*, *Legionella*), viruses (e.g., flu, adeno, RSV, parainfluenza, rhino), and endemic fungi (e.g., cocci, histo, blasto). Atypical pathogens cannot be identified by Gram stain or routine bacterial culture (require special media) and/or are resistant to β -lactam antibiotics, which are 1st line drugs for empiric treatment of CAP.

The etiology for CAP is determined in about 38% of cases (viruses [*Rhinovirus* leading] detected in 27% and bacteria [*Streptococcus pneumoniae* leading] detected in 14%). There are some risk factors that predispose to certain pathogens (see [Pathogens on page 6-55](#)).

In 2019, the IDSA/ATS came together to issue guidelines for evaluating, diagnosing, and treating CAP. Think about CAP from 2 perspectives:

- 1) **Empiric** treatment (when the organism is not known)
- 2) **Pathogen-directed** treatment (when it is known)

Presentation of CAP

Symptoms are variable (from mild to severe) and include fever, anorexia, sweats, dyspnea, sputum production, cough, and pleurisy. Nausea, vomiting, and diarrhea occur in 20%. **Elderly** patients are also often **confused**.

Exam findings include tachycardia, tachypnea, evidence of consolidation (i.e., increased tactile fremitus, bronchial breath sounds, crackles), and/or parapneumonic effusion (decreased tactile fremitus and percussion).

There is **overlap** in signs and symptoms caused by typical and atypical pathogens—so you cannot reliably use the history of symptoms or the chest x-ray findings to differentiate typical from atypical pathogens.

Diagnosis of CAP

Per the IDSA/ATS 2019 guidelines, the initial workup of CAP is very **limited**. A more **aggressive** workup is recommended for patients:

- with risk factors for severe disease (e.g., underlying structural lung disease or uncontrolled comorbidities),
- with a severe presentation (requiring ICU), or
- who are unresponsive to empiric treatment.

Diagnostic Tests

Chest x-ray is required for diagnosis of CAP. Some confusion in reading the x-ray can result from coexisting HF, COPD, or malignancy. Remember that an infiltrate may not appear in a volume-depleted patient until after the patient is volume resuscitated or in a neutropenic state. For a comparison of lower lobe and middle lobe pneumonia, see [Figure 6-21](#) and [Figure 6-22](#).

Do a **sputum Gram stain and culture** in patients with:

- severe or unresponsive CAP,
- COPD or structural lung disease,
- failed outpatient antibiotic therapy,
- a history of alcohol abuse,
- immune compromised systems,
- illness requiring hospitalization,
- cavitary infiltrates, and/or
- a pleural effusion.

In the intubated patient, send a deep-suction endotracheal aspirate to the lab as soon as possible because targeted antibiotics in the ICU **do** affect outcome for these inpatients, whereas outpatients do just as well with empiric therapy. Add an acid-fast stain if tuberculosis is in your differential based on the presentation and chest x-ray. Do **not** do sputum tests on those patients who do not meet these indications or on outpatients with CAP.

Sputum interpretation: The culture and sensitivity results are accurate only if there are > 25 neutrophils and < 10 epithelial cells per low power field. If more epithelial cells are present, then it is contaminated from the mouth. If the patient gives you a cup with what looks like saliva mixed with a few

mucoid globs, fish out these goobers and send them to the lab (higher yield)!

Order **blood cultures** for patients with:

- sepsis,
- severe or unresponsive CAP,
- illness requiring hospitalization,
- COPD,
- liver disease,
- a history of alcohol abuse,
- cavitary infiltrates,
- asplenia,
- pleural effusion,
- leukopenia, and/or
- a positive pneumococcal urine antigen test.

Do **not** do blood cultures in admitted CAP patients who do not meet these indications or in outpatients.

Other tests: In patients with severe CAP, add urine antigen tests for pneumococcus and *Legionella* to the blood and sputum cultures.

Figure 6-21: LLL pneumonia
Source: Vinay Maheshwari, MD

Figure 6-22: RML pneumonia
Source: Vinay Maheshwari, MD

Additional admission tests are CBC, chemistry panel, liver function tests, and O₂ saturation.

Serologic tests are usually **not** helpful in the initial evaluation. DNA probes and nucleic acid amplification are **not** indicated.

Treatment of CAP

Remember to think of CAP from 2 perspectives: **empiric** treatment and **organism-specific** treatment. The following treatment discussion is based on the 2019 IDSA/ATS guidelines. As you read, see the summary in Figure 6-23 on page 6-56.

Empiric Treatment of CAP

Empiric treatment is started before pathogen identification and is based on:

- **Severity** of the illness and need for hospitalization. See the pneumonia severity index (PSI) in Table 6-14.
- **Likelihood** of a specific pathogen based on associated risk factors

What you prescribe empirically is partly determined by whether the patient will be admitted. (Usually, outpatients = oral, and inpatients = parenteral.)

The PSI scoring class can supplement the clinician's decision if the patient needs to be admitted to the hospital based on risk of mortality. Scoring Class 1 is for those < 51 years of age with no comorbidities. For Classes 2–5, comorbidities are a factor in score calculation. Factors such as ability for oral intake, cognitive impairment, or homelessness also play a role in decision-making.

A rapid 5-point scoring system applying to patients ≥ 65 years of age to aid in the decision to admit or not is the CURB-65 (confusion, uremia, respiratory rate, blood pressure, and age ≥ 65 years) scale. Each parameter represents 1 point. If the score sums to > 1 point, then consider hospitalization or close follow-up.

Pathogens

Remember that treating empirically means treating on the basis of an educated guess about the causative organism. The most commonly seen pathogens in CAP are *S. pneumoniae* and viruses. For discussion of specific pathogens, see **Typical Organisms of CAP** on page 6-57 and **Atypical Organisms of CAP** on page 6-60.

In addition, know these **organism-specific** associations:

- COPD or immunoglobulin deficiency (especially IgG): *Moraxella catarrhalis* and *H. influenzae*
- Cattle or sheep exposure: *Coxiella burnetii* (Q fever)
- Bird fanciers: *Chlamydophila psittaci* (psittacosis)
- Hunters: *Francisella tularensis* (tularemia)
- Bat caves, especially in the Mississippi and Ohio River valleys: *Histoplasma capsulatum* (histoplasmosis)

Table 6-14: The Pneumonia Severity Index (PSI)

	Findings	Points Assigned
Demographic Factors	Males	Age (years)
	Females	Age – 10
	Nursing home residents	Age + 10
Comorbid Illnesses	Neoplastic disease	+ 30
	Liver disease	+ 20
	Heart failure	+ 10
	Cerebrovascular disease	+ 10
	Renal disease	+ 10
Physical Exam	Altered mental status	+ 20
	Respiratory rate ≥ 30 bpm	+ 20
	Systolic BP < 90 mmHg	+ 20
	Temp < 95°F (35°C) or ≥ 104°F (40°C)	+ 15
	Pulse ≥ 125 bpm	+ 10
Laboratory	pH < 7.35	+ 30
	BUN ≥ 30 mg/dL	+ 20
	Na ⁺ < 130 mEq/L (130 mmol/L)	+ 20
	Glucose ≥ 250 mg/dL (13.9 mmol/L)	+ 10
	Hct < 30%	+ 10
	P _a O ₂ < 60 mmHg or O ₂ sat < 90%	+ 10
	Pleural effusion	+ 10
Scoring	Points	Mortality (%)
1	0	< 0.1
2	< 70	≥ 0.6
3	71–91	≥ 0.9
4	91–130	≥ 9.3
5	> 130	≥ 27

- Travel to California or Southwest: *Coccidioides immitis* (coccidioidomycosis)
- Living in or travel to the southeast, mid-Atlantic, and central states—especially Illinois and Arkansas, but often associated with hunting or working in wooded areas: *Blastomyces dermatitidis* (blastomycosis)
- Risk factors for HIV/AIDS or other immunocompromise: *Pneumocystis jirovecii* pneumonia (PJP) and TB
- Chronic disease, immunosuppression, and alcoholism: gram-negative organisms
- Diabetes, cancer, kidney disease, HIV/AIDS, or a recent cruise ship or hotel stay in winter or summer: *Legionella*

Empiric Antibiotics

As we go through this discussion for the treatment of CAP, see [Figure 6-23](#). Know that identifying the specific microbial cause of CAP is expensive and difficult (successful < 50% of the time).

Except in ICU cases, no data has shown that targeted treatment of a specific organism is superior to empiric treatment of possible organisms. Therefore, empiric treatment is accepted as appropriate and is initially preferred in guideline-directed therapy rather than attempting to diagnose the specific pathogen. Guideline-directed therapy leads to improved outcomes, with shorter hospital stay, decreased mortality, and more rapid improvement. This is why sputum cultures are done only in special cases.

Outpatients

The majority of patients with CAP are treated as outpatients, based on a severity index indicating low risk, with either macrolides (**azithromycin** or **clarithromycin**) or **doxycycline**. Note that erythromycin is a choice, but GI side effects limit its use, and it is less effective against *H. influenzae* than the advanced macrolides. Azithromycin has antiinflammatory properties and is associated with more ICU-free days in patients with severe sepsis, with pneumonia.

If the patient has risk factors (see *Streptococcus pneumoniae* [Pneumonia](#)) for drug-resistant *S. pneumoniae* (DRSP) or has comorbidities that can affect outcome (i.e., modifying factors), use a respiratory quinolone or high-dose amoxicillin (because the resistance can sometimes be overcome with larger β -lactam doses) plus a macrolide. An alternative is to pick an oral cephalosporin with known activity against DRSP plus a macrolide. Doxycycline can be substituted for

* Modifying factors = Risks for DRSP (age > 65 years, β -lactam Rx within past 3 months, alcoholism, immunosuppression, exposure to child in day care), and/or any of following comorbidities: COPD, diabetes, renal or heart failure, malignancy

β -lactam choices for outpatients (oral): high-dose amoxicillin or amoxicillin/clavulanic acid in patients with risk factors for DRSP; alternatives: cefpodoxime or cefuroxime

β -lactam choices for inpatients (intravenous): cefotaxime or ceftriaxone

AG = aminoglycoside (gentamicin, tobramycin, or amikacin)

AZI = azithromycin

Carbapenem = imipenem or meropenem

CEF = cefepime

CLARI = clarithromycin

DOXY = doxycycline

P-T = piperacillin-tazobactam

QR = respiratory quinolone (levofloxacin, gemifloxacin, or moxifloxacin)

DRSP = Drug-resistant *Streptococcus pneumoniae*

Figure 6-23: Treatment of outpatient and inpatient community-acquired pneumonias

the macrolide. If the patient cannot tolerate a β -lactam or quinolone, lefamulin, a new FDA-approved (2019) antibiotic, can be chosen as monotherapy.

Inpatients

Non-ICU inpatients are treated intravenously with a respiratory fluoroquinolone; **or** cefotaxime, ceftriaxone, or ampicillin-sulbactam; **or** ertapenem **plus** either a macrolide **or** doxycycline **or** ceftaroline. If the patient is at risk for influenza, *Pseudomonas*, or CA-MRSA, refer to Figure 6-23 for empiric antibiotic choices. Start treatment **immediately** once you determine that admission is necessary.

ICU patients (with no risk factors for *Pseudomonas*) are treated with intravenous cefotaxime, ceftriaxone, or ampicillin-sulbactam **plus** a respiratory fluoroquinolone **or** a macrolide.

If the ICU patient has risk factors for *P. aeruginosa*, start:

- piperacillin-tazobactam, or
- cefepime, or
- a carbapenem (imipenem or meropenem)

Plus:

- ciprofloxacin or levofloxacin, or
- an aminoglycoside and a respiratory fluoroquinolone, or
- an aminoglycoside and azithromycin.

If CA-MRSA is suspected based on historical risk factors, add linezolid or vancomycin. Start treatment immediately.

Narrowing Empiric Therapy

By day 3, you know whether your patient is improving, and you might have an organism identified if you sent any specimens for microbiology (i.e., sputum and blood cultures, urine antigen tests).

If the lab identifies an organism, narrow the treatment to focus on that organism. Switch to oral medications if patient is improving with stable BP and PO tolerance.

Treatment varies from 5–7 days depending on the antibiotic selected, but duration may extend to 7 days for HAP or VAP or even longer if the patient is in an immunocompromised state or there is slow clinical improvement. Follow up with a chest x-ray about 4–6 weeks after discharge and consider malignancy in the patient who has persistent lung abnormalities.

If your patient deteriorates over the first 3 days on empiric treatment, think of these possibilities:

- You have the **wrong diagnosis**, and it is not an infectious infiltrate (e.g., PE, HF, collagen vascular disease, hypersensitivity pneumonitis).
- Your empiric regimen is **not covering** the causative organism. Revisit the list of risk factors and associations. What did you miss? If you are giving the right drugs, are you giving the correct doses?

- There is a **new infection** in addition to the original one (e.g., staphylococcal pneumonia in addition to an original viral pneumonia). Think empyema if a parapneumonic effusion was present on admission or even if it was not there initially, since effusions can sometimes develop or enlarge during treatment. Chest x-rays that demonstrate development of pneumatoceles (thin-walled cysts) or lung abscesses over the first few days should make you think pneumococcus, CA-MRSA, and *Pseudomonas*.

TYPICAL ORGANISMS OF CAP

PREVIEW | REVIEW

- Which patients are at increased risk for infection with drug-resistant *S. pneumoniae* (DRSP)?
- Name some potential pulmonary complications of pneumococcal pneumonia.
- Describe the patients who should be vaccinated with PPSV23.
- Name some potential complications of staphylococcal pneumonia.
- Which drug choices are available for targeted treatment of *S. aureus* pneumonia
- The bulging fissure sign is seen with which organism that causes pneumonia?
- Which antibiotics must be added for empiric treatment of pneumonia in the ICU patient with risk factors for *Pseudomonas*?
- Describe the microbiologic characteristics of *Moraxella*.

Now let's talk about the individual organisms that cause CAP. We've briefly covered some of this information before, but it's time for a focused discussion.

It is important to know which organisms are common in your area and what the local antibiotic resistance patterns are when making empiric treatment decisions. This information may be available to you from your hospital microbiology lab in the form of an **antibiogram**.

Streptococcus pneumoniae Pneumonia

Pneumococci live in the nose and throat of up to 40% of healthy children. Any adult who has contact with children, day care centers, and other crowded conditions (e.g., military barracks, dormitories, homeless shelters, prisons) is at risk for becoming colonized and subsequently infected with *S. pneumoniae*.

Children who receive frequent antibiotic prescriptions for viral illnesses are a source of drug-resistant strains because the colonizing organisms mutate under the drug's selective pressure. Upper respiratory inflammation from a cold virus in the colonized patient then sets the stage for bacterial pneumonia and/or sinusitis.

Patients most at risk for pneumococcal disease are > 65 years of age or have comorbidities (e.g., diabetes, alcoholism, and lung, heart, or renal disease). Asplenic patients (e.g., sickle cell) and patients with humoral immunodeficiencies (e.g., AIDS, myeloma, chronic lymphocytic leukemia [CLL], lymphoma) are especially at risk because pneumococci are encapsulated organisms.

DRSP is linked with age ≥ 65 years, recent (within 3 months) β -lactam therapy, alcoholism, immunosuppression, multiple comorbidities, and exposure to a child in day care. DRSP generally refers to resistance against penicillins, macrolides, tetracyclines, cephalosporins, TMP/SMX, and, rarely, fluoroquinolones.

In addition to the generic signs and symptoms of pneumonia, think pneumococcus if your at-risk patient presents with shaking chills, pleuritic chest pain, and rust-colored sputum. CBC reveals a high WBC count. (Leukopenia carries a higher mortality risk.) Chest x-ray often shows lobar consolidation; see Figure 6-24. The diagnosis of *S. pneumoniae* pneumonia is supported when a good-quality sputum Gram stain identifies the lancet-shaped gram-positive diplococci and the organism is grown in sputum culture. A positive blood culture or pneumococcal urinary antigen test is diagnostic. Blood cultures are positive in 25% of hospitalized cases of pneumococcal pneumonia.

Figure 6-24: Round pneumonia (often seen in pneumococcal pneumonia)

Source: Vinay Maheshwari, MD

Look out for these complications: lung abscess and empyema in the patient with even potential parapneumonic effusion.

Pneumatocoles are thin-walled, air-filled cysts that develop within the lung parenchyma. They are most often the sequela of acute pneumonia, and they can develop secondary to trauma and positive pressure ventilation. The possible etiology of the infectious type is due to the inflammation of the pneumonia that causes a narrowing of the bronchus and partial epithelial sloughing. This leads to the formation of an endobronchial flap or ball valve effect with a one-way airflow, leading to distal dilation of the bronchi and alveoli and occasionally a pneumothorax.

Know that multilobar disease, bacteremia, and peripheral blood WBC $< 6,000/\mu\text{L}$ ($6 \times 10^9/\text{L}$) indicate increased mortality.

Do not forget about the evolving resistance.

DRSP strains are treated with a cephalosporin with known activity against DRSP, a respiratory quinolone, or higher doses of a β -lactam (with hopes of overcoming the resistance—a useful strategy if the infection is not severe).

There are 2 vaccines licensed for pneumococcal disease in the U.S.: the 23-valent polysaccharide vaccine (PPSV23, which contains 23 prevalent serotypes) and the 13-valent protein conjugate vaccine (PCV13, which contains 13 serotypes).

Administrative timing for these vaccines varies depending on whether the patients are > 65 years of age, whether they have been vaccinated before, and which vaccine they received initially. Comorbid conditions also play a role. See the CDC vaccine schedules at cdc.gov/vaccines/schedules.

Haemophilus influenzae Pneumonia

Haemophilus influenzae can be encapsulated or unencapsulated (a.k.a. nontypeable). Due to the widespread use of the Hib vaccination, most *H. influenzae* infections in the U.S. are nontypeable and result from the invasion of these bacteria across the mucous membranes. Pneumonia from nontypeable strains is most often seen in patients with underlying lung disease (i.e., COPD) and AIDS.

Diagnosis: This pneumonia presents generically with fever, cough, and dyspnea. A good sputum sample often demonstrates the organism on Gram stain—pleomorphic gram-negative coccobacilli. Definitive diagnosis is growth of the organism in culture from a normally sterile site (e.g., pleural fluid or blood).

Treatment: Antibiotics effective against *H. influenzae* include amoxicillin/clavulanic acid (ampicillin alone should be avoided due to common resistance, unless susceptibility is demonstrated), 3rd generation cephalosporins, doxycycline, fluoroquinolones, and macrolides. TMP/SMX resistance is 25%.

Staphylococcus aureus Pneumonia

Staphylococcus aureus colonizes the anterior nares and gets distributed to the skin by fingers. Regular *Staphylococcus* strains do not cause problems in immunocompetent patients without skin breaks. However, if the immune system or skin barrier break down, *Staphylococcus* can invade tissues or the blood stream.

There are also particularly virulent strains of *S. aureus*. A Panton-Valentine leukocidin-producing strain (PVL-SA) can cause a virulent necrotizing CA-MRSA infection in immunocompetent patients.

Staphylococcus species can either be susceptible to methicillin (and subsequently to other β -lactams) or resistant to methicillin (MRSA, a surrogate marker for resistance to all β -lactam drugs).

S. aureus CAP is usually seen in patients with a preceding **influenza** infection as a superinfection (although de novo pneumonia due to CA-MRSA occurs). It is also seen in patients with right-sided endocarditis with pulmonary emboli.

Clinical presentation is typical for acute bacterial pneumonia with fever, dyspnea, and cough. However, patients with *Staphylococcus* can have hemoptysis with **salmon-pink** sputum, diffuse lung infiltrates, and pneumatoceles.

Consider a superinfection with *S. aureus* if the history is consistent with a resolving **influenza** infection that worsens with new symptoms of dyspnea and cough.

Think of CA-MRSA in cases of severe pneumonia with pink sputum and pneumatoceles in an immunocompetent patient with poor hygiene or a history of close contact with others.

Diagnosis: As with other pneumonias, diagnosis is supported when gram-positive cocci in clusters are demonstrated on a good sputum sample, followed by the growth of the organism in culture. Blood cultures are helpful if positive, but they are usually negative.

Complications include empyema (frequent), an immune-complex type of glomerulonephritis, and pericarditis.

Treatment: **Methicillin-sensitive** *S. aureus* (MSSA) pneumonia can be treated with a β -lactam. Nafcillin is typically the drug of choice.

Treat **MRSA** pneumonia with vancomycin, telavancin, or linezolid. Daptomycin is **ineffective** for respiratory infections; do **not** use it to treat staphylococcal pneumonia!

CA-MRSA strains often have preserved susceptibility to TMP/SMX, quinolones, and clindamycin. These drugs are fine to use in treating skin infections with CA-MRSA but not lung infections. Use vancomycin or linezolid or telavancin for serious MRSA lung infections.

***Klebsiella pneumoniae* Pneumonia**

A major CAP-causing enteric gram-negative organism is *Klebsiella pneumoniae*. It typically colonizes the oropharynx of those with alcohol use disorder and patients with uncontrolled lung disease or diabetes. It is an uncommon cause of CAP without these risk factors. *Klebsiella* CAP presents with typical features of pneumonia (cough, dyspnea, and fever). As the pneumonia worsens, the lung can become necrotic, and patients get sicker.

Be aware of some buzzwords for this gram-negative pneumonia:

- **Currant jelly** sputum: bloody sputum that resembles jelly
- **Bulging fissure** sign: a lobar consolidation where the affected portion of the lung is overexpanded and causes the abutting fissure to bulge
- **Friedlander** pneumonia: a lobar pneumonia caused by *Klebsiella*

Diagnosis is made by Gram stain and culture of sputum and blood (usually performed because a patient with a gram-negative pneumonia often presents with severe disease and may end up in the ICU).

Treatment: Know that many enteric gram-negatives are either innately resistant to ampicillin or have acquired ampicillin resistance. When you suspect a gram-negative pneumonia, your empiric antibiotic choice should be broad in spectrum (i.e., an extended-spectrum penicillin with a β -lactamase inhibitor, such as piperacillin-tazobactam). This covers most gram-positive organisms until the lab identifies an organism for you. Once cultures identify an organism, you can narrow the treatment based on the susceptibilities. Often, an oral quinolone is adequate to finish therapy.

Pertussis

Adults are the major reservoir for *Bordetella pertussis*. Although pertussis, the disease, is usually self-limited in adults, it can be deadly for infants. Treatment with a macrolide is for 5–7 days. The incubation period is typically 7–10 days. There are 3 stages:

- 1) **Catarrhal stage:** The catarrhal stage presents as a typical, uncomplicated upper respiratory infection lasting 5–12 days. Patients are most infectious during this stage.
- 2) **Paroxysmal stage:** It is not until the paroxysmal stage develops, with its characteristic paroxysms of coughing followed by a “**whoop**,” that pertussis becomes clinically apparent. This lasts 1–2 weeks.
- 3) **Convalescent stage:** An often-prolonged cough occurs (lasting several weeks to months).

To help protect children and infants from acquiring pertussis, it is recommended that all adults receive 1 booster with Tdap. In addition, pregnant women should receive Tdap with each pregnancy.

***Pseudomonas aeruginosa* Pneumonia**

Pseudomonas species grow in **moist** environments. Patients who are infected with this organism have an **underlying illness** that allows their alveoli and airways to remain moist. Most often, the underlying disease process requires either chronic or intermittent antibiotic use. Selective pressure from antibiotics allows colonization of the lung with resistant and hardy gram negatives.

Hence, *Pseudomonas* CAP occurs in patients with underlying lung disease, **especially CF and bronchiectasis**, in patients who use steroids or antibiotics frequently, or in those with HIV infection. The presentation is typical with cough, dyspnea, and fever. The patients with chronic lung disease usually are sicker because *Pseudomonas* CAP aggravates an already-dwindling reserve.

Patients without lung disease who inhale a large amount of steam from **hot tubs** that are heavily contaminated with *Pseudomonas* can also develop pneumonia from this

organism. *Pseudomonas* is not a common cause of CAP. More often, it causes a HAP or VAP.

The diagnosis of *Pseudomonas* CAP is tricky because the organism is **hard to find**. A sputum Gram stain with many polys and a sputum culture that grows the organism suggests infection. Of course, it takes a while for the culture to grow, so you must have a high index of suspicion for this organism and treat it empirically.

Treatment: If you suspect *Pseudomonas* based upon underlying chronic disease or hot tub exposure, empirically treat as outlined in the ISDA guidelines. Once the culture result and susceptibility are available, narrow the regimen.

***Moraxella catarrhalis* Pneumonia**

Moraxella catarrhalis colonizes the mouth and upper airway of both children and adults and is a frequent cause of otitis and sinusitis. However, this organism causes CAP **primarily in patients with underlying lung disease or immunosuppression**, and 45% of patients die from their disease within 3 months of infection.

Moraxella CAP is slightly less acute than disease caused by pneumococcus or *H. influenzae*, and symptoms are less severe. The chest x-ray pattern is variable, ranging from lobar infiltrates to diffuse involvement and even interstitial disease in some cases.

Diagnosis is typically straightforward because a quality sputum sample shows an overwhelming number of **gram-negative diplococci**. It is useful to look at the Gram stain yourself because the organisms line up side-by-side and look like a pair of kidneys (not usually reported by the micro tech on the Gram stain result).

Treatment is also straightforward because the organism is generally susceptible to most drugs used to treat pneumonia: doxycycline, macrolides, cephalosporins, or amoxicillin/clavulanic acid. Penicillin is not a good choice because up to 90% of isolates produce a β -lactamase that breaks down penicillins but not cephalosporins.

ATYPICAL ORGANISMS OF CAP

PREVIEW | REVIEW

- What are the extrapulmonary manifestations of infection with *Mycoplasma pneumoniae*?
- Pneumonia caused by *C. pneumoniae* can be biphasic. What is the characteristic throat symptom in the 1st phase? The 2nd phase?
- Pneumonia in a patient with associated mental status changes and diarrhea should make you think of which organism?
- Which patients were at increased risk of developing severe pneumonia and death from infection with novel H1N1?

- Name the drug options for empiric treatment of influenza A or B.
- Your patient returns from a trip to the southwest U.S. and comes to you with erythema nodosum. Which fungus do you include in your differential?
- Which fungus is endemic to areas of the southern and midwestern U.S.?
- Which endemic fungus causes hilar adenopathy, focal alveolar infiltrates, and multiple lung nodules?
- Describe the microbiologic characteristics of *Blastomyces*.

Recall that atypical organisms of CAP are defined as atypical because they are not identifiable by Gram stain or routine bacterial culture or are resistant to β -lactam antibiotics. These organisms require special culture media (+/- serologic tests, viral panels) to establish the diagnosis.

Bacterial Pneumonias

Mycoplasma pneumoniae

Mycoplasma pneumoniae is a common cause of CAP in **young** patients. It is transmitted by infectious droplets person to person, so outbreaks occur (e.g., college dorms, military barracks). Incubation is 2-3 weeks, and the onset of dyspnea, intractable cough, and fever is typically insidious (although occasionally the presentation can mimic pneumococcal disease). Extrapulmonary manifestations of *Mycoplasma* infection include hemolytic anemia, splenomegaly, erythema nodosum and erythema multiforme (and Stevens-Johnson syndrome), arthritis, myringitis bullosa, pharyngitis, tonsillitis, and neurologic changes (especially **confusion**).

PCR is the diagnostic test of choice. If PCR assay is not available, measure acute and convalescent IgM antibody titers using enzyme immunoassay. If the convalescent titer rises by $\geq 4\times$ the acute titer, you can then make the diagnosis retrospectively with > 95% sensitivity and specificity. Chest x-ray typically shows patchy infiltrates or reticulonodular pattern but are nonspecific.

Patients can develop an autoimmune hemolytic anemia. Cold agglutinin disease is an autoimmune disease characterized by the presence of a high concentration of circulating antibodies (usually IgM) directed against RBCs. It is a specific form of autoimmune hemolytic anemia, one in which the antibodies only bind to the RBCs at low body temperatures. This complication is treated with warming, steroids, and possibly plasmapheresis.

Treatment of *Mycoplasma pneumoniae* is with a macrolide (azithromycin for 5 days is favored) or fluoroquinolone.

Chlamydophila pneumoniae

Chlamydophila pneumoniae (formerly *Chlamydia pneumoniae*) more commonly causes CAP in adults > 65 years of age.

Symptoms and ease of transmission are similar to *Mycoplasma pneumoniae* with the addition of **pharyngitis** and **hoarseness**. Often, there is a biphasic illness. The patient presents with a sore throat that is negative for group A *Streptococcus*; 2–3 weeks later, hoarseness and pneumonia develop. Again: Sore throat → pneumonia + hoarseness = *C. pneumoniae*.

Confirm the diagnosis of pneumonia due to *C. pneumoniae* by PCR of respiratory secretions.

Treatment: Effective antibiotic therapy includes azithromycin for 5 days or fluoroquinolone for 7 days. The postinfectious dry cough can last several weeks.

Legionella pneumophila

Legionella pneumophila causes CAP when the organism is inhaled from contaminated water or soil, typically in the winter and summer months. Epidemics are seen in hotels and on cruise ships, and the organism can also cause HAP when hospital water systems are contaminated. No person-to-person spread has been shown.

Presentation can be similar to, and is often confused with, *Mycoplasma pneumoniae*. The disease begins with headache, GI symptoms (especially diarrhea), and occasionally confusion, then evolves into high fevers and lung-related symptoms of cough and dyspnea. Pleural effusions are not uncommon in *Legionella* pneumonia.

Labs can show hyponatremia, hypophosphatemia, thrombocytopenia, elevated liver function tests, elevated ferritin, and hematuria.

The preferred diagnostic tests for *L. pneumophila* pneumonia are PCR and urinary antigen. The gold standard remains sputum culture on special media (buffered charcoal yeast extract agar (high iron content), but results take > 3 days). The urinary *Legionella* antigen test detects only *L. pneumophila* Serogroup 1, which causes 90% of cases of *Legionella* pneumonia. Consequently, this test has about 80% sensitivity and specificity of 97–100%.

Treatment is with macrolides (especially azithromycin) or quinolones for 5–7 days and up to 10 days for slow clinical responders.

Viral Pneumonias

Influenza

Influenza **A** (common subtypes: H3N2, seasonal H1N1, and 2009 H1N1 [swine flu]) and **B** viruses can cause primary viral pneumonia or can be associated with a secondary bacterial superinfection. Diagnosis can be made by viral culture of respiratory secretions (takes days for results) or with rapid PCR test (takes minutes for results).

Consider **influenza** pneumonia in a patient who has typical influenza symptoms, including myalgias and fever with progressive worsening of cough and dyspnea. Examination is typical for pneumonia, but there is scant sputum production. Hypoxemia is common. In 2009–2010, a pandemic caused by the novel H1N1 swine influenza carried with it an increased morbidity in very young people and in pregnant women.

Consider **secondary bacterial** pneumonia as an influenza complication in the patient whose flu-like illness appears to be improving then suddenly worsens with signs of pneumonia (cough, dyspnea, and a new fever). Think of *S. aureus*, pneumococcus, and *H. influenzae*. Gram stain and culture of sputum usually show the superinfecting organism.

More common than either of the previously described presentations is the **mixed viral and bacterial** pneumonia seen with influenza outbreaks. This is the patient who gets influenza and then eventually gets associated bacterial pneumonia. Time does not lapse between obvious flu and pneumonia. Rather, the clinical picture is one of blended disease. In this situation, the patient coughs up purulent sputum after a few days of influenza illness, then waxes and wanes between improvement and exacerbation. Chest x-rays show areas of consolidation, and sputum shows an abundance of bacteria.

Influenza A and B are diagnosed rapidly with a nasal swab PCR. An assay that distinguishes between influenza A and B is especially recommended. However, the rapid tests are not 100% sensitive, and false negatives are common. Subtyping analysis requires molecular PCR testing, and this is only done at specialized labs.

Treatment: Primary prophylaxis is recommended for exposed individuals in nursing homes and in those with chronic diseases. Empiric treatment of influenza requires the use of **zanamivir** (Relenza), peramivir (Rapivab), **oseltamivir** (Tamiflu), or baloxavir. Since most cases of influenza A have acquired **resistance** to amantadine and rimantadine, they are not recommended for use. (Influenza B is inherently resistant to amantadine and rimantadine.) Some H3N2 and seasonal H1N1 subtypes of influenza A even have resistance to oseltamivir, but novel H1N1 (swine flu) remains susceptible. Treatment within 48 hours of presentation has the most clinical benefit.

Adenovirus

Adenovirus in adults initially causes cold symptoms (sore throat, runny nose, and cough) with eventual development of pneumonia in a small subset. Most cases of adenovirus pneumonia have been observed in the military. Immunodeficient patients can develop life-threatening adenovirus pneumonia.

Diagnostics are typically not done except in immunosuppressed patients (culture of respiratory secretions and PCR testing).

Treatment is supportive.

RSV

Respiratory syncytial virus (RSV) generally causes a cold in most adults, but the elderly and patients with immunosuppression can get pneumonia.

Diagnosis can be made by PCR testing of the respiratory secretions.

Treatment is supportive except in those with bone marrow transplants (then use ribavirin).

Endemic Fungal Pneumonias***Coccidioides immitis***

Coccidioides immitis infection (coccidioidomycosis) is endemic in the southwestern U.S. (especially in Arizona and in California's San Joaquin Valley). It is often referred to as valley fever.

History typically involves travel to an endemic area followed by nonspecific symptoms including fatigue and arthralgias. The resulting illness can be subclinical and self-resolve, or CAP can develop within 2–3 weeks of exposure.

Erythema **nodosum** and erythema **multiforme** are associated skin findings. Chest x-ray findings vary from normal to adenopathy, infiltrates, nodules, and persistent thin-walled cavities.

Disseminated coccidioidomycosis is seen in immunocompromised or HIV-infected individuals. This is a fulminant disease that can involve the brain, skin and bone. Treatment is with an azole or amphotericin B. Relapses are common.

Diagnose by enzyme-linked immunoassay (EIA), culture, immunodiffusion, or complement-fixing antibodies. The finding of coccidioidomycosis from any tissue is evidence of infection as it is never normal flora.

The common form of coccidioidomycosis is **self-limited** and does not require treatment, although it can leave thin-walled lung cavities. The 2016 IDSA guidelines recommend the treatment of patients who have:

- Risk for dissemination
- Persistent fevers for ≥ 1 month
- $> 10\%$ weight loss
- > 3 weeks of night sweats
- Infiltrates in at least 50% of 1 lung (or portions of both lungs)
- Prominent or persistent lymphadenopathy
- High *Coccidioides* antibody titer
- Difficulty working
- > 2 months of symptoms
- Immunocompromise
- Diabetes
- Pregnancy
- Debilitations

Treat Hispanic, African American, and Filipino individuals due to increased risk of extrapulmonary infections.

When treatment is required for coccidioidomycosis, treat with fluconazole or itraconazole for 3–6 months and amphotericin B for severe pneumonia.

See the **Infectious Disease** section for more on coccidioidomycosis.

Histoplasma capsulatum

Histoplasmosis is endemic in areas of the southern and midwestern U.S. It is especially seen in the Mississippi and Ohio River valleys. (Do not confuse this with coccidioidomycosis, a.k.a. San Joaquin Valley fever. Refer to *Coccidioides immitis*.) Remember that the “H” and “Os” in HistOplasmOs is go with the “H” and “Os” in OHio. Or, think of “histoplasMOsis (Mississippi, Ohio).” It is caused by animals living in soil (e.g., chickens) and cave-dwelling animals (e.g., bats).

With acute histoplasmosis, the chest x-ray shows hilar adenopathy and focal alveolar infiltrates. Heavy exposure (epidemic, disseminating form) is suggested by a chest x-ray revealing **multiple nodules** in addition to the hilar adenopathy. The majority of fibrosing mediastinitis cases are from the sequelae of histoplasmosis and can cause obstruction of the superior vena cava, esophagus, and trachea.

Diagnosis of histoplasmosis:

- If there is systemic disease, use the antigen test of the blood, bronchoalveolar lavage (BAL), or urine in addition to fungal culture.
- If there is an acute **pneumonia**, the urinary antigen test can be used. Serologic tests can be used; complement fixation is more sensitive than immunodiffusion.

No treatment is indicated for localized disease, although some recommend itraconazole depending upon the severity of the illness and the state of the host.

Disseminated or severe disease is treated with amphotericin B. The liposomal preparation is preferred because it has better penetration into the lymph nodes, spleen, and marrow (locations where the majority of histoplasmosis replication takes place). HIV patients require chronic suppression with itraconazole.

For more on histoplasmosis, see the **Infectious Disease** section.

Blastomyces dermatitidis

Blastomycosis is uncommon, and the great majority of patients will need treatment with an antifungal agent. It is usually acquired after exposure to soil in the central, southeast, and mid-Atlantic states. (Think of “having a blast” in Chicago.)

Progression can be indolent to severe. The respiratory system is usually the mode of entry, and the condition can present as acute or chronic pneumonia. Hematogenous dissemination to the skin can occur with microabscesses forming along a new verrucous skin lesion.

Chest x-ray can show nodules, alveolar infiltrates or dense mass-like infiltrates.

No skin test is available for the diagnosis of blastomycosis. It is more pyogenic than the other fungi, and patients can cough up purulent sputum that reveals the organism with KOH prep. The buzz phrase for blastomycosis is “broad-based budding yeasts” (Figure 6-25).

Figure 6-25: Methenamine silver stain of pathology specimen shows the broad-base budding of blasto yeasts
Source: CDC

Treatment of blastomycosis:

- Indolent (uncommon): observation or oral itraconazole
- Mild to moderate: itraconazole for 6 months
- Severe: First use amphotericin B, then switch to itraconazole. HIV patients require chronic suppression with itraconazole, similar to histoplasmosis (refer to *Histoplasma capsulatum*).

For more on blastomycosis, see the [Infectious Disease](#) section.

Mycetoma

Mycetomas are balls of fungus that grow in cavities from prior lung disease (e.g., TB, nontuberculous mycobacteria [NTM], fibrocavitary sarcoid, bronchiectasis, bullae). A ball consists of live and dead fungal hyphae, fibrin, and other debris or fungal elements. Balls are often attached to the lung wall by a stalk, but they are sometimes mobile. *Aspergillus* is by far the most common cause, but rarely other fungi as well as some bacteria (e.g. nocardia) can form a mycetoma.

Mycetomas present as a very indolent disease of the lung, with cough, hemoptysis, and constitutional symptoms. Chest x-ray shows cavities with fluid or fungus balls. The CT scan or occasionally the chest x-ray may show a crescent sign: air in a crescent around the mycetoma. Aside from chronic wasting and necrosis of the surrounding lung, the major complication is life-threatening hemoptysis.

Sometimes patients do not develop typical fungus balls, called aspergillomas, but instead they have chronic infection of prior cavities with *Aspergillus*. This presentation

is simply called **chronic pulmonary aspergillosis**. The galactomannan and β -D-glucan assays, in addition to the culture, can be used to diagnose chronic pulmonary aspergillosis.

For hemoptysizing patients, early antibacterial treatment is recommended due to frequent bacterial superinfection. Embolization by interventional radiology (IR) may be needed once the source of bleeding is localized. Antifungal therapy generally does not work on the mycetoma itself, but it may in some cases be helpful if there is semiinvasive disease associated with the mycetoma. In some cases surgery may be warranted if the patient has had massive hemoptysis and the nature of the lesion allows surgery (i.e., there is no extensive pleural reaction around the area of the mycetoma).

VENTILATOR-ASSOCIATED PNEUMONIA (VAP) AND HOSPITAL-ACQUIRED PNEUMONIA (HAP)

PREVIEW | REVIEW

- Which organisms are the usual causes when a patient requires intubation and then develops pneumonia within the 1st couple of days after admission?
- Characterize the organisms that cause pneumonia in patients who have been in the ICU on the ventilator for > 5 days.

HAP refers to pneumonia not associated with mechanical ventilation. The 2016 IDSA/ATS guidelines state that patients with HAP and patients with VAP should be regarded as 2 distinct groups.

VAE (ventilator-associated event), used as a VAP surveillance tool, occurs when the patient is on a ventilator > 48 hours and develops worsening oxygenation with an increase in F_iO_2 or PEEP (now you have a VAC [ventilator-associated condition]) and/or evidence of infection or inflammation, with leukocytosis or leukopenia, fever, or a new antibiotic started (now you have an IVAC [infection-related ventilator-associated complication]).

VAP is defined as pneumonia that develops > 48 hours after endotracheal intubation.

HAP is defined as pneumonia that develops > 48 hours after admission to the hospital.

These 2 types of pneumonia are more likely than CAP to have multidrug-resistant (MDR) organisms.

VAP

The organisms that cause VAP vary depending on how soon after admission the patients are intubated. VAP in patients intubated within 1–4 days of admission is more likely to be caused by CAP organisms and less likely to be drug resistant. The more time that elapses between

admission and intubation (usually > 5 days), the more likely the patient is to develop pneumonia from **hospital organisms** that have colonized the oropharynx and the upper airways. These organisms are more likely to be **MDR**.

The most commonly encountered VAP MDR infections are:

- MRSA
- *Pseudomonas* species
- *Stenotrophomonas maltophilia*
- *Acinetobacter* species

Suspect pneumonia in any patient who develops new fever or clinical deterioration while on a ventilator. The incidence is highest in the first 5 days of ventilator use. **Malnutrition** in the ICU is an important predisposing condition.

The 2019 IDSA/ATS guidelines recommend noninvasive sampling (endotracheal aspirate of sputum) with semiquantitative cultures to determine the microbiologic etiology of VAP rather than invasive sampling (BAL, protected specimen brush [PSB]); blind bronchial sampling [a.k.a. mini-BAL] with quantitative cultures.

The treatment of VAP is often initially empiric but then guided by the results of **endotracheal (ET) aspirate culture**.

Empiric treatment should be guided by the local antibiogram, providing information about the distribution of organisms and their antibiotic susceptibility profiles. This local information should be as specific as possible for the hospital and ICU where the patient is being treated.

For empiric treatment of VAP:

- It is recommended that coverage for *S. aureus*, *Pseudomonas aeruginosa*, and other gram-negative bacilli be used in any empiric regimen.
- Vancomycin or linezolid should be used to cover for the possibility of MRSA.
- 1 or 2 antipseudomonal agents should be used depending on the patient's risk factors for MDR organisms and/or the local antibiogram. If there are no such risk factors present (i.e., septic shock, ARDS, acute renal replacement therapy), then 1 drug can be used to treat *Pseudomonas* pneumonia.

Deescalation to pathogen-specific treatment is recommended once culture results return and condition allows. A course of 7 days is generally recommended.

Extended-spectrum β -lactamase-producing organisms should be definitively (not empirically) treated according to results of antimicrobial susceptibility testing results.

Acinetobacter treatment is usually with a carbapenem, broad-spectrum cephalosporin, or a combination

ampicillin/sulbactam/ β -lactamase inhibitor or based on antibiotic susceptibility testing results.

Note: If the patient was recently admitted with pneumonia and intubated, treat for CAP organisms per [Figure 6-23 on page 6-56](#) unless MDR organisms are suspected.

Procalcitonin and clinical criteria together may be used to discontinue antibiotics if suspected pneumonia was a false alarm. However, initiation of antibiotic therapy in suspected HAP/VAP should be decided on clinical grounds and not by procalcitonin.

HAP

The approach to HAP is similar to that of VAP. The organisms are often the **same**, except MDR organisms are less frequently involved, and patients are less sick. Empiric antibiotic therapy follows the same principles discussed for VAP. However, treatment for HAP subsequently should be guided by noninvasive **sputum culture** rather than ET aspirate (as in VAP)—i.e., de-escalating from empiric therapy.

ASPIRATION SYNDROMES

PREVIEW | REVIEW

- Describe the presentation of a patient with an aspiration pneumonia.

There are 5 main types of aspiration syndromes:

- 1) Aspiration of gastric acid causing a chemical pneumonitis (a.k.a. Mendelson syndrome)
- 2) Aspiration of bacteria from oral and pharyngeal areas causing an aspiration **pneumonia**
- 3) Aspiration of exogenous and endogenous lipid material resulting in a lipoid or cholesterol pneumonia
- 4) Aspiration of a foreign body
- 5) Aspiration of food or liquid

With aspiration syndromes, infection generally occurs only after a **large amount** of material is aspirated (e.g., after endotracheal intubation or seizures or in a severely intoxicated patient). The infiltrate usually occurs in the right lower lobe (RLL), the right middle lobe (RML), or, in some cases, bilaterally in the lower lobes. If the patient is supine at the time of aspiration, infiltration is most likely to occur in the superior segment of a lower lobe. If the patient is upright, the aspiration can preferentially occur in the RML, but may also occur in the lingula or lower lobes. When a patient aspirates, it is not necessary to start antibiotics immediately because the stomach contents often only cause a chemical pneumonitis. The onset of fever, leukocytosis, change in sputum to thick yellow or green sputum, and persistent

infiltrate suggests aspiration pneumonia, which generally will benefit from treatment with antibiotics.

Observe the patient carefully because cavitating pneumonia and/or empyema may develop. The breath can be extremely malodorous in those with anaerobic infections! The most common infection-causing anaerobic bacteria are *Fusobacterium nucleatum*, *Bacteroides melaninogenicus*, and anaerobic streptococci. However, aspiration pneumonias are often polymicrobial.

Diagnosis is typically clinical, based on the history of aspiration. The radiograph may show an infiltrate, with possible subsequent organization into a cavity (Figure 6-26). Gram stain shows mixed flora. Sputum is unreliable. Changes in the volume, color, and thickness of the sputum, often with persistent fever and leukocytosis, suggest bacterial aspiration pneumonia.

Treatment is with a β -lactam combined with a β -lactamase inhibitor (e.g., amoxicillin/clavulanic acid or ampicillin-sulbactam) or, alternatively, with clindamycin.

Figure 6-26: Left upper lobe cavitary pneumonia from aspiration
Source: Vinay Maheshwari, MD

lesions (in the upper lobes and the posterior segment of the lower lobes in cases of aspiration). Septic emboli, with or without cavitation, appear as multiple nodules in the mid-to-lower lung zones, in accordance with the circulation.

Diagnosis is usually clinical and relies substantially on the history. There is a need to exclude TB and other organisms that may cause cavitation; anaerobes are particularly difficult to culture.

Treatment: β -lactams or β -lactamase inhibitors are drugs of choice. Once there is clinical improvement, you can switch the patient to oral amoxicillin-clavulanate. Duration of treatment can exceed 3 weeks.

LUNG ABSCESS

PREVIEW | REVIEW

- Describe the presentation of a patient with a lung abscess.

A lung abscess forms after an infection causes a necrotic lung to cavitate. The most common cause is aspiration of organisms from the oropharynx. Risk factors for aspiration include seizures, alcoholism, esophageal abnormalities, and swallowing problems. Typical organisms that live in the mouth are gram-positive bacteria such as *Staphylococcus* and *Streptococcus*, while patients with poor dentition are predisposed to anaerobes. People with alcohol use disorder have a high incidence of gram-negative enterics (e.g., *Klebsiella*).

Lung abscesses as foci of metastatic infection can occur with right-sided staphylococcal endocarditis, in IV drug abusers, and in dialysis and chemotherapy patients who have chronic venous access.

A lung abscess presents with malaise, weight loss, and an indolent cough with progressive purulent, often fetid, sputum (especially in anaerobic infections). Abscesses due to metastatic staphylococcal infection (septic emboli) are more acute. The chest x-ray typically shows cavitary

MYCOBACTERIAL INFECTIONS

PREVIEW | REVIEW

- Describe the differences between primary tuberculosis (TB), latent TB, and reactivation TB.
- How do you make the diagnosis of active pulmonary TB?
- What is the percentage of patients who have active pulmonary TB and nonreactive TB skin tests?
- What do you do differently to read the TB skin test in the patient who has received the bacillus Calmette-Guérin (BCG) vaccine?
- In which direction relative to the arm is the TB skin test read?
- In which groups of patients is a reactive TB skin test of ≥ 5 mm significant? ≥ 10 mm? ≥ 15 mm?
- List some reasons why a patient with true latent TB might have a negative TB skin test.
- What are you going to do for the patient who is high risk for TB disease but has a negative skin test?
- What is the booster effect seen with TB skin testing?

- What is the definition of a new converter?
- Which patients should be screened with IGRA tests?
- Can a patient with a negative TB skin test still have TB? What about with a negative IGRA?
- What is the usual treatment (and for how long) for an asymptomatic, HIV-negative 30-year-old with a positive TB skin test and normal chest x-ray?
- What is the usual treatment for latent TB? (Hint: The patient in the last question has latent TB.)
- What are the 4 drugs used to treat active TB?
- In the 4-drug regimen used to treat active TB, how long is each drug given?
- Which side effects can result from the different antimycobacterial drugs? What is the required screening?
- What is Lady Windermere syndrome?
- What do you do for the healthy patient with a single sputum sample positive for *M. kansasii*?
- A patient returns from a vacation to Mexico with complaints of chronic drainage from a recent tummy tuck incision. What is the likely organism?

TUBERCULOSIS (TB)

TB is one of the top 10 causes of death worldwide, infecting nearly 2 billion people. The countries with the highest incidence are India, Indonesia, China, Nigeria, Pakistan, and South Africa. Although the incidence in the U.S. is considered low, it is still a significant problem, especially in those infected with HIV. Much of the following topic discussion is in accordance with the ATS/IDSA/CDC 2017 guidelines. You can download them from cdc.gov/tb.

You must know TB thoroughly. There is not a lot of yellow highlighting here because you must know this entire topic perfectly!

The TB infection sequence is primary infection → latent infection → reactivation.

Primary TB occurs when aerosolized, contaminated droplets are inhaled and droplet nuclei reach the alveoli. The bacteria multiply locally for a while and then spread to areas of the body with high oxygen tensions (e.g., bone, brain, kidneys, lung apices). Acquired and cell-mediated immunity arrest the dissemination in > 90% of those affected, and further growth of organisms stops during this initial stage (the latency period). Patients who do not have functional cell-mediated immunity can then develop active TB—termed **primary TB**. Disease occurs throughout the lungs and can disseminate (e.g., meningitis, pericarditis), and symptoms may manifest quickly after initial exposure. **Children, AIDS patients, and those on TNF-α inhibitors** are most at risk for primary disease.

Latent TB occurs in the exposed patient with a functional immune system. The organisms are held at bay

by the formation of granulomas, and the patient does not develop a primary infection. In the lung, the granulomas sometimes calcify and can be observed as **Ghon complexes**. Usually, this sensitized person is asymptomatic—but a TB skin test reacts, showing that they are infected with the organisms. A significantly reactive TB skin test in a patient with no evidence of active tuberculosis is called latent tuberculosis infection (**LTBI**). Only assess for latency if treatment will be considered, either by tuberculin skin testing or with interferon-γ release assays.

Reactivation TB occurs when the cell-mediated immune system loses its ability to keep the organisms in check. This loss of ability occurs with aging and the development of comorbidities and may take months, years, or even decades to develop. Reactivation disease tends to be localized to the lung apices, and dissemination is generally uncommon. The risk of reactivation is highest after exposure (5% within the first 2 years and another 5% thereafter; HIV/AIDS patients are an exception and have a 40% risk of reactivation within months).

Common systemic signs of reactivation TB include fever, weakness, night sweats, and weight loss. Pulmonary disease is indicated by cough, pleuritic chest pain, and hemoptysis. Pleural effusions associated with TB may be either a manifestation of reactivation (most common) or primary TB. The pleural effusion is exudative and predominantly lymphocytic, with an elevated protein and LDH and with no or few eosinophils.

The chest x-ray may show an upper lobe infiltrate, hilar lymphadenopathy, and cavitory lesions (Figure 6-27 and Figure 6-28). Patients who develop cavities have the largest burden of organisms.

Most reactivation TB is pulmonary, 15% is extrapulmonary. Consider TB in a patient with indolent, chronic arthritis or chronic meningitis.

Miliary TB is the term given to uncontrolled hematogenous spread. The clinical presentation is variable—from overwhelming disease with multisystem organ failure (in primary infection) to chronic wasting (in reactivation infection). This form of TB is most common among infants and children < 5 years of age, as well as in immunocompromised individuals. The classic chest x-ray shows a faint and diffuse reticulonodular infiltrate (Figure 6-29).

The 2017 CDC-recommended approach to the diagnosis of active pulmonary TB (Figure 6-30 on page 6-68) includes:

- TB skin test or interferon-γ release assay (IGRA)
- Chest x-ray
- Acid-fast smears and cultures of the sputum
- ≥ 1 nucleic acid amplification test (i.e., NAA, PCR)

Acid-fast bacilli (AFB) smears are cheap but are only up to ~ 80% sensitive (false negatives) and have a 50-80% positive predictive value. (The AFB can be NTM—you do not know until you get the organism precisely identified.)

Figure 6-27: RUL pneumonia, consistent with TB (noncavitary)
Source: Vinay Maheshwari, MD

Figure 6-28: Reactivation TB with RUL cavitary lesion

Some of these issues are resolved with mycobacterial cultures, but they take a long time to grow.

NAA tests can be done on both smear-positive and smear-negative sputum samples and improve the sensitivity to ~ 95% because PCR can distinguish between TB and NTM.

Do **not** wait for the test results before treating reactivation TB if your clinical suspicion for disease is high (i.e., positive TB skin test or IGRA with risk factors). Initial treatment is with isoniazid, rifampin, pyrazinamide, and ethambutol. Subsequent treatment is determined by the drug susceptibility results, 2-month culture conversion, and the presence of cavitation on the initial chest radiograph.

Report all persons with current reactivation TB or suspected current reactivation TB to the appropriate state or local health departments.

Figure 6-29: Miliary TB with reticulonodular infiltrates
Source: Vinay Maheshwari, MD

We will cover the treatment of LTBI and active TB after we discuss the screening for LTBI.

Screening for Latent Tuberculosis Infection (LTBI)

Who gets screened?

High-risk groups include:

- HIV or those at high risk for HIV
- Close contacts with those with TB
- IV drug abusers
- Low-income, medically underserved populations
- Homeless individuals
- Migrant workers
- Residents of long-term care facilities (e.g., nursing homes, jails)
- Individuals with medical conditions that predispose to the progression to active TB disease (e.g., DM, silicosis, immunosuppression)

How are they screened?

There are 3 methods:

- 1) **Tuberculin skin test** (most widely used)
- 2) **IGRAs**
- 3) Chest x-ray, sputum for AFB, and the IGRA (Use these to screen for active disease in patient populations that are easily **lost to follow-up**; e.g., those in jails and in homeless shelters.)

AFB = acid-fast bacilli; NAA = nucleic acid amplification; TB = tuberculosis; NTM = nontuberculous mycobacteria

* A negative NAA result should be accompanied by a negative test for inhibitors that may limit amplification (if the enhanced amplified *Mycobacterium tuberculosis* direct [E-MTD] assay was used). The Xpert MTB/RIF assay contains a positive control that signals an invalid result if an inhibitor is detected.

An invalid NAA result indicates failure of the assay. An invalid result is usually reported after the test has been repeated using the same specimen. Receipt of an invalid NAA result should prompt a repeat test using a new specimen.

† TB remains possible; the organism burden may be too low to meet the sensitivity threshold for detection via NAA or smear.

Data from:

Lewinsohn, D.M., Leonard, M.K., LoBue, P.A., et al. Official American Thoracic Society/Infectious Diseases Society of America/Centers for Disease Control and Prevention Clinical Practice Guidelines: Diagnosis of Tuberculosis in Adults and Children. *Clin Infect Dis* 2017; 64:e1. World Health Organization. Global Tuberculosis Report, 2016. WHO, Geneva 2016.

Centers for Disease Control and Prevention (CDC). Updated guidelines for the use of nucleic acid amplification tests in the diagnosis of tuberculosis. *MMWR Morb Mortal Wkly Rep* 2009; 58:7.

Figure 6-30: TB disease workup

The tuberculin skin tests react in most **infected** people. That said, know that **25%** of patients with active pulmonary TB have **nonreactive TB skin tests**. So, a negative TB skin test does not exclude TB in patients who have a high pretest probability of disease. The tuberculin skin test is contraindicated **only** if there was a necrotic skin reaction to a previous test.

The TB skin test may be given if the patient has had the bacillus Calmette-Guérin (BCG) vaccine; this is used in some countries as a TB vaccine. Because most of these people were vaccinated as infants and the immune response to these antigens wanes with time, the purified protein derivative (PPD) result will probably be **valid**. Interpret the diameter of induration at 48–72 hours in the **standard** fashion and treat accordingly. Still, the CDC prefers the IGRA over the TB skin test in these patients; it is not affected by the BCG vaccine.

The standard TB skin test uses the Mantoux method of an intradermal injection of 0.1 mL (5 tuberculin units) of PPD tuberculin in the forearm. The injection site is evaluated 48–72 hours after the injection. The reading is based on the diameter of the **indurated/swollen** area—not the erythematous area—measured perpendicular to the long axis of the forearm (Figure 6-31).

The 2017 recommendations from ATS/IDSA/CDC as to what constitutes a significant reading take into account the degree of clinical suspicion of LTBI and the risk group of the patient. A particular diameter of induration may be significant in one group and insignificant in another. As of 2019, once a health care worker's baseline tuberculin skin test is obtained, annual screening does not occur unless known exposure takes place or the health care worker is at high risk for exposure (e.g., pulmonary physicians)

All of the following are considered positive skin tests (i.e., require treatment).

Figure 6-31: Properly reading the TB skin test (indurated area perpendicular to long axis of forearm)

Source: CDC

≥ 5 mm is positive for those in the high-risk groups:

- HIV or major cell-mediated dysfunction
- Fibrotic changes on chest x-ray consistent with prior TB
- Close contact with a documented TB case
- Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of **≥ 15 mg/day** of prednisone for **≥ 1 month**, or receiving TNF-inhibitor, or receiving chemotherapy)

≥ 10 mm is positive for those in the intermediate-risk groups:

- Homeless persons
- Recent immigrants (within 5 years) from high-prevalence countries
- IV drug users who are HIV-negative
- Prisoners and corrections officers
- Health care workers with high exposure risk
- Patients with DM, silicosis, malignancy, and malnutrition
- New converters (see [New Converter and the Booster Effect](#))

≥ 15 mm is positive for the low-risk groups. This includes most people in the community.

The most concise way to remember this:

- HIV, positive chest x-ray, close contacts, severely immunocompromised **≥ 5 mm**
- No risk factors **≥ 15 mm**
- All the rest **≥ 10 mm**

The **negative** TB skin tests can be a true negative or a false negative. Interpretation of the **negative** test requires that you consider the following:

- Was the test placed too soon? It takes up to **10 weeks** to react after an exposure. If a recently exposed patient has a negative TB skin test, then recheck it 10–12 weeks after exposure. Whether you treat this patient in the interim depends on whether you think the patient is really high risk for TB (an individual judgment—not based on specific parameters). This

may be done in infants or in young children or in immunocompromised individuals. A nurse, for example, is more high risk than an accountant, which can also influence the decision in this window period.

- Can the patient actually react to the test? Is the patient possibly anergic? HIV positive patients who initially test negative are not retested until CD4 levels are **> 200** secondary to false-negative results. Consider **anergy** in patients with immunosuppression and sarcoidosis. However, know that control tests are no longer recommended. As we said, up to 25% of people with active disease have a negative PPD, even when the control test is reactive. Therefore, the control test does not help you interpret a nonreactive TB skin test. In fact, this has been a cause for misinterpreting test results in the past!

Here's the bottom line: If you **strongly suspect TB** in a patient (e.g., exposure in a high-risk individual), then **start empirical treatment** even if the patient has a negative TB skin test result. Be aggressive about continuing the workup.

New Converter and the Booster Effect

The term new converter is used to discuss certain patients who are monitored with yearly skin tests (e.g., inmates in correctional facilities and homeless shelters as well as staff with negative baseline skin test screening and known exposure).

The induration that occurs with TB skin testing is a delayed-type hypersensitivity reaction mediated by the memory T-cell response to *M. tuberculosis*, nontuberculous mycobacteria, or BCG. Now, some people's T cells "remember" better than other people's T cells. Most people who have an LTBI have induration within 48–72 hours of a skin test, but the sensitized people who have memory-impaired T cells (often, the elderly) may not respond within 72 hours. Retesting a week later with a 2nd TB skin test often stimulates the memory-impaired T cells to better recall previous antigen exposure and indurate.

Stimulating memory-impaired T cells in this manner is called boosting. Significant induration occurring on the 2nd test following no induration on the 1st test is called the **booster effect**. This booster effect starts at 1 week after the 1st dose and can persist for 1 year after the 1st TB test, so it can be difficult to determine if the new induration on a yearly screening reflects the booster effect (indicating LTBI from an old primary infection) or a new conversion from a recent exposure (in which case the patient is then labeled a **new converter**). A new converter has a **≥ 10-mm increase** in the TB skin test **induration** within **2 years** from the 1st nonreactive test. Treat all new converters and all with a positive booster effect the same as you would for any positive TB skin test!

Here's the classic way that boosting gets confused with new conversion.

A correctional officer who has constant potential exposure to TB gets the 1st annual TB skin test. There is no reaction. One year later, during the required yearly TB screen, there is 10 mm of induration. Is this new induration because an LTBI developed in the last year (and is the patient thus a new converter), or is it due to boosting? You do not know.

Therefore, in patients who are scheduled for annual TB skin tests, a 2-step TB skin test regimen is often employed for the 1st screening. In this 2-step regimen, the patient gets an initial test, and if the initial test is nonreactive, the patient is retested in a week, with the 2nd test establishing the patient's baseline result. If the patient has a negative baseline test but develops significant induration with the following year's test, you can say with certainty that the new induration is from recent exposure and that the patient is a new converter.

Again, understand that 10 mm of induration in a health care worker at high risk merits treatment regardless of whether it is a boosted result or a new conversion.

Interferon-γ Release Assays

Interferon-γ release assays (IGRAs) are used in clinical practice and are endorsed by the CDC to screen for active and latent TB in lieu of the TB skin test. The 2 commercially available, FDA-approved IGRAs are the QuantiFERON-TB Gold In-Tube test and the T-SPOT.TB assay.

IGRAs test for antigen-specific interferon-γ release during TB infection. The tests cannot distinguish active from latent disease, so do not use them to diagnose active TB. Also, false-negative tests in active disease can be a problem. The test results can be known in 1–2 days. There is no booster response. BCG does not cause a false-positive result.

The 2017 CDC recommendations for the use of IGRA include:

- IGRAs are preferred over TB skin testing in noncompliant patients and in those who have been given BCG.
- TB skin testing is preferred in children < 5 years of age.
- All other patients can either get the IGRA or the TB skin test, but not both.

A negative IGRA, like a negative TB skin test, does not exclude infection in patients who have a high pretest probability of disease. Manage indeterminate tests based on the likelihood of having TB.

Positive Purified Protein Derivative (PPD) Considerations

What do you do when a patient has a positive skin test or IGRA?

A positive test indicates that the patient has or has had LTBI but not necessarily active disease. If the patient has had no previous TB workup, perform a workup for active

disease. This includes a full review of systems, a good physical exam, a chest x-ray, sputum for an AFB smear and culture, and at least one PCR test for *M. tuberculosis*.

(Sputum testing is not required if the chest x-ray does not demonstrate abnormalities and the patient's review of systems is inconsistent with active disease.)

If the PPD or IGRA is positive and active disease is present, treat for active tuberculosis (see Treatment of Active TB).

If the PPD or IGRA is positive and no active disease is present, the decision to treat for LTBI is determined by the risk of the patient progressing to active TB vs. the risk of treatment. An 80-year-old with a long-standing positive PPD may have already used up most of his or her lifetime risk. However, if such a patient has a newly positive PPD and is truly a close contact of an active TB patient, their risk is much higher and warrants treatment for LTBI. Care must be given to minimize hepatotoxicity.

Treatment for LTBI

Treatment is provided to eradicate the TB infection before it can develop into active disease. Again, the risk of conversion is 5% within 2 years for the general population and ~ 40% within several months for HIV patients. See Table 6-15.

For treatment of LTBI in HIV-negative adults, the American Thoracic Society, CDC, and Infectious Diseases Society of America (2016) specify 4 main management options:

- INH and rifapentine (RPT) for 3 months
- INH for 9 months
- Rifampin (RIF) for 4 months
- INH and RIF for 3 months

Again, what about negative IGRAs or PPDs?

Patients who have been a close contact of someone with active TB but have a negative TB test can either be observed or treated for LTBI, depending upon their risk (e.g., an HIV-positive patient would probably be treated, whereas a healthy person with no other risks would probably be observed). Children are definitely treated. Retest the negative cases in 10–12 weeks. If treating with INH, add pyridoxine to avoid peripheral neuropathy.

Treatment of Active TB

The emergence of multidrug-resistant strains has changed the treatment of active TB. Let's first define the 4-drug and 3-drug regimens.

The 4-drug regimen:

- 1) RIF
- 2) INH
- 3) Pyrazinamide (PZA)
- 4) Either ethambutol (oral, preferred) or, much less commonly, streptomycin (injection)

Table 6-15: Positive PPD Determination Based on Preexisting Conditions

Treatment of Latent Tuberculosis Infection (LTBI): Certain groups are at high risk of developing TB disease once infected. These people are candidates for treatment regardless of their age—after ensuring active infection is not present. The treatment regimen for patients who are not HIV-positive depends on compliance and comorbidities.

Treat all of the following (all ages):

PPD Result (Induration)	In People with the Following Conditions
≥ 5 mm is positive in these high-risk groups	- Known/Suspected HIV infection - Close contacts (e.g., same household) of active cases - Chest x-ray suggests previous inactive tuberculosis - Organ transplants and other immunosuppressed patients with > 1 month of equivalent prednisone use (>15 mg/day)
≥ 10 mm is positive in these intermediate-risk groups	- Recent immigrants from a country with a high prevalence - IV drug users - Employees and residents of high-risk settings (e.g., prisons, jails, hospitals, homeless shelters, mycobacteriology lab workers) - Patients with certain comorbidities (e.g., silicosis, DM, advanced chronic kidney disease, leukemia, lymphoma, solid tumor malignancies, recent weight loss of > 10% of predicted body weight (PBW), gastrectomy, post-jejunoileal bypass surgery) - Children < 4 years of age and others with high-risk comorbidities
≥ 15 mm is positive in low-risk patients	No known risk factors
PPD negative but high-risk	High-risk (e.g., immunocompromised) contacts of active TB cases

The **3-drug** regimen consists of the first 3 drugs (remember: may the TB patient who doesn't get RIF, INH, and PZA rest in peace). The use of PZA in pregnant patients in the U.S. has been discouraged, but there has been extensive safe use outside of the U.S. in this population.

In the U.S., all patients with active TB are initially treated for **2 months** with the **4-drug therapy**, unless criteria for the 3-drug therapy are met. Give the first 3 drugs for the full 2 months, and the 4th drug may be dropped if the susceptibility testing shows sensitivity to the first 3 drugs. **After** the first 2 months, give **INH and RIF** for an additional **4 months** (i.e., 6 months total).

HIV-infected patients on protease inhibitors (PIs) are usually given rifabutin instead of rifampin, depending upon the antiretroviral therapy used. Consult the CDC's tables of recommendation for treatment modifications when highly active antiretroviral therapy (HAART) is used with TB medications. Early initiation of HAART within the first 2 weeks or so, particularly in those with a low CD4 count, increases survival. Duration of therapy for HIV-infected patients also is 6 months, but this may be increased in patients with CNS or skeletal involvement or with cavitary lung lesions that stay culture positive. If the patient did not complete 2 months of PZA or there is drug-resistant disease, treatment is extended per the CDC recommendations.

Someone must **observe** all patients taking the medication unless compliance is absolutely assured. This directly observed therapy (**DOT**) is supervised by the local health department. Hospitalized patients with known or suspected active TB are monitored through infection control programs. Airborne infection isolation and respiratory protection are used to prevent the nosocomial

transmission of disease. Patients treated in the outpatient setting are recommended to stay home, away from others, particularly those susceptible to TB, during the diagnostic evaluation. N95 masks should be worn by health care workers while the patient is hospitalized. As an outpatient, the patient should wear a mask when seeing visitors or when leaving the home while pulmonary symptoms are present.

When can **3 drugs** be used?

Only if there is a slight chance of drug-resistant infection and **all** the following criteria are met:

- New TB patient and isolate susceptible to both INH and rifampin
- No known exposure to a patient with a drug-resistant infection
- Does not come from a high-prevalence country

Additional notes:

- Give vitamin B₆ (pyridoxine) with INH-containing regimens to prevent peripheral neuropathy and mild CNS effects.
- If the patient cannot take PZA, give INH and RIF for a total of 9 months.
- If the TB is resistant to INH only, stop INH and give the other 3 drugs for 6 months total or RIF and ethambutol for 12 months.
- Multidrug-resistant TB (i.e., to INH and RIF) is difficult to treat. Treatment is based on sensitivities. Consult a specialist.
- Mothers who have untreated (infectious) TB should not breastfeed, but they can provide expressed milk for their infants. Breastfeeding can resume when the mother has been treated for 2 weeks.

- Tuberculous meningitis: Add adjuvant corticosteroids.
- PZA inhibits uric acid excretion, so do not use during acute gouty flares.
- Ethambutol and PZA can cause rash.

Know these side effects:

- INH, RIF, and PZA are all hepatotoxic.
- In all patients on INH, regardless of age, monitor monthly for signs and symptoms of liver toxicity. Laboratory testing is necessary only if signs or symptoms develop or if they are at risk for hepatotoxicity! Such risks largely include older age, pregnancy (see the [Women's and Men's Health](#) section for TB in pregnancy), concomitant hepatotoxic medications, history of viral hepatitis, and IV drug abuse.
- Ethambutol is not hepatotoxic, but it can cause a decrease in visual acuity. Often, decreased color perception is the 1st sign of this deterioration. It is usually reversible if the drug is quickly discontinued. Patients should have an ophthalmologic exam before treatment and have periodic checks thereafter (i.e., Snellen chart, gross confrontation eye exam, pseudo-isochromatic color vision plates, and clinical history). Any inflammatory disease of the eyes is at least a relative contraindication for ethambutol.
- Streptomycin is an older aminoglycoside. It is ototoxic and nephrotoxic.

NONTUBERCULOUS MYCOBACTERIA (NTM)

NTM include mycobacteria species other than *M. tuberculosis* and *M. leprae*. Many NTM species have been found to cause infections in humans, especially in immunocompromised patients and in patients with structural lung disease. Representative common examples include *M. avium* complex (MAC), which includes *M. avium* and *M. intracellulare*; *M. kansasii*; and *M. goodii*. These species are sometimes found incidentally in the sputum of healthy individuals.

Pulmonary Infections with NTM

There are 2 basic groups of NTM clinical lung disease seen in non-HIV patients:

Pattern 1: A middle-aged male with underlying lung disease (e.g., COPD, bronchiectasis) presents with cough, weight loss, and lung infiltration—possibly even cavitory lesions. This presentation is very similar to TB, but the progression is more indolent. Radiographs are often difficult to interpret because of the underlying lung disease.

Pattern 2: A middle-aged, female nonsmoker presents with cough productive of purulent sputum and interstitial infiltrates on radiograph. When the infiltrates are in the right middle lobe or right lingular segment, the presentation is termed **Lady Windermere syndrome**—based on a character from one of Oscar Wilde's plays. Radiographs or CT scans often show bronchiectasis or nodules.

Because the immune response of these 2 patient groups is generally intact, the NTM do **not** spread **outside** of the lungs.

The diagnosis is made using the ATS criteria. They require that a chest x-ray or HRCT scan of the lungs shows specific abnormalities (bronchiectasis and nodules). In addition, the criteria require either ≥ 2 sputum culture-positive samples for the same organism, a lung biopsy showing granulomas, a positive AFB with 1 sputum culture-positive sample, or 1 BAL with growth of NTM. Nucleic acid probes are available to make a rapid diagnosis of MAC on sputum samples.

Know that an isolated sputum sample growing NTM in a healthy person is not diagnostic of disease and does not require treatment! Consider treatment in patients who have pulmonary symptoms and significant nodular or cavitory opacities. Often, clinicians look for signs that these are active or radiologically progressive to distinguish it from residual scarring due to prior disease.

Patients with severe immunodeficiencies (e.g., AIDS with **CD4 counts < 100 cells/ μ L**) are unable to hold the infection at bay in the lung. Instead, they may develop disseminated disease with positive blood cultures and manifestations in the lungs, liver, and bone marrow. Patients present with constitutional symptoms and often diarrhea. Labs indicate systemic disease with leukopenia, anemia, and elevated transaminases—blood cultures for mycobacteria are often positive.

Treatment of NTM is tough and lengthy, usually 1–2 years (at least 12 months and two consecutive negative sputum cultures). Guide treatment by culture results and an assessment of the risk and benefits. With no symptoms and stable chest imaging, observation is an option. Clarithromycin (or azithromycin) with rifampin and ethambutol are given 3 $\times$ /week for most patients with nodular-bronchiectatic disease, while daily therapy with these agents is used for more severe nodular-bronchiectatic, cavitory, and disseminated disease. Rifabutin is an alternative for rifampin in the treatment of the latter conditions. Also consider using an injectable, such as amikacin or streptomycin, for severe disease.

Hospitalized patients with known NTM do **not** require respiratory isolation (unlike patients with known or suspected TB).

Cutaneous Infections with NTM

Know that NTM can cause infections of **surgical sites** in immunocompetent patients. Patients with immune deficiencies can have disseminated disease that starts with a skin infection. If you see the classic history of recent plastic surgery, travel with exposure to sand and water, and an indolent drainage from the surgical site, think about these culprit organisms: *M. abscessus*, *M. fortuitum*, *M. chelonae*, and *M. marinum*.

TB Skin Tests and NTM

Memory T cells that have been stimulated by NTM react to the antigen in the TB skin test, but the reaction is usually not as robust as with true TB sensitization. Still, this reaction to NTM is why we have cut-off measurements for significant reactions with TB skin testing.

This is somewhat useful to know when you are evaluating a patient who has an indurated, but not significant, TB skin test result and AFB+ sputum. (The AFB may possibly end up being identified as NTM in culture.) NAA testing for *M. tuberculosis* is really helpful in this situation to exclude true TB.

IMMUNOSUPPRESSED PATIENTS

PREVIEW | REVIEW

- In developed countries, what are the 2 most common causes of pneumonia in patients with HIV/AIDS?
- What is the preferred regimen for the treatment of *Pneumocystis jiroveci* pneumonia (PJP)?
- How does the preferred regimen for the treatment of PJP differ when the patient has a $P_aO_2 = 60$ mmHg?
- Discuss the various types of *Aspergillus* pulmonary infections.
- What is the recommended treatment of invasive pulmonary aspergillosis (IPA)?

IMMUNE DYSFUNCTION

Note: The following is covered in more depth in the [Infectious Disease](#) and the [Allergy & Immunology](#) sections.

Bacterial pneumonia is the most frequent cause of death in immunodeficient patients. Mortality is 50%.

Humoral dysfunction: B-cell dysfunction or decreased antibodies are seen in most patients with ALL, CLL, and multiple myeloma. These patients are especially susceptible to **encapsulated** organisms, including *S. pneumoniae*, *H. influenzae*, and meningococci.

Patients with hypogammaglobulinemia, asplenia, sickle cell, or abnormal complement also tend to acquire infections caused by the same encapsulated organisms.

Cell-mediated dysfunction: T-cell defects are seen in patients with AIDS, lymphoma, and uremia, post-organ transplant, and after use of steroids or alkylating agents. These patients are susceptible to infections caused by encapsulated bacteria, *Pneumocystis* (PJP), mycobacteria, viruses (CMV and HSV), fungi (*Cryptococcus*), *Legionella*, and *Nocardia*. Although the incidence of PJP has dramatically decreased with the use of prophylactic drugs and HAART, *Pneumocystis* is the 2nd most common cause of pneumonia in AIDS patients in developed countries (the 1st is bacterial pneumonia).

In some developing countries, TB is the most common pulmonary infection in AIDS. A minority of patients with ALL have a T-cell variant, and these patients may have a T-cell deficiency.

Neutrophil dysfunction is seen in AML, CML (the **myelogenous** leukemias), bone marrow transplant, and patients who are otherwise getting ablative chemotherapy. These patients tend to get infections with gram-negative organisms, *Staphylococcus* species, *Corynebacterium jeikeium*, and fungi (*Candida* and *Aspergillus*).

ORGAN TRANSPLANT

Organ transplant patients get the same infections as patients with T-cell defects. Briefly:

- During the **first 30 days**, the immune system is still working, and patients most commonly get the usual nosocomial and surgery-related infections. Common lung infections are **gram-positive and gram-negative** pneumonias.
- During the first **1–6 months**, opportunistic infections start appearing. Lung infections during this period especially include CMV, *Pneumocystis*, *Aspergillus*, and *Cryptococcus*.
- **After 6 months**, infections are more likely to be community acquired.

Think of CMV if there is a mixed bag of “-itises” because patients often get concurrent pneumonitis, hepatitis (generally mild), and adrenalitis, leading to adrenal insufficiency!

Diagnosis: Finding inclusion bodies on BAL **suggests** CMV colonization. Finding inclusion bodies on a tissue sample (lung biopsy) **confirms** invasive CMV disease. Also, use CMV serology and blood PCR to guide management.

Treatment: Ganciclovir. Can consider adding IV CMV immunoglobulin if no response occurs.

See the [Allergy & Immunology](#) section for more on post-transplant infections.

MYELOPROLIFERATIVE DISORDERS

If a patient with a myeloproliferative disorder gets a localized infiltrate, it is typically caused by a **gram-negative bacterial** pneumonia. Treat it empirically.

LUNG PATHOGENS IN THE IMMUNOSUPPRESSED

Bacterial Pneumonia

Bacterial pneumonia, usually due to *S. pneumoniae* or *H. influenzae*, occurs in HIV/AIDS patients with **CD4 counts ~ 300 cells/ μ L** (0.3×10^9 cells/L)—higher than those with PJP. HIV-positive patients have a 6× increased risk of pneumonia and a **100×** increased risk

of bacteremia with pneumococcus compared to HIV-negative individuals. When considering a pneumonia diagnosis in a patient with risk factors for HIV, think about PJP and pneumococcus.

***Pneumocystis jiroveci* Pneumonia (PJP)**

PJP, a.k.a. PCP and *Pneumocystis* pneumonia, is the most common opportunistic infection in AIDS patients. A history of PJP and/or a CD4 count of < 200 cells/ μ L (0.2×10^9 cells/L; or 14% of all T cells by flow cytometry) confers the greatest risk. The incidence of PJP in patients who are adherent to both antiretroviral therapy (ART) and PJP prophylaxis is near zero.

Patients with PJP present with indolent, progressive dyspnea and cough with scanty sputum (+/- fever). Think about PJP in any HIV+ patient with pulmonary symptoms. Oxygen desaturation with or without ambulation may be present. Chest x-ray typically shows diffuse, bilateral, symmetrical interstitial and alveolar infiltrates. CT can be helpful if the diagnosis remains unclear; if CT reveals no findings, diagnosis of PJP is unlikely.

PJP is diagnosed with sputum or BAL examination using dye-based stains, fluorescent antibody stains, or PCR assays.

Treatment: TMP/SMX (by IV or PO) is the preferred 1st line agent. Alternatives include atovaquone, dapsone/TMP, or clindamycin/primaquine and IV pentamidine. The latter 2 can be used in severe disease if unable to use 1st line therapy. A majority of PJP patients improve on the initial course of therapy (usually 3 weeks' duration), but a good number have intolerable side effects from the treatment (e.g., rash and bone marrow suppression with TMP/SMX).

Give steroids to PJP patients with a $P_aO_2 < 70$ mmHg or an A-a gradient > 35 mmHg. Corticosteroids given concomitantly with the initiation of anti-PJP treatment reduce the likelihood of respiratory failure and death in patients with moderate-to-severe pneumonia.

Remember to check for G6PD deficiency if you prescribe dapsone or primaquine.

Mycobacteria

For TB disease in HIV/AIDS, the treatment is largely the same as for any other patient (refer to the discussion of [Treatment for LTBI on page 6-70](#)) except the following: rifabutin may be required for those on specific HAART regimens, intermittent treatment is not recommended, and a weekly rifapentine-based continuation regimen is not recommended. Most AIDS patients with TB come from areas where there is already a high prevalence of TB.

The most effective treatment for NTM (*M. avium* complex [MAC]) is to get the CD4 count > 100 cells/ μ L (0.1×10^9 cells/L; with ART) and to initiate combination

therapy against MAC—typically using clarithromycin or azithromycin with rifabutin and ethambutol.

Fungi

Aspergillus

Aspergillus can cause invasive disease in patients with AML, ALL, Hodgkin disease, heart or bone marrow transplant, chronic corticosteroid use, and granulocytopenia lasting > 25 days (slow growing!). Occasionally, we see this disease in AIDS patients.

Sputum cultures growing *Aspergillus* are usually ignored in patients with competent immune systems because *Aspergillus* is often found incidentally in normal sputum.

The spectrum of *Aspergillus* disease depends on the immune system of the patient and includes aspergilloma, invasive sinusitis, invasive pulmonary aspergillosis (IPA), and hematogenous dissemination to various organs (the most severe manifestation).

IPA once was one of the most-feared complications of treating hematologic malignancies because of a very high mortality rate. Improved antifungal therapy and preventive prophylaxis in high-risk patients have reduced the mortality rate from IPA in this population.

IPA presents as either an acute or an indolent pulmonary syndrome of fever, cough, dyspnea, and occasional hemoptysis in a severely immunocompromised patient. Occasionally, no symptoms are present in marrow transplant patients because they lack any immune response. Chronic necrotizing pulmonary aspergillosis may occur in patients with severe COPD treated with systemic steroids.

Diagnosis of IPA requires quick recognition of the clinical picture, HRCT of the chest (the buzzword is “halo sign,” which is a hemorrhage surrounding a nodule, signifying early evidence of pulmonary infarction), and lab tests. Lung samples can be obtained and cultured—sometimes the organism is visible in path specimens and grows in culture. Galactomannan is a polysaccharide that is a major component of *Aspergillus* cell walls. Because it is a water-soluble carbohydrate, it is found in blood, urine, CSF, and BAL of infected patients. This aids in the diagnosis of aspergillosis. Know that piperacillin/tazobactam contains a significant amount of galactomannan antigen and may cause a false-positive test. β -D-glucan, a component of most fungal cell walls, is also used to diagnose invasive fungal infection by blood test.

Treatment of *Aspergillus* infections depends on the form of disease:

- IPA in the immunosuppressed: IV voriconazole +/- an echinocandin. Liposomal amphotericin B or isavuconazole is an alternate if the patient cannot tolerate voriconazole.

- Chronic pulmonary disease: PO itraconazole or voriconazole
- Rhinosinusitis: surgery + antifungal (lipid amphotericin B, voriconazole, or isavuconazole)

Cryptococcus

Cryptococcal pulmonary disease is linked with Hodgkin lymphoma, corticosteroids, and transplants but **not** with PMN defects or neutropenia. Chest x-ray may show nodules or mass lesions. *C. neoformans* in sputum **indicates** infection (contrary to *Aspergillus*). Needle aspiration and lung biopsy are also an accurate means of diagnosing cryptococcal pneumonia. If found, perform a lumbar puncture to evaluate for CNS infection.

Patients with HIV/AIDS and **CD4 counts < 100 cells/μL** (0.1×10^9 cells/L) are especially susceptible to cryptococcal meningitis.

Coccidioides

Coccidioides immitis is endemic in the southwestern U.S. (particularly California and Arizona). Most immunocompetent patients with infection are asymptomatic or develop a **mild** flu-like illness that is self-limited. Disseminated or chronic infections are most common in patients with myeloproliferative disorders, Hodgkin lymphoma, transplants, and AIDS.

Histoplasma

Disseminated histoplasmosis is common in AIDS patients with CD4 counts < 100 cells/μL (0.1×10^9 cells/L) who live in endemic areas, such as the southern and midwestern U.S. and the Caribbean. It is especially found in the Mississippi and Ohio River valleys.

Nocardia

Nocardia asteroides lung infections are usually seen in T-cell deficient patients (not those with humoral deficiency) and in patients with pulmonary alveolar proteinosis. The pulmonary lesions may cavitate. Brain abscesses and subcutaneous dissemination can occur. This is treated with sulfonamides.

Candida

Candida pneumonia is **very rare and difficult** to diagnose in markedly immunosuppressed patients. *Candida* in the sputum is nonspecific and almost always signifies colonization.

Mucormycosis

Patients with **leukemia** are at especially high risk of pulmonary mucormycosis. It is also seen in uncontrolled **diabetics** with frequent DKA. This infection has a **poor** prognosis.

Reactivation Infections

TB, toxoplasmosis, HSV, cryptococcosis, histoplasmosis, and strongyloidiasis can reactivate in the immunosuppressed.

NONINFECTIOUS INFILTRATES

PREVIEW | REVIEW

- Name some causes of noninfectious pulmonary infiltrates.

Drugs may have cytotoxic or noncytotoxic lung effects:

- Methotrexate is the most common cause of **noncytotoxic** lung reactions and causes a hypersensitivity interstitial pneumonitis.
- Bleomycin is the most common cause of cytotoxic pulmonary toxicity.
- Gold-induced lung disease is reversible—just stop the drug.
- Amiodarone, bleomycin, and the nitrosoureas all cause **dose-related** pulmonary interstitial disease (while almost all other offending drugs have a hypersensitivity or idiosyncratic effect). Amiodarone may also cause an idiosyncratic reaction manifested in the lung. Uremia, supplemental O₂, and radiation therapy exacerbate bleomycin lung toxicity. Lung biopsy is the diagnostic procedure of choice, but it is typically not needed.
- **Crack** cocaine can cause a hypersensitivity pneumonitis, diffuse alveolar hemorrhage, infarctions, and COP.

Hemorrhage is **common** in patients with **AML**—it can be the **sole** cause of pulmonary infiltrates in these patients. But remember: In AML, rule out *Aspergillus* infection as the cause of the hemorrhage. (Also remember, hemorrhage may be caused by idiopathic pulmonary hemosiderosis, Goodpasture's, and SLE and can occur after bone marrow transplantation.)

Leukemic noninfectious pulmonary infiltrates most commonly occur in **ALL**, and they **always** imply a high percentage of blasts. Leukostatic infiltrates (globs of WBCs in the pulmonary **vessels**) occur in myeloid leukemias when the WBC count is > 100,000 cells/μL and can cause dyspnea and hypoxia. 50% of **lymphoma** patients have infiltrates.

Radiation changes in the lung usually present **within 6 months** of treatment. These changes are divided into 2 phases, with **radiation pneumonitis** occurring within 6 weeks. Radiation changes (pneumonitis/fibrosis) have a characteristic chest CT appearance with **sharp boundaries** corresponding to the field of radiation exposure.

CRITICAL CARE

PREVIEW | REVIEW

- Characterize the acute respiratory distress syndrome (ARDS) Network approach to fluid management in patients with ARDS.
- Describe the ventilator-induced lung injury that can happen when treating ARDS.
- What is considered the optimal ventilator setting TV for ARDS?
- Describe the specifics of permissive hypercapnia.
- Discuss the different modes of mechanical ventilation.
- Name the DESAT causes of failure to wean.
- What are the 2 categories of actions to keep in mind when adjusting a ventilator?
- When should you use PEEP?
- A patient with severe chronic obstructive pulmonary disease is placed on the ventilator. She suddenly becomes hypotensive. What steps do you follow to stabilize her?
- What is the best route to provide nutrition for a mechanically ventilated patient?
- What is refeeding syndrome and how is it prevented?
- Discuss the potential complications of pulmonary artery catheters.
- Predict pulmonary artery catheter values in hypovolemic shock and in cardiogenic shock. See [Table 6-16 on page 6-85](#).
- A patient presents with *E. coli* sepsis. Predict cardiac output, wedge pressure, and SVR in relation to normal values. See [Table 6-16 on page 6-85](#).

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

ARDS is hypoxemic acute respiratory failure due to bilateral inflammatory lung injury with bilateral non-cardiogenic pulmonary edema.

ARDS can have a **direct** or **indirect** precipitating event. **Direct** causes include aspiration, pneumonia, and inhalation injuries. **Indirect** events are sepsis, pancreatitis, multiple transfusions, and trauma. Aspiration and sepsis are the most common. Risk of ARDS increases with multiple precipitating events.

Diagnosis

The 2012 Berlin Conference definition of ARDS has replaced the 1994 American European Consensus Conference definition.

The Berlin definition eliminates the acute lung injury (ALI) category and categorizes ARDS as mild, moderate, or severe based upon the ratio of P_aO_2/F_iO_2 and the response to applied positive end-expiratory pressure (PEEP).

The Berlin definition requires that all of the following 4 criteria are met for diagnosis of ARDS:

- 1) Onset of respiratory symptoms within **1 week**
- 2) Chest x-ray or lung CT findings consistent with **(noncardiogenic) pulmonary edema**—not otherwise explainable
- 3) Increased hydrostatic pressure is ruled out (by echocardiogram if needed) so that the respiratory failure cannot be fully explained by increased hydrostatic pressure from fluid overload or cardiac failure.
- 4) Moderate-to-severe hypoxemia—the degree of hypoxemia defines severity. By definition, in a patient on a ventilator with $PEEP \geq 5$ cm H_2O :
 - **Mild ARDS:** $P_aO_2/F_iO_2 > 200$ but ≤ 300
 - **Moderate ARDS:** $P_aO_2/F_iO_2 > 100$ but ≤ 200
 - **Severe ARDS:** $P_aO_2/F_iO_2 \leq 100$

As shown above, P_aO_2/F_iO_2 is the ratio of P_aO_2 in mmHg over F_iO_2 as a decimal (0.21–1.00).

ARDS mnemonic:

- **Acute** onset
- **R**estrictive lung mechanics from pulmonary infiltrates
- **D**iffuse panendothelial inflammatory injury manifested in the lungs—i.e., not due to hydrostatic pressure
- **S**hunt hypoxemia—The degree of hypoxia defines severity of ARDS.

There is typically a **48–72-hour** lag time between the injury and ARDS; it is quicker with neurologic insults and trauma-related lung injury. All of the factors that lead to the leaky lungs in ARDS are still unknown. Injury results in local edema with subsequent fluid accumulation in the interstitium and the alveoli, compounded by the presence of inflammatory cells and their mediators. The inflammation causes chaos and heterogeneous disease in the lungs, from microthrombi clots in local vessels to aggregates of protein, surfactant, and cellular debris that clog up the alveoli in whorls. Inflammatory cells invade the interstitium and alveoli *en masse*, releasing more mediators. Eventually, large sections of lung simply collapse, resulting in massive shunting and hypoxemia. The microthrombotic occlusion of pulmonary vessels leads to nonperfusion of ventilated areas, causing dead space and hypercapnia—in addition to severe hypoxemia ([Figure 6-32](#) and [Figure 6-33](#)).

Patients initially present with symptoms of the underlying cause with dyspnea, increased work of breathing, and eventual respiratory fatigue.

Figure 6-32: Anteroposterior chest showing ARDS
Source: Vinay Maheswari, MD

Figure 6-33: CT chest showing ARDS
Source: Vinay Maheswari, MD

With supportive care, patients improve and enter a proliferative phase, during which their lungs repair and organize. Usually, this is when they can be weaned from ventilator support. A few patients go on to develop mild fibrosis as part of healing and remain ventilator- and/or oxygen-dependent for a prolonged period. A restrictive pattern may be detectable on pulmonary function tests (PFTs) even after a year. As yet, there is no prophylaxis for ARDS.

The death rate is 25–58% and has decreased with the use of lung-protective ventilatory support strategies and improved critical care support. The most common cause of death within the first 3 days after the onset of ARDS is the underlying problem! Respiratory failure is not the most common cause of death in ARDS patients after 3 days; it's nosocomial pneumonia and sepsis.

Making the diagnosis of pneumonia in the patient with ARDS is difficult because infiltrates and leukocytosis are common in ARDS. Bronchoscopy is only performed if the diagnosis is uncertain or if a specific diagnosis is

entertained (e.g., controlled mechanical ventilation [CMV] or *Pneumocystis jiroveci* pneumonia [PJP]) and therapy is altered by bronchoscopy results. Give antibiotic therapy as indicated by Gram stain, culture, and sensitivity results.

Treatment

Prevention of pneumonia and other complications of critical illness in a patient with ARDS is important. Adequate hand washing and using sterile technique are mandatory.

Treatment of ARDS: Treat the underlying condition and provide optimized cardiopulmonary support. If the patient has an undrained abscess in the abdomen or elsewhere, encourage surgeons to remove it or use interventional radiology to drain it. Give empiric antibiotics if sepsis is the suspected cause.

Keep patients slightly hypovolemic. **However**, it is very important to provide enough volume to maintain adequate cardiac output and tissue oxygen delivery. The goal is to prevent worsening lactic acidosis and the resultant multiorgan failure.

The ARDS Network FACT trial (data released in 2006) demonstrated that conservative fluid replacement (targeting normal central venous pressure [CVP], pulmonary artery occlusion pressure [PAOP], and hemodynamic function) was better than a liberal strategy; less (fluid) is more (beneficial). It led to decreased ICU and ventilator time and decreased organ dysfunction. Mortality, however, was similar. This trial also concluded that management with CVP is as good as using a pulmonary artery catheter. This fluid algorithm can be found at ardsnet.org/tools.shtml.

Nutrition should be **enteral** rather than parenteral, if possible. This reduces the risk of catheter-induced sepsis and may also prevent the translocation of endotoxin and gram-negative colonic bacteria. Special formulas high in omega-3 fatty acids have not shown benefit in ARDS and septic shock and are discouraged.

Ventilator Support for ARDS

PEEP stands for **positive end-expiratory pressure**. On the ventilator, a valve shuts when the patient is near end-expiration, while there is still positive intrathoracic pressure.

ARDS displays shunt physiology. The best way to improve oxygenation is to recruit, or “pop open,” atelectatic and fluid-filled alveoli. At the same time, you want to avoid barotrauma and oxygen toxicity. To avoid oxygen toxicity, try to get a P_aO_2 of 60 mmHg with $F_iO_2 < 60\%$ ASAP. To pop open alveolar units, use PEEP. To avoid ventilator-induced lung injury (VILI), use **adequate but not excessive** PEEP (i.e., the minimum level of PEEP that allows an adequate mean arterial pressure (MAP) and a safe F_iO_2 of 60%).

When managing ventilators, keep in mind the potential for VILI, which arises from overdistended alveoli (from an increased tidal volume [TV] or an increased end-inspiratory plateau pressure) and the cyclic opening and closing of atelectatic alveoli (recruitment-derecruitment). An adequate level of PEEP prevents repetitive closure and opening of lung units.

Recommendations from 2000 from the NIH ARDS Network (and reconfirmed with a Cochrane analysis in 2013) indicate improved outcome with low TVs = 6 mL/kg and PEEP at adequate levels. (Lung protective ventilatory support strategy is discussed later under this topic.) Initiating low TVs early in the course of the disease appears to be critically important, and 6 mL/kg is considered the optimal TV. Generally, we start worrying about VILI due to excessive plateau pressures at > 30 cm H₂O.

Previously, TVs in the range of 12–15 mL/kg had been used, but this is too high for many patients with ARDS because their TLC is much smaller than normal. There is a trend to lower TVs in all patients on ventilators, whatever the cause (although there is no strong data to support a benefit, as there is in ARDS).

No single ventilator mode has proven better than another for ARDS patients. An assist-control, volume-cycled ventilator mode was used in the ARDS Network trial.

Initial settings:

- $F_iO_2 = 1$ (then follow a P_aO_2 goal as per Figure 6-34)
- TV = Start at 6 mL/kg of the ideal body weight (IBW). Monitor end-inspiratory plateau pressure! Maintain it at ≤ 30 cm H₂O.
- Inspiratory flow = Start at 60 L/minute.
- PEEP: See Figure 6-34. The PEEP is determined using a nomogram of F_iO_2 and achieving the P_aO_2 goal of 55–80 mmHg.
- Some physicians use a PEEP pressure just greater than the lower inflection point on the ventilator pressure-volume (PV) curve. Yet others use an empiric regimen, in which they adjust the PEEP to maintain an adequate S_aO_2 of at least 90% and a low enough F_iO_2 (< 60%). PEEP typically starts at ≤ 5 cm H₂O and usually goes up to 10–20 cm H₂O. For more information, see Positive End-Expiratory Pressure (PEEP) on page 6-82.

Novel therapies (e.g., granulocyte-macrophage colony-stimulating factor [GM-CSF], stem cells, nitric oxide, surfactant, ketoconazole) have not been demonstrated to improve survival.

A meta-analysis demonstrated a survival benefit from prone positioning, a.k.a. proning. The 2013 large PROSEVA multicenter trial demonstrated a survival

benefit with early initiation of prolonged (16 hours) proning. Issues around proning:

- Data supports increasing the P_aO_2/F_iO_2 ratio with prone positioning, which stabilizes the anterior chest wall, causing improved physiology and recruitment of previously unused alveolar units.
- The prone position was found to get the heart off of the left lower lobe and help with expansion.
- The prone position can cause pressure necrosis complications of the face and anterior body surfaces. In fact, if the ICU team is not experienced with prone positioning, bad things can happen (e.g., extubation, venous catheters fall out, blindness, even fractures). Well trained ICU staff is paramount for successful prone positioning success. Specialty beds are not required for successful proning maneuvers.

No clear mortality benefits exist with the empiric use of neuromuscular blockade.

Permissive hypercapnia: The ARDS Network low TV lung-protective ventilatory support protocol is the standard of care for ventilatory support in patients with ARDS. The study results demonstrated a mortality decrease. More specifically, some evidence suggests that respiratory acidosis may decrease lung injury and be protective. Permissive hypercapnia is acceptable in patients with ARDS. However, most nonparalyzed patients with ARDS on assist/control mode maintain a satisfactory minute ventilation.

The goal in a patient with ARDS is to maintain adequate tissue oxygenation—maintaining the $S_aO_2 > 88\%$. Do not worry so much about the P_aCO_2 . Allow hypercapnia to develop. The resultant acidosis can be corrected by any of the following:

- Increasing the respiratory rate (RR)
- Increasing the TV if the end-inspiratory plateau pressure is low
- Using NaHCO₃

Remember: Giving NaHCO₃ typically results in a subsequent increase in CO₂ as $NaHCO_3 + H^+ \leftrightarrow Na^+(Cl^-) + H_2O + CO_2$.

Renal compensation for the respiratory acidosis usually ensues, and typically you do not need to give an alkali or increase the minute ventilation. Permissive hypercapnia is acceptable in severe exacerbations of obstructive lung disease as well. Again, the therapy-determining measurement is the S_aO_2 , not the P_aCO_2 .

Permissive hypercapnia is not recommended in patients with intracranial hypertension or hemodynamic instability.

Trials show no proven survival advantage in the following treatments for ARDS: early high-frequency oscillation, surfactant administration, NSAIDs, antiendotoxin therapy, inhaled nitric oxide, and IV N-acetylcysteine (as an antioxidant).

NIH NHLBI ARDS Clinical Network Mechanical Ventilation Protocol Summary (Part I)

INCLUSION CRITERIA: Acute onset of

1. $P_aO_2/F_iO_2 \leq 300$ (corrected for altitude)
2. Bilateral (patchy, diffuse, or homogeneous) infiltrates consistent with pulmonary edema
3. No clinical evidence of left atrial hypertension

PART I: VENTILATOR SETUP AND ADJUSTMENT

1. Calculate predicted body weight (PBW).
Males = $50 + 2.3 [\text{height (inches)} - 60]$
Females = $45.5 + 2.3 [\text{height (inches)} - 60]$
2. Select any ventilator mode.
3. Set initial TV to 8 mL/kg PBW.
4. Reduce TV by 1 mL/kg at intervals ≤ 2 hours until TV = 6 mL/kg PBW.
5. Set initial rate to approximate baseline minute ventilation (not > 35 bpm).
6. Adjust TV and RR to achieve pH and plateau pressure goals below.

OXYGENATION GOAL: P_aO_2 55–80 mmHg or SpO_2 88–95%

Use incremental F_iO_2 /PEEP combinations below to achieve goal. [Note: Higher PEEP options (lower row) will decrease F_iO_2 and may be preferred in patients with high F_iO_2 who can tolerate higher PEEP (stable blood pressure, no barotrauma). Survival is similar with both PEEP approaches.]

F_iO_2	0.3	0.4	0.4	0.5	0.5	0.6	0.7	0.7
PEEP	5	5	8	8	10	10	10	12
	12–14	14	16	16	18–20	20	20	20

F_iO_2	0.7	0.8	0.9	0.9	0.9	1.0	1.0	1.0
PEEP	14	14	14	16	18	20	22	24
	20	20–22	22	22	22	22	22	24

PLATEAU PRESSURE GOAL: ≤ 30 cm H₂O

Check Pplat (0.5 second inspiratory pause) at least q 4h and after each change in PEEP or TV.

If Pplat > 30 cm H₂O: Decrease TV by 1 mL/kg steps (minimum = 4 mL/kg).

If Pplat < 25 cm H₂O and TV < 6 mL/kg, increase TV by 1 mL/kg until Pplat > 25 cm H₂O or TV = 6 mL/kg.

If Pplat < 30 and breath stacking or dys-synchrony occurs: may increase TV in 1 mL/kg increments to 7 or 8 mL/kg if Pplat remains < 30 cm H₂O.

pH GOAL: 7.30 – 7.45

Acidosis Management: (pH < 7.30)

If pH 7.15–7.30: Increase RR until pH > 7.30 or $P_aCO_2 < 25$ (Maximum RR = 35).

If pH < 7.15 : Increase RR to 35.

- 1) If pH remains < 7.15 , TV may be increased in 1 mL/kg steps until pH > 7.15 (Pplat target may be exceeded).
- 2) May give $NaHCO_3$.

Alkalosis Management: (pH > 7.45)

Decrease vent rate if possible.

Figure 6-34: NIH NHLBI ARDS Clinical Network Mechanical Ventilation Protocol summary

To summarize, when using the ventilator in the treatment of ARDS, avoid VILI and oxygen toxicity by doing the following:

- Start the TV at 6 mL/kg of the IBW. Keep plateau pressure ≤ 30 cm H₂O.
- Start the F_iO_2 at 1 and follow the recommendations set by the ARDS Clinical Network (Figure 6-34).
- Use adequate but not excessive PEEP.
- Use permissive hypercapnia if needed.
- Use the mentioned ARDS Network PEEP dosing tables (on ardsnet.org/tools.shtml and reproduced in Figure 6-34) as guidelines but adjust it as necessary to meet the needs of the individual patient.

Corticosteroids for ARDS

The pendulum has swung away from the use of steroids solely for ARDS inflammation. If steroids are used, start early (first 14 days) in moderate-to-severe ARDS.

SEPSIS

Sepsis, as defined in the 2016 Third International Consensus Definitions for Sepsis and Septic Shock (SEPSIS 3) guidelines, is life-threatening organ dysfunction caused by a dysregulated host response to infection. Sepsis is not a specific illness, it is a constellation of clinical signs and symptoms. As such, there is no gold standard diagnostic test. Sepsis and how it evolves in a patient is shaped by pathogen and host factors and how the host responses are amplified. Comorbidities, age, medications, and interventions influence the host responses and the sepsis syndrome.

Septic shock is defined as hypotension (MAP < 65 mmHg), hyperlactatemia, and the need for a vasopressor despite fluid resuscitation.

The Sequential Organ Failure Assessment (SOFA) Score assesses various organ systems, and in each category a score is created with morbidity implications. A SOFA score of at least 2 in conjunction with septic shock predicts a mortality of 40%. SOFA score items include assessment of:

- P_aO_2/F_iO_2 ratio
- Mechanical ventilation
- Platelets
- MAP
- Vasopressor requirement
- Bilirubin
- Glasgow Coma Scale
- Creatinine

Shock from sepsis confers a higher mortality than from nonsepsis etiologies. Prompt evaluation and potential treatment intervention are indicated. Obtain blood and other cultures, as well as lactate and other labs to help explain the findings.

The 2018 Surviving Sepsis guidelines outline correct sepsis management. They dropped protocolized treatment as well as empiric dual antibiotics for *Pseudomonas*. Initiate fluid resuscitation with 30 mL/kg of IV balanced crystalloid if hypotensive or lactate ≥ 4 mmol/L. The patient may require additional fluid when reassessed for volume responsiveness. If the patient has refractory hypotension, administer vasopressor therapy. Use of central venous pressure (static) measurements or pulmonary artery catheters to guide fluid management are no longer routinely recommended. Dynamic measures of fluid responsiveness such as passive leg raise, pulse pressure variation, and stroke volume variation are recommended instead. Effective fluid resuscitation can improve lactate clearance and can be used as a marker of improvement. Lactate should be obtained on initial evaluation and then 4 hours later if > 2 mmol/L.

Early antibiotic administration is a high priority and should be done preferably within the 1st hour and has shown to decrease hospital mortality in a linear fashion. Optimally, obtain cultures 1st and achieve source control of the sepsis. However, these efforts should not delay early antibiotic administration within the 1st hour of sepsis recognition. Give broad-spectrum empiric antibiotics targeting the likely source and cause of infection, usually vancomycin and gram-negative coverage. These can be tailored and then deescalated as cultures and other studies return and the patient improves.

Vasopressors are used for patients who remain hypotensive despite adequate fluid resuscitation. The 1st line recommended vasopressor is norepinephrine (2–12 mcg/minute, though there's no true ceiling). Epinephrine or vasopressin can be added if fluid and norepinephrine are insufficient to support blood pressure. The target MAP is ≥ 65 mmHg. For persistent hypotension, consider reevaluation for other causes, and an echocardiogram can be helpful. This may indicate whether inotropic support is needed. Steroids may be considered for those with refractory hypotension or those who have had exogenous steroids recently that might lead to adrenal suppression.

Critically ill patients (especially patients with sepsis +/- ARDS) can have a **normal** P_aO_2 and still have **abnormal** O_2 uptake by the tissues. This is thought to be a major contributor to multiple organ failure.

Be careful! **Mixed venous** O_2 may be **misleading** in the septic patient because there is significant peripheral shunting. Lactic acid levels may be misleading as an indicator of tissue hypoxia because an increase can also be caused by the liver's failure to clear it. Nevertheless, the lactic acid measurement and clearance is used in the decision-making of the Surviving Sepsis Campaign.

Always correct the underlying problem. Source control may require surgery or drainage of a focal infection, or removal of a catheter or line, **even if** the patient is **unstable**.

As previously stated, the utility of invasive monitoring in most cases of sepsis is highly questionable. A 2014 multicenter trial by the European Society of Intensive Care

Medicine demonstrated that CVP-guided fluid management is not needed. The use of pulmonary catheters in the medical ICU increases mortality; as a result, routine use has declined precipitously. If a pulmonary catheter is used, remember the following general principles regarding pulmonary capillary wedge pressure (PCWP):

- PCWP reflects left ventricular end diastolic pressure (LVEDP), and LVEDP is an indicator of LV function, reflecting compliance and stroke volume.
- Always read the PCWP at end-expiration.
- Read PCWP in all patients on a graphed wave form (not a digital printout).
- Never take the patient off PEEP to read the PCWP.

LVEDP is **often** determined **directly** during **left** heart catheterization just before contrast ventriculography (rather than during a right heart catheterization in the ICU). It is also checked when patients are being evaluated for causes of pulmonary hypertension.

Read more on PCWP in the [Cardiology](#) section.

INVASIVE MECHANICAL VENTILATION

Inflate the cuff of the endotracheal (ET) tube to the lowest possible effective pressure, ~ 15 mmHg. When the pressure exceeds ~ 25 mmHg, serious damage can occur to the tracheal mucosa.

The timing of a tracheostomy is controversial and takes into account specific patient variables and the likelihood of requiring prolonged ventilatory support. Typically, a tracheostomy is not performed during the 1st week of intubation (barring other indications). Tracheostomy is **not** indicated solely to decrease airway resistance during weaning.

VAP is a frequent complication of mechanical ventilation (see more under [VAP on page 6-63](#)). Here is a quick review: Almost all patients are colonized with gram-negative bacteria in the upper and lower airways within 74–96 hours of endotracheal intubation. It can be very difficult to sort out true pneumonia vs. colonization. Ventilator-associated tracheobronchitis (VAT) has also been described for those without infiltrates. The 2016 Infectious Disease Society of America/American Thoracic Society (IDSA/ATS) guidelines recommend against antibiotic treatment for VAT. For a diagnosis of pneumonia, you should see:

- New or worsening infiltrate
- Leukocytosis
- Purulent sputum or endotracheal secretions
- Fever or hypothermia

Noninvasive sampling is preferred to diagnose VAP. Cover both *Pseudomonas* and methicillin-resistant *Staphylococcus aureus* (MRSA) with empiric antibiotic treatment for VAP. In 2016, the CDC proposed a new definition for ventilator-associated events (VAE) that is used for objective, nonclinical surveillance purposes with events reported to the National Healthcare Safety

Network. A VAE is entered based on changes in oxygen or PEEP, changes in antibiotics secondary to changes in oxygenation requirements, fevers, elevation in white blood count, or purulent secretions.

Modes of Mechanical Ventilation

Continuous Ventilation

CMV has a set rate and a set TV that does not allow spontaneous breathing. Patient-ventilator asynchrony is a big problem. Therefore, this mode is best used in patients who are heavily sedated, under anesthesia, paralyzed with muscle relaxants, or in a deep coma.

Assist/control (AC) is CMV with a set rate and TV, but this mode allows the patient to initiate additional breaths “above the ventilator.” When the machine senses that the patient is attempting to take a breath (the pressure sensor detects a negative pressure inspiratory effort that exceeds a set threshold), it kicks in with a full machine-supported breath at the ordered TV. This is a commonly used mode of ventilation. One caveat: If patients are anxious, hyperventilating, or have obstructive lung disease, they continue to trigger additional full machine breaths, get even more hyperventilated, and are at risk for developing auto-PEEP. This usually occurs when the rate is $\geq$ the high teens to twenties.

Intermittent Ventilation

Intermittent mandatory ventilation (IMV) is similar to AC in that you dial in a set rate and TV, but spontaneous breaths at a patient-determined rate and TV can be taken between the set breaths. Because this spontaneous breath requires a lot of work from the patient to suck in a breath through the ET tube and the ventilator circuit, we often add pressure support ventilation to the IMV mode. Therefore, when the patient takes a spontaneous breath, there is a boost of pressure (you set the amount) to help overcome the resistance of the ET tube and the ventilator circuit. Typically, you use a pressure support of 5–20 cm H₂O, but you need to titrate this pressure for an individual patient after you see what kind of spontaneous TVs the patient can generate.

Note: The above volume-cycled ventilators have a pop-off valve set at a certain inflation pressure to prevent over-pressurization of the lungs.

Pressure Support Ventilation (PSV)

PSV, when used in a spontaneously breathing patient (no set TV or RR), supplies only pressure support, and there is no need for mandatory breaths. This is a very comfortable mode for the patient because he or she determines the rate, inspiratory time, and TV. However, you must have a patient with a stable respiratory drive (i.e., not heavily sedated and not paralyzed). More importantly, remember that there is no guarantee as to what TV will be generated at a specific level of pressure support (this will be influenced by airway resistance

and compliance of the respiratory circuit and system). If your patient is prone to—and develops—acute HF, the lungs may acutely become stiffer, or less compliant, and for a given level of pressure support a smaller TV will be delivered, potentially causing tachypnea and respiratory distress. The inspiratory pressure can be increased while the underlying cause is addressed.

Pressure Control Ventilation (PCV)

PCV is a form of ventilation that is actually a throwback to the first ventilators. In this mode, machine breaths are pressure cycled, not volume cycled. You determine the pressure you want the patient to receive on each breath, inspiratory/expiratory ratio, and the rate at which the breaths are delivered. If the patient attempts a spontaneous breath, they get a machine breath at the pressure you have designated.

This may be helpful in limiting airway pressures in patients with high-end inspiratory plateau pressures in other volume-cycled modes that leave them susceptible to barotrauma. Use of this mode lets you use a low TV and a high PEEP strategy for ARDS, because the peak inspiratory pressure is lower on PCV than on AC for any given achieved TV. As with PSV, the TV varies with airway resistance and respiratory compliance. Hence, this mode must be titrated carefully and monitored at the bedside to determine the proper pressure settings and achieved TV.

Weaning and Failure to Wean

Weaning is best accomplished by using protocols. Generally, weaning is performed as the patient stabilizes ($F_iO_2 \geq 40\%$, minimal vasopressor requirements, adequate mentation) and combines a spontaneous awakening trial (sedation/analgesia is reduced to allow the patient to awaken) with a subsequent spontaneous breathing trial (SBT):

- 1) SBT protocols have the patient breathe at low levels of pressure support for 30–120 minutes to see how the patient tolerates spontaneous breathing with no or minimal assistance from the ventilator. The respiratory frequency and minute ventilation are monitored along with the patient's vital signs, respiratory effort, and pattern. If the patient has a suitable cough to protect their airway and secretions expectorated are deemed to be manageable by the patient, they can be extubated. The rapid shallow breathing index or RSBI (RR per minute/TV in liters) can help predict weaning failure. If the RSBI is > 105 breaths/minute the predicted weaning failure rate is increased. The SBT can also be performed on patients who have a tracheostomy in place.
- 2) Patients who are difficult to wean may be subsequently weaned by using pressure support trials with progressive reduction in the amount of pressure support until they are able to tolerate an SBT.

Possible causes of failure to wean (DESAT) include:

- Drugs (e.g., sedatives). Sedation or altered mental status is one of the most common reasons for failure to wean.
- Endotracheal tube and electrolyte imbalances. Sometimes the intraluminal diameter of the tube is too small. Over time, it is common for ET tubes to decrease in diameter due to secretions and biofilms adhering to the internal lumen. Automatic tube compensation is a ventilatory mode that dynamically compensates for the increased resistance of the ET tube, thereby making the final stages of weaning more predictable. Hypocalcemia, hypophosphatemia, and hypomagnesemia all impair weaning.
- Secretions
- Alkalemia (which decreases the respiratory drive)
- Too high or too low a $P_a\text{CO}_2$ just before extubation (Keep these parameters near the patient's baseline.)

There is potential danger in suddenly switching from positive pressure ventilation in patients with limited cardiac function or occult cardiac ischemia to full spontaneous breathing: stopping positive pressure ventilation → increased venous return → increased cardiac filling pressures → need for increased cardiac output → HF or cardiac ischemia in susceptible patients. These patients are often treated with diuresis and even IV nitroglycerin in order to temporarily lower the preload.

Chronic obstructive pulmonary disease (COPD) patients with chronic respiratory failure are less able to get rid of CO_2 , so intubation with a larger-bore endotracheal tube helps decrease airway resistance, and extubation to NiPPV improves outcomes. Also avoid overventilating a patient with COPD who is at baseline a CO_2 retainer. That is, adjust the minute ventilation ($\text{TV} \times \text{RR}$) to match the baseline $P_a\text{CO}_2$ (estimated or known from a blood gas).

Adjusting a Ventilator

Remember: When we are adjusting a ventilator to improve a patient's ABGs, we have to separate our actions into 2 categories:

- 1) Those that change alveolar or minute ventilation ($\text{TV} \times \text{RR}$) change the patient's $P_a\text{CO}_2$ and pH. Remember alveolar ventilation is inversely proportional to $P_a\text{CO}_2$. Alveolar ventilation = $(\text{TV} - \text{dead space}) \times \text{RR}$.
- 2) Those that alter a patient's oxygenation are F_iO_2 , PEEP, and inspiratory/expiratory ratio.

Positive End-Expiratory Pressure (PEEP)

PEEP is a positive pressure that remains in the chest at the end of exhalation. This can be done purposely to a patient on a ventilator by closing a valve during exhalation and not allowing the pressure in the airways to return to zero.

You dial in a PEEP pressure—the desired end-expiratory pressure—typically 5–15 cm H_2O (you can go higher in ARDS). The purpose of utilizing PEEP in mechanically ventilated patients is to help prevent the alveoli from completely collapsing at the end of expiration. This prevents atelectasis and, more importantly, leads to better matching of V/Q while having less of a shunt fraction. PEEP also prevents atelectrauma, which is damage caused by shearing forces that arise during repeated reexpansion of collapsed lung units.

Use higher levels of PEEP only with diffuse lung disease! It can actually decrease the $P_a\text{O}_2$ if used in focal lung disease. Use PEEP in cases of diffuse lung disease if required to maintain the $\text{F}_i\text{O}_2 < 60\%$, while keeping the $P_a\text{O}_2 > 60 \text{ mmHg}$.

An elevated PEEP can cause:

- Pneumothorax, ventricular failure, and alveolar damage, which can precipitate or worsen pulmonary edema. The PEEP level recommended in ARDS is based on a nomogram, as discussed previously. Some advocate using the lowest level of PEEP required to oxygenate the patient with a safe F_iO_2 (60%).
- Decreased venous return, causing decreased cardiac output and hypotension

Auto-PEEP

Auto-PEEP usually happens when the patients are not fully emptying their lungs during expiration prior to the initiation of the next breath. This is known as stacking breaths or generating auto-PEEP. The problem is the RR is too fast to allow complete emptying.

A patient on a ventilator gets auto-PEEP if the ventilator is set up in a way that does not allow the patient to fully exhale before initiating the next breath. This is particularly worrisome in patients who have exacerbations of COPD or who are in status asthmaticus. The auto-PEEP may become severe enough that the patient can suffer barotrauma, hypotension, or hemodynamic collapse secondary to the inability of venous return of blood to the heart.

Auto-PEEP can also occur in spontaneously breathing patients with obstructive lung disease and is responsible for creating dynamic hyperinflation, with all of the consequences of auto-PEEP combined with the increased work of breathing. On physical examination you hear the next breath come in before the exhalation is complete. You can see the potential for auto-PEEP by observing the flow waveform and noting an expiratory flow that does not return to the zero baseline before the initiation of the next breath.

Auto-PEEP can be measured in mechanically ventilated patients using either of the following 2 methods:

- 1) Insert an end-expiratory pause in the ventilator circuit and observe the airway pressure monitor during the pause.

- 2) Use ventilators that automatically measure this.
The pressure curve on the flat panel display does not return to the set PEEP level.

The treatment of auto-PEEP requires treatment of the underlying obstructive lung disease. More immediately, reduce the RR. The principle is to take action to shorten inspiration and lengthen the expiration. This can include the following interventions:

- 1) Decrease the RR, which is the primary effective intervention when there is significant auto-PEEP. This may require sedation if the patient is breathing over the ventilator.
- 2) Decrease the TV, which has minimal effect.
- 3) Increase the peak inspiratory flow rate (PIFR), which has a slight effect.
- 4) Treat bronchospasm and reduce airway secretions (if they are leading to increased airway resistance).

If a patient with severe airway obstruction has hypotension related to auto-PEEP **after** being placed on mechanical ventilation, perform the following steps:

- 1) Disconnect the patient from the ventilator and slowly bag the patient through the ET tube. Check for tension pneumothorax and mucous plugs and otherwise ensure that the ventilator is functioning properly.
- 2) Return the patient to the ventilator with new settings that allow for a longer expiratory phase, generally a lower RR. Specific changes include lowering the RR, increasing the inspiratory flow rate (shortening the time the patient gets for inspiration and, hence, allowing a longer time for expiration), and reducing the TV.

Note that the patient must be sedated or paralyzed to accurately measure the auto-PEEP.

As a historical reference, **inverse ratio** ventilation is a technique that was employed in patients with ARDS, whereby auto-PEEP was purposely generated as a mechanism for “recruiting” alveoli. It has fallen out of favor because of the significant potential for barotrauma, need for deep sedation, and no improvement in mortality.

NONINVASIVE VENTILATION (NIV)

NIV or NiPPV consists of a mask interface (either full face mask over the nose and mouth or nasal mask) and tubing connected to a device that can provide bilevel positive airway pressure (BiPAP) or continuous positive airway pressure (CPAP). CPAP can be used in pulmonary edema to improve oxygenation when there is no problem with ventilation (CO_2 is not markedly elevated), while BiPAP is used most commonly, because it will ventilate the patient (blow off CO_2) and oxygenate the patient. For BiPAP, both inspiratory pressure (IPAP) and expiratory pressure (EPAP) are ordered. The greater the difference between IPAP and EPAP, the more CO_2 will be blown off. Some devices allow

measurement of the achieved TV for given IPAP and EPAP settings. However, you can empirically start with IPAP of 10 cm H_2O and EPAP of 5 cm H_2O and increase these in order to ventilate more (increase IPAP) or oxygenate more (increase EPAP, but also some effect from IPAP).

NIV is utilized in spontaneously breathing, awake individuals who do not have a compromised airway but who are in respiratory distress. The indications are often COPD exacerbation, pulmonary edema, or other etiologies where the patient is expected to respond to acute therapy for a reversible cause. For some patients, NIV is not sufficient to meet their needs, such as those with severe gas exchange abnormalities, marked distress, developing lethargy, or intolerance for the mask interface. Intubate patients in marked respiratory distress, for whom NIV is not likely to be sufficient, or who have contraindications. Contraindications include vomiting, massive hemoptysis, intractable respiratory secretions, ongoing aspiration, poor respiratory drive, cardiac or respiratory arrest, inability to tolerate face mask or pressure, facial trauma, surgery or burns, esophageal or gastric surgery, or severe respiratory failure.

Support and manage NIV with the direct involvement of respiratory therapy. Adjustments may be needed at frequent intervals, and patients should be closely monitored by vital signs, oximetry, and blood gases. Patients started on NIV for respiratory failure are managed in a higher level of care, such as initially in the emergency department and then ICU. The patient should be monitored for deterioration that can happen rapidly and may require intubation.

NUTRITIONAL SUPPORT

Nutritional support in ICU settings is **extremely important** and often underemphasized. Use the **enteral route of nutrition** whenever possible. After major surgery or the onset of sepsis, metabolic requirements increase dramatically. Requirements peak in 3–5 days. If the patient is unable to eat, start enteral feedings (standard formula for most critically ill patients) **in the first 24–36 hours of ICU admission**. It reduces mortality and hospital length of stay. Even though enteral feeding increases the possibility of aspiration, it is preferred over total parenteral nutrition (TPN) because it tends to maintain the intestinal epithelium and its natural defenses against bacteria. TPN also has an increased risk of bacteremia and fungemia.

With enteral feeding, you can decrease the risk of aspiration and pneumonia by keeping the head of the bed elevated $\geq 30^\circ$. The position of the head is more important than where the feeding tube is placed (e.g., pre- vs. postpyloric). Per the 2016 ASPEN guidelines, do not check for gastric residuals in an asymptomatic patient. Routine supplements (e.g., omega-3 fatty acids, arginine, fiber) are not indicated. Prepyloric feeding is satisfactory; usually place postpyloric tubes in those with high risk of aspiration or intolerance to gastric feeding.

Refeeding syndrome occurs when severely malnourished patients; e.g., those with chronic alcoholism, anorexia nervosa, malignancies are fed high-carbohydrate loads (i.e., enteral tube feeds or IVF with glucose). These patients develop low total body levels of electrolytes, specifically phosphorus, Mg^{2+} , and K^+ .

With refeeding syndrome:

- There is a dramatic increase in circulating insulin levels and a resulting swift cellular uptake of glucose, phosphate, Mg^{2+} , and K^+ , resulting in a precipitous drop of these agents in the serum. The resulting severe **hypophosphatemia** (lack of ATP and 2-3-diphosphoglycerate) causes heart and respiratory failure, rhabdomyolysis, RBC and WBC dysfunction, seizures, and coma. Hypomagnesemia can result in arrhythmias, including torsades des pointes.
- Myocardial atrophy from prior starvation increases the propensity for acute heart failure secondary to Na^+ and water retention.

Prevent refeeding syndrome by starting the feeding of severely malnourished patients slowly and by aggressively replacing phosphate, Mg^{2+} , and K^+ .

SHOCK STATES

Shock is a circulatory systemic deficiency that leads to insufficient delivery of oxygen to tissues and may lead to organ dysfunction. There are different types of shock, including hypovolemic, cardiogenic, distributive, and obstructive. It is important to differentiate these.

Hypovolemic shock is due to loss of blood volume or dehydration. Hemorrhage from the GI tract, trauma, ruptured aortic aneurysm, or ruptured ectopic pregnancy cause hypovolemic shock. In addition, diarrhea, poor po intake, vomiting, polyuria, and excessive losses through sweating are other potential causes. Patients with this form of shock are hypotensive and tachycardic. The skin may be cold or clammy. There is low urine output. Volume resuscitation and transfusion, as well as correction of the underlying cause are indicated.

Cardiogenic shock is caused by failure of the pump function of the heart due to loss of myocardial contractility or loss of structural components of the heart. These include myocardial infarction, myocarditis, cardiomyopathy, valve failure, bradycardia, arrhythmia, or hypertrophic cardiomyopathy.

The patient is hypotensive and heart rate varies depending on the cause but is usually rapid and faint. The skin is cool and mottled, jugular venous pressure (JVP) is elevated, and crackles are present on the lung exam. Peripheral edema may be present.

Chest x-ray typically shows pulmonary edema, and there may be evidence of cardiomegaly. ECG may show acute or evolving ischemic changes or arrhythmia or may be normal. Cardiac enzymes may be elevated.

Echocardiography is essential and may show decreased ejection fraction, structural abnormalities, valvular disease, and other findings. In some cases, pulmonary artery (right heart) catheterization is done and generally shows an elevated PCWP (usually > 15 mmHg) and a reduced cardiac output/index.

Management generally includes diuretics, vasopressors, oxygen, and possible mechanical ventilation. In some cases, inotropic support with dobutamine or milrinone may be used. Short-term mechanical assist devices include intraaortic balloon pumps and LV assist devices. For patients with acute coronary syndrome, management includes aspirin, heparin, β -blocker, statin, and consideration for PCI or CABG. Thrombolytic therapy can be used if revascularization procedures are not done.

Distributive shock is most commonly caused by septic shock but may also result from noninfectious causes (e.g., acute pancreatitis, burns, bowel obstruction), anaphylaxis, drug reactions, transfusion reactions, neurogenic shock, liver failure, and toxic shock syndrome.

Pathophysiologically, there is direct vasodilatation due to circulating bacterial endotoxin, other exogenous substances or toxins, and/or circulating inflammatory mediators. In addition, there is loss of responsiveness of vascular smooth muscle to vasoconstrictors that maintain tone. There is often loss of capillary integrity with 3rd spacing of fluid.

Early in septic shock there is a hyperdynamic phase with tachycardia and hypotension, and skin is often warm and flushed. As shock progresses, there is hypoperfusion and often reduced cardiac contractility and skin is often cool.

Fluid resuscitation is indicated, and, for sepsis, vasopressor support. See [Sepsis on page 6-79](#).

Obstructive shock is due to blocked circulation in the great vessels or the heart, with decreased ventricular preload or increased ventricular afterload. Decreased ventricular preload may be due to increased intrathoracic pressure from tension pneumothorax, mechanical ventilation, or status asthmaticus; decreased cardiac compliance from constrictive pericarditis or cardiac tamponade; and direct venous obstruction from intrathoracic tumor. Increased ventricular afterload may result from acute pulmonary embolism, acute pulmonary hypertension, and aortic dissection.

Physical findings vary depending on the etiology but can include unilaterally decreased breath sounds and tracheal shift with tachycardia for tension pneumothorax. Findings of air trapping may be present. Patients with acute pericarditis and/or cardiac tamponade can have chest pain, fever, pulsus paradoxus (> 20 mmHg decrease in normal inspiratory drop in blood pressure), the Beck triad of JVP elevation, hypotension, and muffled heart sounds. Often the patient feels weak or faint.

A systematic approach to evaluating shock should include consideration of obstructive shock

etiologies and lead to appropriate testing. ECG may show ST-segment elevations in acute pericarditis or low voltage in pericardial effusion. Echocardiogram may show thickened pericardium and/or pericardial effusion with collapsed ventricles.

Treatment includes relief of tension pneumothorax with tube thoracostomy and correction of conditions that led to its development. Pericardiocentesis, removal of tamponade fluid to relieve shock, and analysis of fluid help determine cause. In some cases, creation of a surgical pericardial window is needed for chronic pericardial effusions. Acute pulmonary embolism with hypotension that does not respond to IV fluid is treated with thrombolytic therapy or mechanical removal (e.g., embolectomy, retrieval catheters).

PULMONARY ARTERY CATHETERIZATION

Right heart and pulmonary artery catheterization are done with a balloon-floated (i.e., Swan-Ganz) catheter. These catheters have specialized uses in the diagnosis and evaluation of pulmonary hypertension and in cardiac care and presurgical management. Weigh the risks and benefits carefully for each patient. Systematic reviews and clinical trials found that the use of a pulmonary artery catheter did not alter patient mortality or length of stay in the ICU or hospital, but incurred increased costs, and resulted in significant complications. Consequently, pulmonary artery catheters are not routinely used in the ICU setting but may be employed in very specific settings, such as right heart catheterization for diagnosis and evaluation of pulmonary hypertension or to determine etiology of shock. They may be used in the coronary care unit (CCU) or perioperatively in some cases.

Catheter insertion:

- As the catheter is introduced—typically via the internal jugular vein—pressure readings of the central venous right atrial (normal = 0–8 mmHg), RV (0–8 end-diastolic; 15–30 systolic), and the pulmonary artery (3–12 end-diastolic; 15–30 systolic) are taken.
- When the catheter is flow directed to a small pulmonary artery, the balloon at the tip temporarily obstructs the forward flow and the reading (wedge pressure, a.k.a. pulmonary artery occlusion

pressure) is a reflection of LVEDP. LVEDP is a reflection of the LV preload (assuming the compliance is not changed). The LVEDP indicates the likelihood of left ventricular failure and pulmonary edema.

Thermal-dilution cardiac output (CO) is a test that uses the temperature gradient of injected water to calculate the CO.

Mixed venous oxygen saturation (S_{vO_2}) is the last measurement of the venous blood before it gets oxygenated. Normally, the S_{vO_2} is 78%. This number drops as the global tissue oxygen debt increases. If it gets too low, you must boost delivery of O_2 to the tissues (by increasing the O_2 saturation, in particular the cardiac output, or Hgb concentration—discussed under [Oxygen Delivery to Tissues on page 6-9](#)).

The systemic vascular resistance (SVR) measurement reflects vascular tone (i.e., vasodilated vs. vasoconstricted).

$$SVR = (MAP - CVP) \times 80/CO$$

MAP = mean arterial pressure; CVP = central venous pressure.

Complications of Pulmonary Artery Catheterization

Establishing central venous access can cause unintentional puncture of nearby arteries, bleeding, neuropathy, air embolism, and pneumothorax.

Advancing the catheter can cause dysrhythmias, which are usually transitory but may be persistent. Advancement of the catheter can cause right bundle-branch block and, in a patient with left bundle-branch block, this may result in **complete** heart block.

A catheter residing in the pulmonary artery can cause pulmonary artery rupture (with 53% mortality), venous thrombosis, thrombophlebitis, pulmonary embolism, and pulmonary infarction.

The 2006 Fluids and Catheters Treatment Trial (FACTT) by the ARDS Network found similar outcomes when using CVP vs. pulmonary artery catheter to guide the management of ARDS patients. See treatment of ARDS under [Treatment on page 6-77](#).

Know [Table 6-16](#).

Table 6-16: Catheterization and Shock

Pulmonary Artery Catheters: Hemodynamic Subsets of Shock

Type	CO	Wedge Pressure	SVR	Treatment
Hypovolemic	Low	Very low	High	NS or RL
Cardiogenic	Very low	High	High	Variable: Consider inotrope, cardiac catheter, IABP
Distributive*	High-nl-low	Low	Very low	See sepsis guidelines.
Obstructive†	Low	Low	High	Resolve obstructive cause, +/- temporize with fluids.

CO = cardiac output; IABP = intraaortic balloon pump; nl = normal; NS = normal saline; RL = Ringer lactate; SVR = systemic vascular resistance

* As seen in septic, spinal, and anaphylactic shock; have total loss of SVR

† As in massive PE or tension pneumothorax

From John Morrissey, MD

SLEEP-DISORDERED BREATHING

PREVIEW | REVIEW

- Discuss the risk factors for obstructive sleep apnea-hypopnea syndrome (OSAHS).
- What should be avoided in patients with OSAHS?
- Describe OHS and how it relates to OSAHS.

OVERVIEW

There are various types of abnormal respiratory patterns that can occur during sleep. These vary from apnea (with obstructive and central origins) and hypopnea to respiratory effort-related arousals.

Apnea is defined as the cessation of breathing for ≥ 10 seconds during sleep. It becomes clinically significant at 5–15 episodes per hour, and severe cases may have > 30 /hour. Oxygen saturation usually decreases by $> 4\%$ during the apneic episodes.

The American Academy of Sleep Medicine definition of **hypopnea** is a decrease of $\geq 30\%$ of the baseline airflow for ≥ 10 seconds and oxygen saturations decreased by $\geq 3\%$ from baseline with an arousal or $\geq 4\%$ from baseline.

The 2 main classes of sleep apnea are central and obstructive, although both can coexist in a single patient.

Respiratory effort-related arousals relate to multiple arousals from sleep due to obstructive symptoms that do not qualify for the definition of hypopnea.

Patients may have daytime hypersomnolence. History of snoring or arrested breathing (witnessed apneic events) is often obtained from a sleeping partner. When severe, **pulmonary hypertension/cor pulmonale** (from the chronic hypoxia) and personality changes may develop.

Diagnosis is confirmed by **polysomnography** (sleep study). The patient is hooked up to multiple electronic gadgets (i.e., ECG, EEG, electrooculogram, pressure sensors for flow measurement, EMG, oximeter, tidal CO_2 recorder) during sleep. The presence or absence of an inspiratory effort during the apneic episode differentiates between obstructive and central apnea. The frequency of hypoxic apneic episodes determines the severity of the disease. A normal number is $< 0\text{--}4$ /hour, mild is 5–14/hour, moderate is 15–30/hour, and severe disease is > 30 /hour.

OBSTRUCTIVE SLEEP APNEA-HYPOPNEA SYNDROME (OSAHS)

OSAHS is sleep apnea or hypopnea occurring despite a continuing ventilatory effort. The obstructive episode is usually followed by a loud snore. Patients have daytime hypersomnolence and snoring and may have headaches and weight gain. Using the STOP-BANG questionnaire—which assesses snoring, tiredness, observed apneas, high blood pressure, BMI, age, neck size, and gender—a score

can be obtained to determine if OSAHS is expected. A score of ≥ 3 has an 84% sensitivity for the diagnosis of OSAHS. In North America, it is estimated to occur 2–3× more often in men. OSAHS is diagnosed after an overnight polysomnogram with apnea plus hypopnea-associated desaturation of $\geq 3\text{--}4\%$; the apnea hypopnea index (AHI) is ≥ 15 /hour. OSAHS is also diagnosed if the patient has an AHI of ≥ 5 with daytime hypersomnolence, or ≥ 15 with or without daytime symptoms.

Risk factors for OSAHS are obesity, myxedema, and upper airway abnormalities. Causes of an abnormal airway include tonsillar hypertrophy or lymphoma, micrognathia, acromegaly, goiter, and temporomandibular joint (TMJ) disease. Although various medications may worsen OSAHS and should be avoided in these patients, they have not been shown to cause OSAHS.

Know that OSAHS is associated with several severe diseases, including hypertension, metabolic syndrome, coronary artery disease, stroke, nonalcoholic fatty liver disease, and arrhythmias.

Perioperative complications and motor vehicle accidents (2–3× increased incidence) are also common in these patients. Patients with untreated, severe disease and those who have untreated CHD have decreased survival.

Treatment of OSAHS

Prescribe lifestyle modifications, including weight loss (when appropriate), sleep hygiene, side sleeping, and avoidance of alcohol and sedatives. Treat OSAHS with either CPAP, BPAP, or autotitrating CPAP. With CPAP, the patient receives air at constant pressure (usually 5–15 cm H_2O) via a well-sealed mask. This splints the pharynx open at night. It is **very effective**. BPAP is similar but allows independent adjustment for inspiratory and expiratory pressures. This improves comfort and compliance. Autotitrating CPAP adjusts pressure according to the patient's needs and is increasingly being utilized.

Uvulopalatopharyngoplasty (UPPP) and dental or mandibular advancing devices are alternatives to consider in selected patients based upon the anatomy and level of obstruction. However, their efficacy is highly variable. UPPP and dental devices can be offered especially in patients with mild-to-moderate OSAHS but are often considered only after the patient does not tolerate or respond to noninvasive PAP. Both UPPP and dental devices are sometimes used in severe sleep apnea to decrease the amount of PAP required, but as noted, efficacy is not always predictable.

Very severe OSAHS and obesity hypoventilation syndrome (OHS; see **Obesity Hypoventilation Syndrome (OHS)**) may require tracheostomy in some cases, which is effective.

Modafinil is used in patients with daytime somnolence despite compliance with other appropriate therapies, as discussed previously. Other medications include armodafinil and methylphenidate.

CENTRAL SLEEP APNEA SYNDROME (CSAS)

CSAS occurs in < 5% of sleep apnea patients. Cheyne-Stokes breathing is a type of central apnea and is typically seen with CNS and cardiac disease (mainly HF). Central apneas can occur in healthy persons when they wake up suddenly at night (referred to as postarousal centrals). They can also occur at high altitude.

Treatment of CSAS: Avoid CNS depressants, such as alcohol, sedatives, and hypnotics. Encourage weight loss and avoiding sleep deprivation.

Nasal CPAP or BPAP with a mandatory back-up rate are usually the 1st line therapies and may be particularly useful in patients who also have OSAHS.

CSAS treatment is not standardized and depends upon the specific etiology. Try different therapies. Supplemental nighttime oxygen is helpful for those with hypoxemia due to heart failure. Acetazolamide is often helpful; it causes a metabolic acidosis that stimulates a central compensatory response. Acetazolamide is a diuretic and therefore may be useful in patients with Cheyne-Stokes breathing with HF.

Question: When do nocturnal O₂ desats occur **without** apnea? Answer: COPD/emphysema, kyphoscoliosis, and muscular dystrophy.

OBESITY HYPOVENTILATION SYNDROME (OHS)

OHS, a.k.a. Pickwickian syndrome, is defined as hypoventilation while awake, although **most** also have OSAHS.

Patients with OHS have 2 main findings:

- 1) BMI > 30 kg/m² in most
- 2) pCO₂ > 45 mmHg when awake

If no ABGs are available, look for an elevated HCO₃⁻ on the serum chemistry as a clue (due to metabolic compensation for the chronic respiratory acidosis). However, this may be confounded by patients undergoing diuresis causing a hypochloremic metabolic alkalosis. Screen for hypothyroidism!

Treatment: Aim therapy at decreasing obesity and increasing the ventilatory drive. Patients should lose weight. Treatment for OHS is similar to OSAHS, but BPAP is the 1st line therapy in order to address the hypercapnia.

LUNG CANCER

For information on lung cancer, see the [Oncology](#) section.

SUPERIOR VENA CAVA (SVC) SYNDROME

PREVIEW | REVIEW

- List the causes of superior vena cava syndrome, both malignant and nonmalignant.

SVC syndrome is a medical emergency. 80% of cases are due to malignancy with the majority caused by **small cell or squamous cell** lung cancers (less often by lymphoma and metastatic tumors). Permanent central venous access is an emerging nonmalignant cause. Others include fibrosing mediastinitis secondary to histoplasmosis or tuberculosis as well as goiters.

Presentation includes swelling of the neck and face (especially the periorbital region), shortness of breath, and cough. Examination reveals distended neck veins with visible collaterals, edema across the chest and onto the face, and difficulty breathing. Hypotension may also be present. Pemberton sign is seen when the patient elevates both arms and develops facial congestion and cyanosis as well as respiratory distress.

Diagnosis is usually obvious by looking at the patient and noting the turgid face and neck. Contrast CT is the recommended imaging. If the patient does not already carry a diagnosis of malignancy, and the chest CT does not show one, look for it! Tracheal obstruction is a major concern.

Treat less acute cases with diuretics and elevation of the head. Steroids help reduce tumor size only in certain malignancies such as lymphoma. Endovenous stents and radiation may help NSCLC and other solid tumor metastasis. Chemotherapy helps small cell lung cancers. All these interventions are strictly palliative.

In the case in which the cause of SVC is nonmalignant (e.g., aortic aneurysm; goiter; benign tumors; and infections such as fibrosing mediastinitis secondary to tuberculosis, syphilis or histoplasmosis), surgery can help. If the cause is venous thrombosis due to an indwelling central venous catheter, remove the catheter and initiate systemic anticoagulation.

MEDIASTINAL MASSES

PREVIEW | REVIEW

- What are the most common causes of anterior mediastinal masses? Middle? Posterior?

For an overview of mediastinal masses, see [Table 6-17 on page 6-88](#).

Table 6-17: Mediastinal Masses — Type Based on Location		
Anterior	Middle	Posterior
Thymoma Thyroid tumor Parathyroid tumor Teratoma Lipoma Aortic aneurysm Lymphoma Thymus Other endocrine tumors	Lymphoma Cysts Lymphadenopathy Aortic aneurysm Hernia	Neurogenic tumors Gastroenteric cysts Esophageal lesions Aortic aneurysm Hernia
Of the primary mediastinal tumors: 20% = Cysts 20% = Neurogenic tumors 20% = Thymomas* 10% = Lymphomas 10% = Teratomas 20% = Miscellaneous		
* Note that thymomas are associated with autoimmune diseases, such as myasthenia gravis.		

COUGH

OVERVIEW

Cough is a common and often troublesome respiratory symptom, particularly when it becomes chronic (in adults, ≥ 2 months). Social stigma is often associated with cough, due to concerns about potential contagion, but people also find it annoying (both for the person with cough and those around it). A systematic approach is important to the diagnosis and management of cough.

DIAGNOSIS

The history should include onset, factors around the onset (e.g., illness, exposures, environmental conditions, change of home or work), frequency of cough, time of day, changes with position (e.g., lying down), exacerbating factors, new medications, presence or absence of sinus symptoms, postnasal drip, gastroesophageal reflux disease (GERD), wheezing, sputum production, change in sputum color or consistency, dysphagia, and aspiration. Relevant past medical history includes prior respiratory tract infections, bronchiectasis, conditions that predispose to dysphagia (e.g., neurologic conditions) or GERD, sinus disease, and pulmonary illnesses. The occupational history and social history are important, noting habits such as cigarette and drug use. Note should be taken of new medications—notably ACEIs and potentially β-blockers—and of therapies employed to treat the cough previously, including OTC medications.

In the physical examination, take note of any signs of sinus disease, oropharyngeal disease, wheezes, crackles, or rhonchi.

The differential diagnosis for chronic cough includes allergic or nonallergic rhinitis/sinusitis, airway disease (e.g., asthma, COPD), GERD, eosinophilic bronchitis, pulmonary disease (e.g., pulmonary fibrosis, sarcoidosis, bronchiolitis), bronchiectasis, tuberculosis, dysphagia/chronic aspiration, foreign body, endobronchial tumor, malignancy, pertussis, postinfectious cough (e.g., viral), and psychogenic cough.

TREATMENT

Management is generally directed by the findings of the history and physical. Smoking cessation (including of all inhaled substances) and avoidance of or protection from dusts, fumes, and irritants is recommended.

Upper airway cough syndrome results from postnasal drip from allergic or nonallergic rhinitis/sinusitis and sensation of these draining secretions. This leads to cough and frequent throat clearing. Management includes daily nasal steroid, antihistamine therapy, leukotriene antagonist, sinus rinse, temporary use of ipratropium nasal spray for nonallergic causes, removal of inciting factors, and allergy testing with immunotherapy.

Patients with GERD symptoms are encouraged to avoid caffeine, practice lifestyle modifications (e.g., avoid eating late at night, walk after dinner, prop up head of bed on blocks), and use H₂ blockers or proton pump inhibitors 30 minutes before eating.

Spirometry with and without bronchodilators can be helpful in identifying those with bronchospasm that may be manifesting as cough, such as cough-variant asthma. However, spirometry may be normal in some patients who are not symptomatic at the time of the test. A trial of albuterol and/or inhaled corticosteroids with or without a LABA (depending on the severity and frequency of the cough) may be indicated. If the patient does not respond to these treatments or there is suggestive information in history and physical, diagnostic testing may be pursued, including chest x-ray, CT scan of the chest, methacholine challenge, ENT evaluation, and even bronchoscopy.

For patients with bronchiectasis, pulmonary hygiene, flutter valve to help clear secretions, and a mucolytic can be helpful. Further management is directed by the clinical course and findings of the diagnostic workup.

HEPATOPULMONARY SYNDROME (HPS)

OVERVIEW

HPS consists of liver disease cirrhosis, positional deoxygenation, and intrapulmonary shunting due to pulmonary capillary dilatations and direct AVMs. HPS is associated with a poor overall prognosis, with a high mortality within 1–2 years due to GI bleeding and hemorrhagic shock.

EPIDEMIOLOGY

Estimates of the prevalence of HPS in patients with cirrhosis vary from 4–47%. This wide variation is likely due to different cutoffs for deoxygenation that were used in studies. However, mild liver disease can also be associated with HPS.

PATHOPHYSIOLOGY

The pathophysiology is not well understood. Hypoxia may occur via V/Q mismatch or shunting.

DIAGNOSIS

Patients can present with dyspnea, platypnea (shortness of breath when sitting upright but improved when supine), and orthodeoxia (deoxygenation when upright but improving when supine). Clubbing is a common finding. Spider nevi are often associated with systemic and pulmonary vasodilatations.

TESTING

Supine and upright oximetry may not demonstrate oxygen desaturation, while a decrement in pO_2 of $\geq 5\%$ or of ≥ 4 mmHg when upright is considered orthodeoxia. Contrast echocardiography (bubble echo) can demonstrate shunt. Though it is not very sensitive, it is the 1st test to perform. Shunt fraction is estimated via assessing the P_aO_2 while breathing 100% oxygen; if $> 5\%$, it is abnormal. Technetium scanning can also be used. If no shunt is present, the majority of the injected albumin will be trapped in the lungs, but if shunt is present, the uptake will be found in the kidneys or brain. The amount found in the brain and kidney can be used to determine the degree of shunt present. Platypnea with orthodeoxia and a shunt fraction $> 6\%$ is strongly suggestive of HPS.

TREATMENT

Supplementary O_2 may be useful provided shunt is not severe. Various vasoactive medications and supplements have been tried with varied and inconsistent responses and no significant randomized studies. For patients who have a poor response to O_2 (i.e., have a large shunt) the definitive treatment is liver transplant. For patients who are not a candidates for liver transplantation, consideration of transjugular intrahepatic portosystemic shunts (TIPS) have been reported to improve oxygenation in some cases, though the effect does not appear to be sustained. Oral garlic, which decreases nitric oxide and selective coil embolization, may also be used in refractory cases.

THE MEDSTUDY HUB: YOUR GUIDELINES AND REVIEW ARTICLES RESOURCE

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub at

medstudy.com/hub

The Hub contains the **only** online consolidated list of **all** current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source. MedStudy maintains the Hub as a service to the medical community and makes it available to anyone and everyone at no cost to users.

APPENDIX A

The P_aO_2 is relatively consistent in a group of people in a room. It is the P_aO_2 that varies individually with lung problems. It is the **difference** between these 2 partial pressures, or gradient, that is the key indicator of problems with the alveolar-capillary unit. Again, $D_{A-a}O_2$ is increased in all causes of hypoxemia **except** in hypoventilation and high altitudes. In reality, the $D_{A-a}O_2$ is useful only when evaluated on room air since the gradient increases as the F_iO_2 increases. It is difficult to know the exact F_iO_2 when a patient breathes with a nasal cannula or a poorly fitted face mask.

The $D_{A-a}O_2$ is 5–15 mmHg in healthy, young patients. It increases normally with age and abnormally with lung diseases, causing a V/Q mismatch (i.e., blood flow or diffusion abnormality). Note: A patient with a significant pulmonary embolus invariably has an increased $D_{A-a}O_2$, but if the patient is hyperventilating (which is common), the P_aO_2 can be normal!

As mentioned, $D_{A-a}O_2$ increases with age. The 2 rules of thumb for determining a normal $D_{A-a}O_2$ are:

- 1) Normal $D_{A-a}O_2 \leq 0.3 \times \text{age}$ (years)
- 2) Normal $D_{A-a}O_2 \leq (\text{age}/4) + 4$

To find the $D_{A-a}O_2$, first determine the partial pressure of O_2 in the alveoli (P_AO_2)—discussed under **Respiratory Physiology** on page 6-7:

$$P_AO_2 = [(P_b - P_{H_2O}) \times F_iO_2] - [P_aCO_2/0.8]$$

At standard temperature at sea level,

$$P_AO_2 = [(760 - 47) \times 0.209] - [P_aCO_2/0.8]$$

$$P_AO_2 = [149] - [P_aCO_2/0.8]$$

Or, for an easier mental calculation,

$$P_AO_2 = 149 - 1.25(P_aCO_2)$$

So, getting back to the original formula,

$$D_{A-a}O_2 = P_AO_2 - P_aO_2$$

where the P_aO_2 is obtained from the arterial blood gas. Or, for an easier mental calculation at sea level and breathing room air, the formula is shifted around to:

$$D_{A-a}O_2 = 149 - [P_aO_2 + (1.25 \times P_aCO_2)]$$

Okay, got this? You obtain the P_aO_2 and the P_aCO_2 from the ABG report. If at sea level and inspiring room air, take a **quarter more** than the P_aCO_2 and **add** it to the P_aO_2 , then **subtract** the result from 149.

APPENDIX B — OXYGEN TRANSPORT TO TISSUES

Oxygen **transport** to the tissues (DO_2) is defined by the following equation:

$$DO_2 = \text{cardiac output} \times C_aO_2$$

where C_aO_2 is the oxygen content of arterial blood.

This is calculated by

$$C_aO_2 = (1.34 \times \text{Hgb} \times S_aO_2) + (0.003 \times P_aO_2)$$

where S_aO_2 is the hemoglobin saturation and Hgb is the hemoglobin level.

(In practice, we can ignore the miniscule amount of O_2 dissolved in plasma, $0.003 \times P_aO_2$.)

So, essentially,

$$DO_2 = \text{cardiac output} \times (1.34 \times \text{Hgb} \times S_aO_2)$$

Notice from this equation that oxygen transported to the tissues depends upon **3** factors:

- 1) Cardiac output
- 2) Hemoglobin level
- 3) Hemoglobin saturation. This is why the hemoglobin-oxygen (oxyhemoglobin) dissociation curve and the use of pulse oximetry are so important.

RENAL TESTS

PREVIEW | REVIEW

- What disease causes a negative urine dipstick for protein, but high urine protein measured by the lab (protein:creatinine ratio or 24-hour urine protein)?
- What diseases cause positive urine dipstick for heme, but few or no RBCs on urine sediment exam?
- Which findings on the urine sediment exam suggest that hematuria is caused by glomerulonephritis?
- What are the causes of a blood urea nitrogen:creatinine ratio of $> 20:1$?

URINALYSIS (U/A)

The U/A is a set of urine tests that provides information about potential renal and urinary tract disease. The U/A is more than just the dipstick:

- **Visual examination** of the urine: Red or brown (“tea-colored”) urine suggests hematuria, hemoglobinuria, myoglobinuria, or ingestion of beets or certain antibiotics. Cloudy urine may indicate urinary tract infection (UTI) or crystalluria (seen with kidney stones).
- **Reagent strip testing (“dipstick”)**: This tests urine pH, protein, glucose, ketones, blood, heme, bilirubin, urobilinogen, nitrites, leukocyte esterase, and specific gravity.
- **Urine sediment examination (microscopy)**: Look for cells (e.g., red blood cells [RBCs], white blood cells [WBCs], renal tubular cells), casts, and crystals.
- Although technically not part of the U/A, in some situations laboratory testing of the urine is useful (e.g., osmolality, electrolytes, protein).

Many kidney diseases cause proteinuria, hematuria, or both on dipstick. A patient with acute kidney injury (AKI) and a normal U/A probably has either prerenal failure or postrenal failure (ureteral or urethral obstruction). See more in [Table 7-2 on page 7-10](#).

Reagent Strip Testing (Dipstick)

The urine **specific gravity** tells you how dilute or concentrated the urine is. In a patient with AKI, a very concentrated urine (i.e., specific gravity ≥ 1.025) suggests prerenal azotemia such as in volume depletion. In acute tubular injury (a.k.a. acute tubular necrosis [ATN]), the urine specific gravity is similar to plasma (i.e., 1.010) because the tubules cannot concentrate or dilute the urine. In a patient with hyponatremia, a low urine specific gravity (< 1.005) suggests primary polydipsia.

The **urine pH** is important when you are assessing kidney stones or metabolic acidosis. Kidney stones with a high urine pH (> 7.0) are typically struvite or calcium phosphate. When the urine pH is low (< 6.0), stones are usually

uric acid or calcium oxalate. In a patient with a normal anion gap metabolic acidosis (NAGMA; a.k.a. non-anion gap metabolic acidosis), a high urine pH should make you think of distal renal tubular acidosis (RTA; discussed in [Type 1 \(Distal\) RTA on page 7-45](#)).

The urine dipstick for **proteinuria** detects albumin; however, it does not detect other proteins. As a result, immunoglobulins such as urinary light chains in multiple myeloma are not detected on urine dipstick. When the urine dipstick is **negative** for protein, but the spot urine protein:creatinine ratio is high, think **multiple myeloma**. Causes of **false-positive** urine protein on dipstick are very alkaline urine (pH > 8.0), gross hematuria, exposure to intravenous iodinated contrast, and very concentrated urine. Use a spot urine protein:creatinine ratio or a 24-hour urine collection to quantify proteinuria in patients with persistently positive dipstick.

Urine dipstick is very sensitive for the presence of **heme** (detects 1–2 RBCs per high-power field; normal range is ≤ 3 RBCs/HPF). Remember: A positive dipstick for heme can result not only from urinary RBCs; it can also result from free hemoglobin or free myoglobin. When there are few RBCs on microscopic analysis but the urine dipstick is positive for blood, think of hemoglobinuria (intravascular hemolysis) or myoglobinuria (rhabdomyolysis).

Urinary **ketones** are positive in patients with ketosis—diabetic, alcoholic, or starvation ketosis. Glycosuria (positive **glucose** on urine dipstick) may occur in pregnancy, in diabetic patients with hyperglycemia, or Fanconi syndrome (more under [Proximal Tubule on page 7-5](#)).

Nitrites and **leukocyte esterase** suggest the presence of urinary tract infection (UTI). Positive leukocyte esterase indicates WBCs in the urine. Nitrite reflects the presence of bacteria that convert urinary nitrate to nitrite. Note some bacterial infections such as *Enterococcus* are nitrite negative.

U/A is useful in patients with urinary symptoms such as dysuria, urinary frequency, and urinary urgency. U/A, in combination with urine culture, can quickly diagnose UTI. See more in the [Geriatric Medicine](#) section.

Urine Sediment

Cellular Elements

Cells in the urine can include RBCs, WBCs, renal tubular epithelial cells, and squamous cells.

RBCs can be monomorphic (normal shape and size) or dysmorphic (disfigured by the trauma of passing through the glomerulus and tubule). Dysmorphic RBCs (as well as RBC casts; A and B in [Figure 7-1 on page 7-2](#)) suggest glomerular hematuria; monomorphic RBCs can be seen with any cause of hematuria (more under [Hematuria on page 7-2](#)).

Urinary **WBCs** are commonly associated with UTI. However, if the urine culture is negative (i.e., sterile pyuria), consider interstitial nephritis, renal tuberculosis, prostatitis, glomerulonephritis (if RBCs also are present), and nephrolithiasis.

Eosinophiluria can be seen in drug-induced interstitial nephritis but is not a sensitive or specific finding. It can also be seen in UTI, prostatitis, and cholesterol athero-embolic disease.

Squamous cells are from urethral and/or skin contamination and have no pathologic significance.

Casts

Casts are cylindrical structures that are formed in the renal tubular lumen.

Red cell casts (B in Figure 7-1) are seen only with glomerular hematuria, usually glomerulonephritis.

White cell casts are typically seen in pyelonephritis or acute interstitial nephritis; occasionally they are seen in glomerulonephritis.

Coarse granular casts (i.e., muddy-brown or dirty brown casts) are seen with acute tubular injury/necrosis (C in Figure 7-1).

Renal tubular epithelial casts, like granular casts, are seen with acute tubular injury.

Waxy casts typically indicate advanced chronic kidney disease (CKD).

Fatty casts (like **oval fat bodies**, described in **Oval Fat Bodies**) are seen in nephrotic syndrome.

Hyaline casts are a normal finding that can be seen in concentrated urine.

Oval Fat Bodies

Oval fat bodies are lipid-laden renal tubular epithelial cells (D in Figure 7-1) that look like “Maltese crosses” under polarized light (E in the same figure). They are seen in nephrotic syndrome.

Crystals

Know the following crystals in urine sediment examination.

Calcium oxalate crystals are envelope, dumbbell, or needle shaped (A in Figure 7-2). These are seen in patients with calcium oxalate kidney stones; however, they also can be a normal finding. In a patient with possible toxic ingestion, high anion gap metabolic acidosis, and AKI, think ethylene glycol poisoning!

Calcium phosphate crystals are rectangular or wedge-shaped prisms (B in Figure 7-2); urine is alkaline (pH > 7.0).

Uric acid crystals are reddish-brown, rectangular, or rhomboid (C in Figure 7-2); urine is acidic (pH < 6.0). Seen in gout, uric acid stones, and tumor lysis syndrome.

Struvite (a.k.a. calcium-magnesium-ammonium pyrophosphate [triple phosphate]) crystals look like coffin lids (D in Figure 7-2); urine is alkaline (pH > 7.0). Seen with chronic UTI with urea-splitting organisms, struvite crystals lead to formation of staghorn calculi.

Cystine crystals are hexagons (E in Figure 7-2) seen in cystinuria, a genetic cause of kidney stones.

Several drugs can crystallize in the urine (sometimes causing crystal-induced nephropathy), including **sulfonamides**, **indinavir**, **acyclovir**, **atazanavir**, **methotrexate**, and **ciprofloxacin**. Drug crystals are typically needle-shaped and do not have unique morphologies—you will need to determine the drug type from the patient history (more under **Kidney Stones** on page 7-35).

Hematuria

Hematuria can be caused by renal or urologic disease (e.g., UTI, kidney stones, renal/uroepithelial cancer).

Figure 7-1: Urine sediment: Cellular elements and casts. (A) Dysmorphic red blood cells (RBCs). (B) RBC cast. (C) Coarse (“dirty” brown) granular casts. (D) Oval fat bodies. (E) The same oval fat bodies image under polarized light, showing “Maltese crosses.”

Figure 7-2: Urine sediment: Crystals. (A) Calcium oxalate. (B) Calcium phosphate. (C) Uric acid. (D) Struvite. (E) Cystine.

The 1st step in the evaluation of patients with a positive dipstick for heme or with red or brown urine is to confirm hematuria by urine sediment exam. Microscopic hematuria is defined as ≥ 3 RBCs/HPF. If hematuria is confirmed, check for proteinuria and measure the serum creatinine.

If there is no proteinuria and the serum creatinine is normal, it is **isolated microscopic or gross hematuria**. This is likely to be urologic in origin, and urologic workup should be done first:

- Look for signs of UTI (fever, dysuria, dipstick positive for nitrite and/or leukocyte esterase, or urinary WBCs on sediment exam). If present, do a urine culture.
- Unilateral flank pain suggests nephrolithiasis; evaluate with a noncontrast CT.
- In patients at risk for malignancy (> 40 years of age, smoking history, gross hematuria, pelvic radiation, exposure to cyclophosphamide or occupational exposures), do GU imaging with renal ultrasound, MRI, or CT to exclude renal cell or other GU malignancy.
- Refer to a urologist for cystoscopy if other workup is negative.

Hematuria accompanied by proteinuria is usually renal in origin. If **dysmorphic** RBCs and/or **RBC casts** are present in the urine sediment and renal function is declining, consider urgent evaluation for possible glomerulonephritis.

Glomerular hematuria also can occur in the absence of proteinuria and with normal renal function. This is called **isolated glomerular hematuria**. The most common causes are IgA nephropathy, thin basement membrane nephropathy, and early Alport syndrome. Patients with sickle cell trait or disease also can develop isolated glomerular hematuria.

Strenuous exercise can cause transient hematuria.

Proteinuria

Proteinuria is an important indicator of renal pathology. Normal urine protein excretion is < 150 mg/day. Proteinuria > 1.0 g/day usually indicates glomerular disease. Patients with < 1 g/day are more likely to have tubulointerstitial renal disease. Proteinuria > 3.5 g/day (nephrotic-range proteinuria) is caused by specific glomerular diseases (**Nephrotic Syndromes on page 7-23**).

Transient proteinuria is common with fever or after strenuous exercise. Recheck urine when the acute situation has passed. If the repeat U/A is negative, the condition can be considered benign. With **benign orthostatic proteinuria**, there is abnormal proteinuria only when the patient is upright. This diagnosis usually is seen in adolescents and young adults and is confirmed by a normal urine protein:creatinine ratio on the 1st morning void. No further workup or follow-up is needed, and the proteinuria often goes away over time.

The **24-hour urine protein measurement** is the traditional method for quantifying proteinuria. For this test, the patient collects all urine output over a 24-hour period.

Unfortunately, errors of overcollection or undercollection are common, and the test is cumbersome for the patient.

The **spot urine protein:creatinine ratio** has largely replaced the 24-hour urine protein test for quantification of proteinuria because it is much easier to complete, requiring only a random urine sample. Assuming the patient excretes roughly 1 g/day of creatinine (which is true for a 50-kg woman), the ratio of protein to creatinine equates roughly to the 24-hour urinary protein in grams. For example, a protein:creatinine ratio of 3.5 mg/mg approximates a 24-hour urine protein excretion of 3.5 g/day. This test is used to assess and monitor proteinuria in patients with renal disease. Urine protein:creatinine ratio > 0.15 mg/mg ($\sim > 150$ mg/day) is considered abnormal. Urine protein:creatinine ratio > 1 mg/mg ($\sim > 1$ g/day) usually indicates glomerular pathology. Urine protein:creatinine ratio > 3.0 – 3.5 mg/mg ($\sim > 3.5$ g/day) is considered nephrotic range.

Proteinuria is sometimes quantified by measuring albumin, rather than total protein. **Moderately increased albuminuria** (previously called **microalbuminuria**) is albumin excretion between 30 and 300 mg/day (albumin:creatinine ratio = 0.03–0.3 mg/mg). Moderately increased albuminuria is the earliest indicator of diabetic and hypertensive nephropathy. This small amount of albumin is not detectable by urinary dipstick and can only be diagnosed with a spot urine albumin:creatinine ratio.

ESTIMATING RENAL FUNCTION

Serum Creatinine

The serum creatinine (S_{Cr}) provides a quick, easy estimate of renal function (i.e., glomerular filtration rate). However, the serum creatinine is affected by both renal elimination (creatinine clearance) and creatinine production. The more muscle mass an individual has, the higher the creatinine level. Also, if muscle tissue breaks down (as in rhabdomyolysis or myositis), the creatinine level can rise acutely. An unusually rapid rise (> 1.5 mg/dL [$133 \mu\text{mol/L}$] over 24 hours) suggests rhabdomyolysis-induced renal failure. With aging, there is less muscle mass, and the creatinine may be normal despite reduced renal function.

Trimethoprim and cimetidine **increase** the serum creatinine. These drugs inhibit tubular secretion of creatinine (decreasing creatinine clearance and elevating the S_{Cr}); however, glomerular filtration rate (GFR) is not affected. An elevated ($> 20:1$) ratio indicates either prerenal azotemia (i.e., decreased renal perfusion) or increased protein breakdown. Increased protein breakdown can be due to increased dietary protein intake, GI bleeding, total parenteral nutrition, catabolic states, or steroids that increase protein turnover.

Glomerular Filtration Rate (GFR)

GFR is a measure of overall renal function. Historically, GFR was approximated by measuring creatinine clearance (CrCl) using a 24-hour urine collection. It is now typically

estimated from the serum creatinine and demographic variables. Creatinine-based formulas are quicker and easier, and they often give a more accurate estimated GFR (eGFR) than does the CrCl. Estimation of GFR is essential in staging CKD.

There are 2 main creatinine-based eGFR formulas:

- 1) The **Modification of Diet in Renal Disease (MDRD)** equation estimates GFR from serum creatinine, race, sex, and age. The MDRD equation is less accurate when the eGFR is > 60 mL/minute/1.73 m².
- 2) The **Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI)** equation uses the same variables as the MDRD study and is more accurate in patients with normal or mildly reduced GFR (eGFR > 60 mL/minute/1.73 m²).

Laboratories routinely report eGFR using either the MDRD or CKD-EPI equation. Online calculators also are available. Both formulas are normalized to body surface area. The result is given in units of mL/minute/1.73 m² body surface area.

The **Cockcroft-Gault** formula is another acceptable way to estimate GFR. Although it is less accurate than the MDRD and CKD-EPI equations, it can be calculated from basic variables with just the calculator on your smartphone:

$$\text{CrCl} = \frac{(140 - \text{age}) \times (\text{weight}) \times (0.85 \text{ if female})}{72 \times S_{\text{Cr}}} \quad (\text{Eq. 1})$$

In Eq. 1, CrCl is in mL/minute; age is in years; weight is in kg; and S_{Cr} is in mg/dL.

All these methods for estimating GFR based on the serum creatinine are accurate **only** when the serum creatinine level is in a **steady state** and the patient does not have AKI.

eGFR obtained using these methods is also inaccurate when there is an extreme of age and/or weight and in patients with amputations, cirrhosis, or pregnancy. In these situations, collect a 24-hour urine to estimate GFR by creatinine clearance:

$$\text{CrCl} = \frac{U_{\text{Cr}} \times V}{P_{\text{Cr}}} \quad (\text{Eq. 2})$$

In Eq. 2, U_{Cr} = urine creatinine concentration, V = 24-hour urine volume, and P_{Cr} = plasma (or serum) creatinine concentration.

FE_{Na} AND FE_{Urea}

Fractional excretion of sodium (FE_{Na}) is the percentage of filtered Na⁺ that is excreted in the urine:

$$\text{FE}_{\text{Na}} (\%) = \frac{(S_{\text{Cr}} \times U_{\text{Na}}) \times 100}{S_{\text{Na}} \times U_{\text{Cr}}} \quad (\text{Eq. 3})$$

Where U_{Na} is urinary Na⁺ concentration (mEq/L) and U_{Cr} is urinary creatinine concentration (mg/dL). The FE_{Na} is used to differentiate prerenal azotemia from **ATN** in patients with oliguric AKI:

- Prerenal azotemia: FE_{Na} $< 1\%$
- ATN: FE_{Na} $> 2\%$

FE_{Na} $< 1\%$ also can be seen in contrast-induced nephropathy, cardiorenal syndrome, hepatorenal syndrome, nonoliguric ATN, pigment nephropathy (hemoglobinuria = hemolysis, myoglobinuria = rhabdomyolysis), and acute glomerulonephritis.

FE_{Na} $> 2\%$ can occur in prerenal azotemia with recent diuretic use. In this situation, FE_{Urea} can be used. The fractional excretion of urea (FE_{Urea}) is the percentage of filtered urea (BUN) excreted in the urine:

$$\text{FE}_{\text{Urea}} (\%) = \frac{(S_{\text{Cr}} \times U_{\text{Urea}}) \times 100}{\text{BUN} \times U_{\text{Cr}}} \quad (\text{Eq. 4})$$

FE_{Urea} is more accurate than FE_{Na} in patients receiving diuretics because diuretics increase urinary Na⁺ excretion. FE_{Urea} $< 35\%$ suggests a prerenal state.

RENAL IMAGING

Ultrasound (U/S) and Doppler U/S

U/S is a noninvasive, inexpensive way to diagnose urinary tract obstruction. U/S also can give clues to the presence of CKD: small kidney size (< 8 cm), decreased cortical thickness, and increased cortical echogenicity. These findings sometimes are referred to as “medical renal disease.” U/S also can be used to diagnose and monitor renal cysts, renal masses, and polycystic kidney disease.

Doppler U/S evaluates renal vascular flow. It is used to screen for renal artery stenosis and renal vein thrombosis.

Computed Tomography (CT)

When looking for nephrolithiasis, noncontrast CT is the test of choice and is more sensitive than U/S. CT with contrast is used to evaluate renal masses (e.g., tumors) and complex renal cysts found on U/S. Remember: IV contrast can cause AKI (contrast nephropathy).

Magnetic Resonance Imaging (MRI)

Use MRI as an alternative to CT to evaluate renal masses. MR angiography (MRA) can be used to screen for renovascular hypertension (HTN). Although MRI and MRA avoid the risk of contrast nephropathy, the use of older forms of gadolinium is contraindicated in patients with eGFR < 30 mL/minute/1.73 m² because gadolinium has been linked to nephrogenic systemic fibrosis (more under [Imaging in CKD on page 7-33](#)).

KIDNEY BIOPSY

Indications for kidney biopsy include unexplained AKI, nephrotic syndrome, and suspected glomerulonephritis. In transplant patients with AKI, it is routinely used to distinguish between medication toxicity, acute tubular necrosis, viral infections, and acute rejection.

Bleeding is the major risk of kidney biopsy. Risk factors for major bleeding after kidney biopsy include uncontrolled hypertension, severe uremia (with uremic platelet dysfunction), thrombocytopenia, and anemia. Aspirin, NSAIDs, and antiplatelet agents should be held for at least 5–7 days prior to kidney biopsy. Relative contraindications to kidney biopsy are solitary kidney and a need for chronic anticoagulation.

substances (e.g., H^+ , K^+) are secreted. This allows for the excretion of urine concentrated in uremic toxins and balanced to allow for homeostasis of everything else.

Figure 7-3: Normal glomerulus

Refer to Figure 7-4 and Figure 7-5 on page 7-6 as you go through the functions of the different nephron segments.

RENAL PHYSIOLOGY AND DIURETICS

PREVIEW | REVIEW

- Which nephron segment is responsible for reabsorption of the majority of filtered sodium, chloride, bicarbonate, and water?
- Which portion of the nephron is the most permeable to water?
- Which tubule sets up the osmotic gradient for the thin descending segment in the loop of Henle?
- What toxicity can loop diuretics cause in high intravenous doses?
- Which 2 hormones exert their effects in the collecting duct?
- Which diuretic class can be used to prevent kidney stones?
- Which diuretic is especially important to give to patients with systolic dysfunction and low ejection fraction?

PROXIMAL TUBULE

65% of filtered Na^+ , Cl^- , and water is reabsorbed in the proximal tubule. The proximal tubule is very permeable to water, which follows Na^+ and Cl^- reabsorption such that the volume of filtrate is reduced along the tubule but the osmolality and Na^+ concentration remain constant (see Figure 7-4).

Mechanisms of solute reabsorption in the proximal tubule:

- Reabsorption of Na^+ (into the interstitium) is linked to H^+ secretion (into the filtrate) via secondary active transport—stimulated by angiotensin II (AT II) and inhibited by carbonic anhydrase inhibitors.
- Reabsorption of Na^+ (into the interstitium) is linked to K^+ secretion (into the filtrate) via an ATPase transporter—stimulated by AT II.
- Cotransport of Na^+ , Cl^- , K^+ , glucose, and amino acids (into interstitium)
- Paracellular reabsorption of other solutes such as Ca^{2+}

GLOMERULAR FILTRATION

The glomerulus is a specialized capillary plexus surrounded by the Bowman's capsule (Figure 7-3). The capillary endothelium, glomerular basement membrane (GBM), and podocytes together form the glomerular filtration barrier, which allows an ultrafiltrate of the plasma to pass into the Bowman's space. The ultrafiltrate then passes into the tubules, where the “good stuff” (e.g., glucose, water, Na^+ , Cl^- , HCO_3^- , Ca^{2+}) is reabsorbed and excess

90% of filtered HCO_3^- is reabsorbed in the proximal tubule—but the process is indirect and driven by H^+ secretion (1st bullet, above):

- H^+ is secreted into the filtrate and combines with filtered HCO_3^- to form H_2CO_3 (carbonic acid).
- Carbonic anhydrase converts $\text{H}_2\text{CO}_3 \rightarrow \text{H}_2\text{O} + \text{CO}_2$.
- CO_2 passes through the tubular cell membrane and is reabsorbed into the tubular cells.
- CO_2 is converted to HCO_3^- within the tubular cell, again with the help of carbonic anhydrase.
- HCO_3^- is then reabsorbed into the interstitium.

So, for each H^+ that is secreted, 1 HCO_3^- is generated. Figure 7-5 shows the transporters involved.

Carbonic anhydrase inhibitors (CAIs; acetazolamide) disrupt this entire process by reducing the availability of H^+ in the proximal tubular cells and H_2CO_3 in the lumen. When this occurs, the Na^+/H^+ countertransporter does not have substrate, so Na^+ is not reabsorbed and H^+ is not secreted. A mild diuresis ensues, as well as a metabolic acidosis similar to proximal (Type 2) RTA. This makes CAIs useful in patients who are volume overloaded with a metabolic alkalosis.

Know that this Na^+/H^+ countertransporter also is affected by the **K^+ concentration**:

- **Hypokalemia** stimulates H^+ secretion (and thus stimulates HCO_3^- reabsorption) $\rightarrow$ alkalosis. This explains why hypokalemia must be corrected to fix metabolic alkalosis.

- **Hyperkalemia** inhibits H^+ secretion (and thus inhibits HCO_3^- reabsorption) $\rightarrow$ acidosis. Remember that the reverse also is true. Metabolic acidosis causes hyperkalemia (by shifting K^+ out of cells). The 2 can create a vicious cycle!

So, when something goes wrong in the proximal tubules, clinically we can see:

- Failure to reabsorb HCO_3^- = proximal (Type 2) RTA (causing a NAGMA).
- Failure to reabsorb other solutes (Na^+ , Cl^- , K^+ , glucose, amino acids) = Fanconi syndrome +/- hypokalemia.

This is why Fanconi syndrome and proximal RTA often occur together.

LOOP OF HENLE

Follow along in Figure 7-5 as we discuss the physiology of the loop of Henle. Think of the loop as divided into 2 halves with the 1st half (descending) handling reabsorption of water and a little bit of solute and the 2nd half (ascending) handling reabsorption of solutes. The action of the 2nd half of the loop drives the action of the 1st half.

In the descending segment, water moves from the tubular lumen into the interstitium, driven by an osmotic gradient, with maximum concentration at the turn of the loop (i.e., papilla). The renal medulla is very hypertonic—Why? In the thin ascending segment, NaCl passively diffuses into the interstitium, slightly diluting the filtrate. In the

Figure 7-5: The nephron: physiology and diuretic sites of action

thick ascending segment, Na^+ , Cl^- , and K^+ are actively transported from the lumen into the interstitium, increasing the tonicity of the medulla. **That's why!** This active transport is the mechanism that produces hypertonicity in the inner medulla that will later stimulate reabsorption of water when the filtrate gets to the collecting tubule.

In the thick ascending segment, 25% of filtrate solutes are reabsorbed via:

- Countertransport of Na^+ (into the interstitium) and K^+ (into the filtrate) via an ATPase active transport pump; stimulated by AT II
- Cotransport of Na^+ , 2 Cl^- , and K^+ (into the interstitium); **inhibited** by **loop** diuretics
- Paracellular absorption of other solutes such as Mg^{2+} , Ca^{2+} , Na^+ , and K^+ (into the interstitium)

Think about this a minute and look at [Figure 7-5](#); be sure you understand before moving on.

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) inhibit the $\text{Na}^+/\text{K}^+/2 \text{Cl}^-$ cotransporter in the thick ascending segment of the loop of Henle. They **remain effective** when GFR is low ($\text{CrCl} < 20 \text{ mL/minute}/1.73 \text{ m}^2$), but you have to increase the dose and/or give IV. Ethacrynic acid is used for patients with sulfa allergies in whom furosemide, bumetanide, and the thiazide diuretics are contraindicated (because these drugs are sulfa derivatives). Know that furosemide and ethacrynic acid can cause permanent ototoxicity at high IV bolus doses.

Loop diuretics cause diuresis by preventing reabsorption of Na^+ in the thick ascending segment—this prevents the development of the interstitial osmotic gradient, relied upon by the thin descending segment for water reabsorption. The net effect is loss of both Na^+ and water. Look at the specific cotransporter that is inhibited by loop diuretics. Notice that K^+ is also reabsorbed with that cotransporter, so now it makes sense that patients taking loop diuretics also develop hypokalemia.

Loop diuretics also increase Ca^{2+} loss in the urine and have been used in the past to treat severe hypercalcemia. Normal saline was infused at a high rate (to replace the volume losses), and a loop diuretic was added. The saline expands the volume and delivers increased flow to the proximal tubule, which prevents paracellular Ca^{2+} reabsorption. The greatly increased Ca^{2+} load is then delivered to the early distal tubule, overwhelming its ability to absorb Ca^{2+} , so calciuresis ensues.

In current clinical practice, saline is still given to volume-depleted patients with hypercalcemia, but loop diuretics are only used if the patient becomes volume overloaded.

Bartter syndrome is an example of a disease that affects the loop of Henle. In Bartter syndrome, there is a defect in the $\text{Na}^+/\text{K}^+/2 \text{Cl}^-$ cotransporter in the thick ascending segment. This leads to hypokalemia and mild volume depletion—as if the patient were taking a loop diuretic.

DISTAL TUBULE

The distal tubule reabsorbs another 5% of remaining solutes with the following clinically relevant processes:

- Cotransport of Na^+ and Cl^- (into the interstitium); inhibited by thiazide diuretics
- Countertransport of Na^+ (into the interstitium) and K^+ (into the filtrate) via an ATPase active transport pump; stimulated by AT II
- Paracellular absorption of Cl^- (into the interstitium)

Thiazide diuretics (e.g., chlorothiazide, hydrochlorothiazide, chlorthalidone, metolazone) inhibit the Na^+/Cl^- cotransporter in the distal tubule.

Like loop diuretics, thiazides cause hypokalemia. Unlike loop diuretics, which increase Ca^{2+} excretion, thiazides **decrease Ca^{2+} excretion**. Remember: Do not prescribe thiazide diuretics to patients with hyperparathyroidism or hypercalcemia of malignancy, as they can worsen hypercalcemia. On the other hand, thiazides can be useful in reducing **urinary Ca^{2+} in patients with kidney stones**.

Gitelman syndrome is an example of a disease that affects the distal tubule. Here, there is a defect in the Na^+/Cl^- cotransporter. Like Bartter syndrome, these patients present with hypokalemia and volume depletion. Distinguish Bartter syndrome from Gitelman syndrome by measuring the urine calcium. It is high in Bartter syndrome, low in Gitelman syndrome.

COLLECTING DUCT

The **collecting duct** is in charge of fine-tuning acid-base, K^+ , and water homeostasis. The actions of this segment are controlled by **aldosterone** and antidiuretic hormone (ADH).

There are 2 important cell types in the **collecting duct**:

- 1) Principal cells (PCs) reabsorb Na^+ (into the interstitium) via an epithelial Na^+ channel. Na^+ reabsorption is linked to K^+ secretion (into the filtrate). This process is stimulated by aldosterone and hyperkalemia and is inhibited by K^+ -sparing diuretics (e.g., amiloride, triamterene, spironolactone, eplerenone).
- 2) Intercalated cells (ICs) secrete H^+ (into the filtrate) via an ATPase active transport pump. For every H^+ secreted, 1 HCO_3^- is reabsorbed. ICs are one of the major regulators of acid-base balance and reabsorb K^+ (to a minor extent).

Water reabsorption in this segment is controlled by **ADH** (i.e., vasopressin). In the absence of ADH, the collecting duct is relatively impermeable to water. When present, ADH leads to insertion of aquaporin-2 into the tubule cell membrane. This makes the collecting tubule permeable to water. In the setting of a hypertonic interstitium in the inner medulla, water is reabsorbed (from filtrate into interstitium) down its osmotic gradient, leading to a concentrated urine. The effect of ADH may be blocked by vasopressin receptor antagonists, conivaptan (IV formulation only), and tolvaptan (oral). These agents are sometimes used to treat hyponatremia.

K⁺-sparing diuretics act at the collecting duct. They include aldosterone antagonists (i.e., spironolactone and eplerenone) and agents that block the epithelial Na⁺ channel that is activated in the presence of aldosterone (i.e., amiloride and triamterene). Although they have different targets, their effects are similar: They block Na⁺ reabsorption, which in the collecting tubule is linked with K⁺ secretion. Hence, they are weak diuretics, but they cause the blood K⁺ to rise.

Diseases that affect the collecting duct:

- 1) Type 1 (distal) RTA is a NAGMA caused by impaired H⁺ ATPase active transport in the intercalated cells, which leads to the inability to secrete acid (and reabsorb HCO₃⁻); urine pH is always > 5.3.
- 2) Type 4 RTA (hypoaldosteronism) is a NAGMA due to aldosterone deficiency or resistance; hyperkalemia is present.
- 3) Diabetes insipidus is due to inadequate ADH (central) or resistance to ADH (nephrogenic). It manifests as polyuria and, if inadequate access to water, hypernatremia.
- 4) Syndrome of inappropriate diuretic hormone secretion (SIADH) is caused by excess ADH hormone and manifests as hyponatremia.

MECHANISM OF ACTION OF DIURETICS

Now that we have reviewed the different tubular segments, we will go over the 4 classes of diuretics:

- 1) **Carbonic anhydrase inhibitors** (acetazolamide):
 - Effect: inhibit Na⁺/H⁺ countertransport in the proximal tubule
 - Complications: acidosis, hypokalemia
- 2) **Loop diuretics** (e.g., furosemide, bumetanide, torsemide):
 - Effects:
 - Inhibit the Na⁺/K⁺/2 Cl⁻ cotransporter in the thick ascending segment
 - Increase Ca²⁺ excretion
 - Diminish the medullary osmotic gradient in inner medulla
 - Used to treat edema
 - Effective at low GFRs but require higher dosing
 - Complications: dehydration, hypokalemia, calcu-
resis, ototoxicity (with high dose IV), and meta-
bolic ("contraction") alkalosis
- 3) **Thiazides** (hydrochlorothiazide, chlorthalidone, metolazone):
 - Effects:
 - Inhibit the Na⁺/Cl⁻ cotransporter in the distal tubule
 - Decrease renal Ca²⁺ excretion
 - Used to treat HTN
 - Less effective at low GFRs; contraindicated in sulfa allergy

- Complications: hypokalemia, hypercalcemia, hyperuricemia, and metabolic alkalosis; thiazides can cause severe hyponatremia and volume depletion in elderly patients.

4) **K⁺-sparing diuretics** (e.g., spironolactone, amiloride):

- Effect: Inhibit the aldosterone-controlled Na⁺ channels (amiloride and triamterene) or block the mineralocorticoid receptor (spironolactone and eplerenone) in the PCs of the collecting duct. The net effect is the same: inhibition of Na⁺ reabsorption and K⁺ secretion in the collecting duct.
- Used to treat HTN, heart failure (HF); used in combination with loop diuretics to minimize hypokalemia
- Complications: hyperkalemia (all K⁺-sparing diuretics) and gynecomastia (spironolactone)

5) **Osmotic diuretics** (mannitol):

- Effect: Diminish Na⁺ and water reabsorption, primarily in the proximal tubule and loop of Henle (It is a nonreabsorbable solute.)
- Rarely used clinically; lose more water than salt
- Complications: hypernatremia; can precipitate pulmonary edema in HF

Table 7-1 provides a summary of the diuretics. Also see [Diuretics on page 7-63](#).

CLINICAL USE OF DIURETICS

Different diuretics have different clinical uses. By far, loop diuretics are the most effective for treating edema from any cause: HF, cirrhosis, nephrotic syndrome, AKI, and CKD. For edema, the other diuretics play important supporting roles. If high-dose loop diuretic is not adequate, add a thiazide diuretic. If hypokalemia develops, add a K⁺-sparing diuretic. If metabolic alkalosis develops, back off or slow down on diuresis; however, if that is not possible or desirable, add a carbonic anhydrase inhibitor.

Thiazide diuretics are a 1st line treatment for HTN; they also are useful in preventing recurrent kidney stones in patients with hypercalciuria, by decreasing urinary Ca²⁺ excretion. In nephrogenic diabetes insipidus, thiazide diuretics decrease polyuria by inducing mild volume depletion and impairing urinary dilution.

Spironolactone has lots of uses! It reduces mortality in patients with systolic dysfunction and a low ejection fraction (see the [Cardiology](#) section). Spironolactone is the 1st line agent for treatment of HTN in primary aldosteronism and for ascites in cirrhosis. The main side effect (aside from hyperkalemia) is gynecomastia; if this happens, use eplerenone instead. Eplerenone is also an aldosterone antagonist but has greater specificity for the mineralocorticoid receptor—and thus has fewer off-target effects.

Table 7-1: Summary of Diuretics

Diuretic	Examples	Site of Action	Clinical Indications
Carbonic anhydrase inhibitors	Acetazolamide	Proximal tubule	Edema + metabolic alkalosis Prevention of acute altitude sickness Glaucoma Hyperkalemic and hypokalemic periodic paralysis
Loop diuretics	Furosemide Torsemide Ethacrynic acid	Ascending limb of the loop of Henle	Edema in: • Nephrotic syndrome • Heart failure • Cirrhosis • AKI • CKD
Thiazide diuretics	Hydrochlorothiazide Chlorthalidone Metolazone	Distal tubule	Hypertension Kidney stones (hypercalciuria) Edema in HF (in combination with loop diuretic) Nephrogenic diabetes insipidus
K ⁺ -sparing diuretics	Spironolactone Eplerenone	Cortical collecting tubule (mineralocorticoid receptor)	Hypertension (especially primary hyperaldosteronism) Heart failure with reduced ejection fraction (spironolactone and eplerenone) Cirrhotic ascites Edema + hypokalemia
	Amiloride Triamterene	Cortical collecting tubule (Na ⁺ channels)	Edema + hypokalemia
Osmotic diuretics	Mannitol	Proximal tubule + loop of Henle	Cerebral edema

ACUTE KIDNEY INJURY (AKI)

PREVIEW | REVIEW

- What is the definition of oliguria? Anuria?
- What is the underlying cause of prerenal kidney injury?
- With postrenal acute kidney injury (AKI), how does the amount of urine produced relate to the degree of obstruction?
- What are the clinical manifestations of emboli caused by vascular manipulation?
- What causes do you consider in a patient with HTN and severe AKI after initiation of an ACEI/ARB?

OVERVIEW

The term “acute renal failure” has been replaced with “acute kidney injury” (AKI) to better represent a wide spectrum of potential kidney damage—not just failure.

A small increase in serum creatinine can indicate a significant decline in GFR. Evaluate AKI by considering prerenal, postrenal, vascular, and intrinsic renal causes.

The Kidney Disease Improving Global Outcomes (KDIGO) 2012 Clinical Practice Guidelines define AKI as any 1 of the following:

- 1) Increase in the serum creatinine by 0.3 mg/dL (26.5 μ mol/L) within 48 hours **or**
- 2) 1.5-fold increase over baseline within the past 7 days **or**
- 3) Oliguria (urine output < 0.5 mL/kg/hour) for at least 6 hours

AKI can be nonoliguric, oliguric (urine output < 0.5 mL/kg/h), or anuric (urine output < 50–100 mL/day).

Anuria is rare. When it does occur, it is usually caused by severe shock, complete bilateral urinary tract obstruction, renal cortical necrosis, bilateral renal arterial occlusion, or rapidly progressive (crescentic) glomerulonephritis.

Refer to Table 7-2 on page 7-10 and Table 7-3 on page 7-10 while reading about AKI.

Prerenal AKI is caused by underperfusion, either from true loss of intravascular volume or decreased effective arterial blood volume.

Intrinsic AKI is caused by disease or damage to the glomeruli, tubules, interstitium, or vascular structures.

Postrenal AKI is caused by obstruction of the urinary tract.

Vascular disease can cause AKI when it leads to ischemia or infarction of both kidneys.

Table 7-2: Acute Kidney Injury Labs and Clues

Category	Causes	Urine Sediment	FE _{Na} [*]	FE _{Urea}	U _{Osm} (mOsm/kg)	U _{Na} (mEq/L)
Prerenal	Volume depletion Heart failure Liver failure NSAIDs ACEI/ARB	Normal ("bland") Granular casts Hyaline casts	< 1%	< 35%	> 400	< 20
Intrinsic renal	ATN	Granular (muddy-brown) casts	> 2%	> 50%	300–350	> 20
	Glomerulonephritis	Dysmorphic RBCs and/or red cell casts	< 1%	(No data)	(No data)	< 20
	AIN	WBCs and/or WBC casts	> 1%	(No data)	(No data)	> 20
Postrenal	Bilateral ureteral obstruction Unilateral ureteral obstruction with solitary kidney Urethral obstruction	RBCs or bland	Varies	Varies	Varies	Varies
Vascular	Atheroembolic	WBCs, eosinophiluria	(No data)	(No data)	(No data)	(No data)
	Renal infarction, renal vein thrombosis	RBCs	(No data)	(No data)	(No data)	(No data)
	Ischemic nephropathy	Normal ("bland")	< 1%	(No data)	(No data)	< 20

^{*} Recent diuretic use can alter the FE_{Na}; in this setting, FE_{Urea} and FE_{Uric acid} are more reliable.

AIN = acute interstitial nephritis
ATN = acute tubular necrosis

FE_{Na} = fractional excretion of sodium
FE_{Urea} = fractional excretion of urea

U_{Na} = urinary sodium concentration
U_{Osm} = urine osmolality

Table 7-3: Types of Acute Kidney Injury and Presenting Findings

Category	Suspect in a Patient with:
Prerenal	Bleeding Heart failure (cardiorenal) Cirrhosis (hepatorenal) Nephrotic syndrome GI fluid loss (nausea/vomiting/diarrhea) NSAID or ACEI/ARB use Diuretic use
Intrinsic renal	Hypotension, shock (ATN) Sepsis (ATN) Drugs (ATN: aminoglycosides, amphotericin, cisplatin, NSAIDs) Contrasts/IV dyes (contrast-induced nephropathy) Drugs (AIN; any antibiotic, pantoprazole) SLE (GN) Vasculitis (GN) Endocarditis (IRGN) Heroin (if nephrotic, think FSGS) Myeloma (cast nephropathy) Malignant HTN
Vascular	Atheroembolic disease, renal infarction, renal vein thrombosis, ischemic nephropathy
Postrenal	Urinary tract symptoms (i.e., older men with hesitancy, weak stream, nocturia) Risk factors for abdominal or pelvic malignancy

AIN = acute interstitial nephritis
ATN = acute tubular necrosis
FSGS = focal segmental glomerulosclerosis
HTN = hypertension
PIGN = postinfectious glomerulonephritis
SLE = systemic lupus erythematosus

In all patients with AKI, look for nephrotoxin and contrast exposure, volume status, and episodes of hypotension. Check orthostatic vital signs, U/A, fractional excretion of Na⁺, and renal U/S.

AKI — EVALUATION AND TREATMENT

For all patients with AKI, evaluate:

- Volume status—especially volume overload (e.g., HF, pulmonary edema)
- Electrolytes—especially look for hyperkalemia, hyperphosphatemia, and hypocalcemia
- Acid-base status—metabolic acidosis
- Uremic symptoms such as decreased mental status and pericarditis

Initial treatment depends on the suspected cause. For example:

- If urinary retention is suspected (e.g., elderly male with bladder distention), place a **urinary catheter**. This can be a diagnostic and therapeutic procedure.
- Treat hyperkalemia with ECG changes (e.g., peaked T waves) with immediate medical therapy (IV calcium gluconate or calcium chloride, insulin + glucose, albuterol, sometimes bicarbonate [HCO₃⁻]). Dialyze if unresponsive. See [Hyperkalemia on page 7-54](#) for more information.
- Treat hyperphosphatemia with dietary phosphate restriction and oral phosphate binders. Treat hyperphosphatemia before giving IV Ca²⁺ to treat hypocalcemia—normalizing phosphate level often corrects the Ca²⁺ level.

- Treat severe metabolic acidosis ($\text{pH} < 7.2$) with IV sodium bicarbonate.
- Treat volume overload (pulmonary edema, severe peripheral edema) with loop diuretics.

Indications for urgent dialysis in AKI:

- Hyperkalemia refractory to medical treatment
- Metabolic acidosis refractory to medical treatment
- Severe volume overload refractory to diuretics
- Severe uremic symptoms, especially uremic pericarditis

PRERENAL AKI

Causes of Prerenal AKI

Prerenal AKI is, by definition, due to a real or “effective” **decrease** in GFR due to hemodynamic changes—most often, decreased renal **perfusion**, as seen in:

- Volume depletion, blood loss, hypotension, or diuretics (common; treated with volume expansion)
- Heart failure (cardiorenal syndrome)
- Drugs that cause vasoconstriction of the afferent arterioles:
 - NSAIDs
 - Calcineurin inhibitors (CNI; cyclosporine, tacrolimus)
- Drugs that cause vasodilation of the efferent arterioles: angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs)
- Hepatorenal syndrome
- Abdominal compartment syndrome

Know: ACEIs/ARBs exacerbate prerenal AKI by blocking AT II-mediated constriction of the efferent arteriole (which maintains GFR in situations of low renal plasma flow), and NSAIDs block the prostaglandins that provide afferent vasodilation. Stop these drugs in any patient with AKI. If the patient has no evidence of hypovolemia on physical exam, consider the other causes listed above—all are associated with reduced glomerular perfusion.

An additional clue to a specific prerenal cause of AKI is NSAIDs in the history. As discussed in **Other Drug-Induced Nephropathies on page 7-28**, NSAIDs cause **constriction** of the **afferent** arteriole and a decrease in GFR in patients who are prostaglandin dependent to maintain GFR, specifically those patients who have comorbidities with preexisting, decreased effective arterial blood volume such as systolic dysfunction or cirrhosis.

Hepatorenal syndrome is a form of prerenal AKI seen in patients with advanced hepatic cirrhosis. Severe vasomotor disturbance caused by splanchnic dilation leads to renal hypoperfusion. There is almost always evidence of **portal HTN** (think ascites, esophageal varices, splenomegaly, leukopenia, thrombocytopenia, anemia) and **jaundice**.

Diagnostic criteria for hepatorenal syndrome, as established by the International Club of Ascites (2015):

- Cirrhosis with ascites and evidence of portal HTN
- A serum creatinine $> 1.5 \text{ mg/dL}$ ($132.6 \text{ } \mu\text{mol/L}$) that progresses over days to weeks
- Lack of improvement in renal function after withdrawal of diuretics and volume expansion with albumin (1 g/kg of body weight per day up to 100 g/day) for at least 2 days
- No evidence of parenchymal kidney disease (i.e., normal U/A, proteinuria $< 500 \text{ mg/day}$, normal renal U/S)
- Absence of any other apparent cause of AKI, including shock, nephrotoxins, and infection (except peritonitis)

Therapy with midodrine and octreotide is aimed at stabilizing patients until they receive a liver transplant.

Abdominal compartment syndrome is a rare cause of prerenal AKI. Abdominal compartment syndrome refers to organ dysfunction caused by intraabdominal HTN (sustained intraabdominal pressure $> 20 \text{ mmHg}$, with or without abdominal perfusion pressure $< 60 \text{ mmHg}$).

Elevated intraabdominal pressure reduces blood flow to the abdominal viscera. Abdominal compartment syndrome can occur with abdominal trauma, massive ascites, intraperitoneal bleeding, acute pancreatitis, and any other condition that raises the intraabdominal pressure. AKI most likely occurs secondary to renal vein compression, which increases venous resistance and impairs venous drainage.

Similar to other causes of prerenal AKI caused by reduced perfusion, the renal indices usually are decreased ($\text{FE}_{\text{Na}} < 1\%$ and $\text{FE}_{\text{Urea}} < 35\%$).

Treat with either surgical decompression (trauma patients) or high-volume paracentesis (in patients with massive ascites).

Prerenal AKI — Labs

BUN:Cr ratio is typically increased to **$> 20:1$** .

Urine is very concentrated with osmolality **$> 400 \text{ mOsm/kg}$** (400 mmol/kg), and often $> 700 \text{ mOsm/kg}$ (700 mmol/kg).

Urine Na^+ is $< 20 \text{ mEq/L}$ (20 mmol/L), indicating normal tubular function (and avid reabsorption of Na^+ reflecting activation of the renin-angiotensin-aldosterone system).

Urine sediment is generally normal but can show granular or hyaline casts.

FE_{Na} is $< 1\%$ in both prerenal AKI and acute GN (see **FE_{Na} and FE_{Urea} on page 7-4**). AKI with an $\text{FE}_{\text{Na}} < 1\%$ and a normal urine sediment $\pm$ a few granular or hyaline casts = **prerenal** azotemia. Dysmorphic red cells, red cell casts, and protein indicate GN.

Patients who are on diuretics can have $FE_{Na} > 1\%$ and still have prerenal AKI. In these situations, FE_{Urea} is more accurate than FE_{Na} . $FE_{Urea} < 35\%$ is suggestive of a prerenal state. You can also use $FE_{Uric\ acid}$ in these situations ($FE_{Uric\ acid} < 12\%$ is suggestive of prerenal AKI). See [Table 7-2 on page 7-10](#).

POSTRENAL AKI

Postrenal AKI (a.k.a. obstructive uropathy) can occur at any point along the urinary tract: the renal papilla and renal pelvis, ureters, bladder, or urethra. Urinary tract obstruction can be either chronic or acute. It can result from external compression (e.g., malignancy) or intraluminal obstruction (e.g., nephrolithiasis). When complete and bilateral (or urethral), urinary tract obstruction can present with anuria. But know that **normal urine output does not rule out obstruction**, particularly when obstruction is chronic and/or partial or intermittent. Obstructed patients can even have increased urine output because of chronic damage to the tubules that impairs their ability to reabsorb water and solutes.

Upper Urinary Tract Obstruction

Obstruction anywhere upstream of the ureterovesical junction is considered upper tract obstruction; most commonly, it occurs at the level of the ureters. Consider unilateral ureteral obstruction if the patient develops AKI and has only 1 kidney. Patients with 2 kidneys generally do not get renal failure from unilateral ureteral obstruction because the 2nd kidney continues to function normally; however, if ureteral obstruction is bilateral, AKI or CKD can ensue.

Ureteral obstruction can be caused by **kidney stones** (more under [Kidney Stones on page 7-35](#)). Acute obstructing nephrolithiasis presents with severe flank pain (i.e., renal colic). Certain **drugs**—especially **methotrexate**, **indinavir**, **acyclovir**, **ganciclovir**, and **sulfa antibiotics**—can cause ureteral obstruction by crystallizing and forming stones.

Intraabdominal **malignancies**, particularly lymphoma and endometrial cancer, can cause upper urinary tract obstruction by compressing the ureters.

Papillary necrosis (the renal papillae are just proximal to the renal pelvis) is rare but can occur in the settings of severe pyelonephritis, chronic analgesic abuse, and sickle cell disease. The sloughed papillae obstruct the urinary tract, often within the kidneys at the level of the renal pyramids and renal pelvis. Patients with papillary necrosis often present with flank pain. U/A shows **sterile pyuria** with or without **WBC casts**.

Retroperitoneal fibrosis is a rare disorder in which there is inflammation and fibrosis in the retroperitoneum that can encase and obstruct the ureters. Often, it is idiopathic. However, it can occur in the setting of IgG4-related disease. For more on IgG4-related disease, see the [Rheumatology](#) section. Retroperitoneal

fibrosis typically presents with back pain and non-specific complaints such as weight loss and fatigue. Ureteral obstruction can be either acute (causing postrenal AKI) or chronic (presenting with atrophic kidneys and advanced CKD). Depending on the etiology, corticosteroids are sometimes used in conjunction with mechanical relief of the obstruction (more under [Obstructive Uropathy — Treatment](#)).

In children, ureteral obstruction is commonly due to **anatomic anomalies** such as stricture at the ureterovesical (ureter-bladder) junction. If undiagnosed or untreated, such children present frequently with advanced CKD in early adulthood, with bilateral renal atrophy.

Ureteral obstruction is usually first diagnosed by U/S, which shows hydronephrosis and/or hydroureter in the absence of bladder distention. CT scan helps determine the site of the obstruction.

Acute Urinary Retention

Acute urinary retention is the sudden onset of lower urinary tract obstruction, occurring at the level of the bladder or urethra. When complete, this can present with anuria and severe renal failure. Patients may have suprapubic pain from the distended bladder. Causes include:

- **Benign prostatic hyperplasia (BPH)**: Patients often (but not always!) report a history of chronic lower urinary tract symptoms, reflecting chronic prostatic hypertrophy. BPH is discussed in the [Women's and Men's Health](#) section.
- **GU malignancy**, especially prostate cancer, bladder cancer, and cervical cancer
- **Kidney stones** that pass through to the bladder also can cause acute urethral obstruction (more under [Kidney Stones on page 7-35](#)).
- **Medications** can cause urinary retention, particularly anticholinergics (e.g., oxybutynin, dicyclomine), sympathomimetics (e.g., phenylephrine, pseudoephedrine), antihistamines (e.g., diphenhydramine), and psychiatric medications (e.g., haloperidol, amitriptyline).
- **Urethral stenosis** also can cause bladder outlet obstruction.

When you suspect acute urinary retention, focus the H&P on eliciting a history of chronic obstructive symptoms, palpating the distended bladder, looking for pelvic masses, performing the prostate exam, and looking for lymphadenopathy. The diagnosis is quickly confirmed or excluded with a bedside bladder ultrasound completed after the patient voids or attempts to void.

Chronic Urinary Retention

Chronic lower urinary tract symptoms are common in aging men and are usually due to **BPH** and consequent

bladder outlet obstruction. However, other etiologies such as **urethral stricture** and **prostate cancer** can sometimes present with chronic symptoms. The same medications that can cause acute urinary retention also can cause chronic problems (more under [Acute Urinary Retention](#)).

Obstructive symptoms include nocturia, urinary frequency, hesitancy, weak stream, and/or incomplete voiding. Renal function (S_{Cr}) should be checked if there is hydronephrosis or high postvoid residual bladder volume. For more information on BPH, see the [Women's and Men's Health](#) section.

Obstructive Uropathy — Diagnosis

Renal insufficiency with elevated creatinine (either acute or chronic) may occur, particularly when obstruction is bilateral, severe, or complete. U/A is typically “bland” (no abnormalities). Chronic obstruction can cause Type 4 RTA (with NAGMA plus **hyperkalemia**).

Lower urinary tract retention can be diagnosed with a bedside bladder ultrasound or postvoid residual measurement. Diagnosis of upper tract obstruction requires a renal U/S or CT scan (if you suspect stones) showing hydronephrosis (dilatation of the renal pelvis; [Figure 7-6](#)) or hydroureter (dilatation of the ureter). Know that hydronephrosis may be absent in ureteral obstruction due to retroperitoneal fibrosis, as the fibrosis can encase the renal pelvis and prevent dilatation.

Figure 7-6: Hydronephrosis from ureteral stones

Obstructive Uropathy — Treatment

Treatment of obstructive uropathy is theoretically simple: Resolve the obstruction. In general, mechanical intervention is indicated acutely, particularly when renal failure is present. For upper tract obstruction, options include placement of percutaneous nephrostomy tubes or ureteral stents. For lower tract obstruction, placement of an indwelling bladder catheter or intermittent bladder catheterization often provides a short-term solution.

Long-term treatment depends on the underlying etiology. Treatment of BPH can include medications (primarily α -blockers such as tamsulosin) and surgical intervention. If malignancy is present, surgery, radiation, and/or chemotherapy may be indicated. Treatment of kidney stones can include lithotripsy and mechanical stone extraction.

VASCULAR AKI

Atheroembolic Disease

Patients who have had vascular manipulation (e.g., cardiac catheterization, angiogram, abdominal aortic aneurism repair) are at risk for atheroembolic disease (a.k.a. cholesterol embolic disease). Unlike contrast-induced nephropathy, this does not cause ATN, but results in delayed kidney injury (after 72 hours) with a gradual deterioration in renal function over weeks to months.

Clinical features include livedo reticularis, eosinophilia, systemic and cutaneous emboli, low serum complement, and a stepwise increase in the creatinine. Hollenhorst plaques also can occur. These are cholesterol emboli in the retinal arterioles appearing as orange-white dots interrupting the circulation. If diagnosis is in doubt, biopsy of 1 of the skin lesions can show a cholesterol embolus.

Treatment of renal disease due to cholesterol emboli is supportive only. Do not anticoagulate.

Renal Infarction

Renal infarction is most often due to thromboembolic disease originating in the heart. Risk factors include atrial fibrillation, mechanical heart valves, and cardiomyopathy. Patients with hypercoagulable states are also at increased risk for renal infarction. Occasionally, renal infarction can occur as a result of a vascular event such as renal artery dissection or aortic dissection involving the renal arteries. Renal infarction must be severe and usually bilateral to cause significant AKI. Septic emboli from infectious endocarditis can sometimes cause renal infarction, though this is seldom severe enough to cause AKI.

Clinical signs of renal infarction include flank pain, hematuria, and elevated LDH. High LDH without other LFT abnormalities? Think renal infarction! Diagnose by CT with contrast (wedge-shaped infarct). Management is usually supportive; however, when infarction is severe and detected early, emergency thrombectomy (by vascular surgery or interventional radiology) may save the kidney. Anticoagulation is usually indicated to prevent recurrent thromboembolic events.

Renal Vein Thrombosis

Thrombosis of the renal vein, like renal infarction, can lead to loss of renal blood flow, ischemia, and AKI. Renal vein thrombosis is most often seen in the setting of hypercoagulable states. Nephrotic syndrome, particularly from membranous nephropathy, is a classic cause of renal vein thrombosis.

Renal vein thrombosis is usually chronic and asymptomatic. Often, it is discovered as an incidental finding on other imaging such as CT to evaluate for pulmonary embolism. However, when renal vein thrombosis is acute and bilateral, flank pain hematuria and acute kidney injury can be seen, resembling renal infarction. If acute complete renal vein thrombosis is suspected, diagnose by CT angiography or MR venography. Kidney ultrasound with Doppler has low sensitivity and can miss the diagnosis. In the absence of AKI or other severe symptoms, treat with anticoagulation alone. Thrombolytics or thrombectomy (by interventional radiology) can be considered if AKI or flank pain are present.

Ischemic Nephropathy

Renovascular disease (i.e., renal artery stenosis) is an important secondary cause of HTN (more under [Renovascular HTN on page 7-61](#)). Renovascular disease is caused by stenosis in one or both renal arteries, either due to atherosclerotic disease or fibromuscular dysplasia. When severe, renovascular disease can lead eventually to chronic renal ischemia and loss of renal function—**ischemic nephropathy**. Ischemic nephropathy usually causes CKD, but occasionally can cause a more rapid deterioration in kidney function (AKI). ACEIs and ARBs can precipitate AKI in patients with bilateral renal artery stenosis. Diagnosis is by kidney ultrasound with doppler (less accurate), CT angiogram, or MR angiogram. Although intervention (e.g., percutaneous angioplasty and stenting) is not usually beneficial for the treatment of the HTN, revascularization can preserve kidney function in patients heading toward renal failure.

INTRINSIC RENAL AKI

The intrinsic causes of AKI require in-depth discussion and are covered under the next 3 main headings:

- 1) **ATN**, discussed first because it is the **most common** cause of **intrinsic renal AKI** (more under [Acute Tubular Necrosis \(ATN\)](#))
- 2) Tubulointerstitial disease (more under [Tubulointerstitial Nephritis on page 7-16](#))
- 3) Glomerular disorders (more under [Glomerular Disorders on page 7-17](#))

ACUTE TUBULAR NECROSIS (ATN)

PREVIEW | REVIEW

- What are some common causes of nephrotoxic (drug-induced) acute tubular necrosis (ATN)?
- What are the lab findings in rhabdomyolysis?
- What are the urine findings in ATN?

OVERVIEW

ATN is the **most common** cause of **intrinsic** AKI—more than interstitial disease or glomerulonephritis. ATN causes ~ 1/2 of the cases of AKI in the hospital.

Tubular dysfunction is the hallmark of ATN. Renal epithelium necrotizes, and the tubules essentially fill up with debris. Failure of tubules to appropriately reabsorb water and solutes leads to activation of tubuloglomerular feedback, leading to a profound decrease in GFR.

ATN follows a 3-phase progression of initiation, maintenance, and recovery:

- 1) **Initiation:** Following the insult, there is an acute and severe decrease in GFR, with associated rapid increases in BUN and serum creatinine.
- 2) **Maintenance:** The severe reduction of GFR usually persists for 1–2 weeks. BUN and creatinine continue to rise.
- 3) **Recovery:** Tubular function returns. Urine volume increases; BUN and creatinine gradually return to normal.

CAUSES OF ATN

Ischemic ATN

Ischemic ATN is the most common form of ATN. It can occur in any form of shock (i.e., hemorrhagic, hypovolemic, cardiogenic, septic) or any condition that causes an **abrupt decrease in renal perfusion**. Frequently, ischemic ATN is seen in ICU settings.

Nephrotoxic ATN

Nephrotoxic ATN has both endogenous and exogenous causes:

- **Endogenous:**
 - Myoglobin (rhabdomyolysis)
 - Free hemoglobin (intravascular hemolysis)
 - Excess uric acid (tumor lysis syndrome)
- **Exogenous:**
 - Contrast-induced nephropathy (iodinated contrast media, used in CT scans and angiography, including cardiac catheterizations); more under [Imaging In CKD on page 7-33](#)
 - Drugs (amphotericin B, **aminoglycosides**, cisplatin, cidofovir, tenofovir, foscarnet, and many others)
 - Osmotic nephropathy (e.g., IVIG with sucrose, mannitol, dextran; patients with CKD are especially vulnerable)
 - Acute phosphate nephropathy (bowel purgatives containing sodium phosphate); more under [Acute Phosphate Nephropathy \(APN\) on page 7-16](#)

Notes on drug-induced nephrotoxic ATN:

- With **amphotericin B**, risk of ATN is based on cumulative dose and is especially likely at > 3 g total dose. Amphotericin B has a direct nephrotoxic effect and

can cause Type 1 or 2 RTA (more under RTAs on page 7-45) and hypomagnesemia. Liposomal forms of amphotericin have a much lower risk of renal toxicity and should always be used if available.

- **Aminoglycosides** cause proximal tubule damage, resulting in a nonoliguric ATN and hypomagnesemia. Correct hypomagnesemia or hypokalemia prior to aminoglycoside treatment to decrease the risk of nephrotoxicity. **Gentamicin** is the most nephrotoxic aminoglycoside. Once-daily dosing of an aminoglycoside is less nephrotoxic than multiple daily doses. Monitor serum levels in all patients getting aminoglycosides for > 72 hours. GFR usually begins to fall 5–7 days after the start of treatment.
- **Cisplatin** is a common chemotherapeutic cause of ATN. It also causes hypomagnesemia.
- **Tenofovir** and **cidofovir** can cause a Fanconi-like syndrome in addition to AKI.
- **Foscarnet** is used to treat ganciclovir-resistant CMV infection. Renal toxicity and hypocalcemia are common; risk is reduced by pretreatment with IV fluids.
- Note: Contrast nephropathy, rhabdomyolysis, and intravascular hemolysis can cause profound renal vasoconstriction with Na^+ retention that can present with a low urine Na^+ and consequent $\text{FE}_{\text{Na}} < 1\%$. This contrasts with other types of ATN, which typically have $\text{FE}_{\text{Na}} > 2\%$.

Heme Pigment–Induced AKI

Hemoglobin and myoglobin are heme pigments that can cause acute tubular injury when present in the circulation at high levels.

AKI from myoglobin can occur in the setting of severe **rhabdomyolysis**. Rhabdomyolysis occurs when muscle damage results in the release of creatine kinase (CK), myoglobin, and electrolytes into the bloodstream. All the following are causes:

- Crush injuries (compartment syndromes), coma, or prolonged immobilization
- Prolonged surgeries
- Strenuous exercise
- Generalized seizures
- Heat stroke
- Severe volume contraction
- Ethanol
- Drugs—cocaine, amphetamines, statins, colchicine, anesthetics causing malignant hyperthermia, neuroleptic malignant syndrome
- Infections—usually viral, especially influenza A and B
- Endocrinopathies—diabetic ketoacidosis, hypothyroidism, hyperthyroidism, and pheochromocytoma
- Electrolyte abnormalities—severe hypokalemia, hypophosphatemia (e.g., in alcoholics during refeeding)

Patients present as a result of the underlying cause and/or with muscle tenderness and cola-colored urine. Labs show increased CK > 100,000 U/L with increases in AST and ALT. It is important to be sure that there is no component of prerenal azotemia contributing to the AKI. Creatinine is typically elevated. Hyperkalemia, hyperphosphatemia, increased uric acid, and hypocalcemia are common complications. U/A shows muddy-brown casts consistent with ATN. The urine is colored brown due to myoglobin pigment. The urine test strip is positive for blood, but no RBCs are visible in the sediment on microscopy.

Early in rhabdomyolysis, hypocalcemia is common, caused by deposition of calcium phosphate in damaged muscle and other tissues.

In recovery, patients can have significant hypercalcemia from mobilization of Ca^{2+} tissue deposits formed during the acute phase. To minimize risk of late hypercalcemia, do not treat early hypocalcemia with calcium replacement unless it is severe or the patient is symptomatic.

Treat as soon as possible with aggressive isotonic fluid resuscitation (1–2 L/hour for the first few hours). After initial resuscitation, continue IV fluids unless/until the patient shows signs of volume overload. Consider using isotonic IV sodium bicarbonate instead of isotonic saline: Alkalinization of the urine may prevent myoglobin-induced tubular damage, though clinical evidence is limited. However, do not use sodium bicarbonate if hypocalcemia is present (it can precipitate seizures) or if the patient is already alkalotic (arterial pH > 7.5 and/or serum bicarb > 30 mEq/L [30 mmol/L]). Watch out for hyperkalemia. Use loop diuretics only to treat volume overload. Dialysis is used in severe cases.

Hemoglobinuria has urine findings similar to those seen in rhabdomyolysis (dipstick positive for heme, but few or absent RBCs on microscopic exam of the urine sediment). Hemoglobin can be released from severe intravascular hemolysis. It also can cause ATN—not due to toxicity, but rather mechanical obstruction from heme pigment casts. Treatment is the same as for rhabdomyolysis.

Contrast-Induced Nephropathy

Contrast-induced nephropathy is defined as acute kidney injury 24–48 hours of contrast exposure. Typically, it resolves spontaneously over days to weeks.

The best way to prevent contrast-induced nephropathy is by avoiding the use of contrast agents, especially in high-risk patients. Use noncontrast CT, MRI, or U/S.

If contrast must be used:

- Avoid volume depletion.
- Administer IV normal saline before and after contrast exposure.
- Randomized trials have failed to demonstrate a benefit of *N*-acetylcysteine (NAC), although some providers still use it in high-risk patients.

- Use the lowest possible volume of contrast.
- Use a low-osmol or isoosmolar contrast agent.
- Avoid NSAIDs.
- Avoid gadolinium (used in MRIs) in patients with estimated GFR < 30 mL/minute/1.73 m². Although it does not cause AKI, it can cause systemic nephrogenic fibrosis in CKD and end-stage renal disease (ESRD) patients.

Acute Phosphate Nephropathy (APN)

APN is a form of AKI that occurs after the use of bowel purgatives containing sodium phosphate. Transient hyperphosphatemia after ingestion or enema containing sodium phosphate leads to an increased intratubular phosphate concentration. This precipitation and tissue deposition of calcium phosphate salts in turn leads to luminal obstruction and direct tubular epithelial injury.

Risk factors for developing APN include underlying kidney dysfunction (GFR < 60 mL/minute/1.73 m²), advanced age, volume depletion, HTN, diabetes, and use of ACEIs or ARBs.

The diagnosis of APN is suggested by AKI with a recent history of receiving bowel purgatives that contain **sodium phosphate**. Confirm the diagnosis by the presence of hyperphosphatemia out of proportion to the degree of kidney injury (or preceding kidney injury).

Prevention: Avoid use of bowel purgatives that contain **sodium phosphate** in high-risk patients.

LABS IN ATN

BUN and Cr rise rapidly early in ATN. BUN:Cr ratio remains normal at 10:1 to 15:1 (> 20:1 suggests prerenal disease). Urine osmolality is usually < 350 mOsm/kg (< 350 mmol/kg) because tubules cannot concentrate the urine. Urine Na⁺ is > 40 mEq/L (40 mmol/L). FE_{Na} is typically > 2%. However, FE_{Na} can be low in contrast-induced nephropathy, severe rhabdomyolysis, and hemoglobinuria. Granular casts in the urine are a hallmark finding of ATN: **muddy-brown, "dirty" granular casts** (C in Figure 7-1 on page 7-2) and renal tubular epithelial cell casts. Sometimes, tubular epithelial cells are seen.

If severe volume depletion is the cause for ATN, then labs can be consistent with a prerenal picture (high BUN:Cr ratio, low urine Na⁺, and low FE_{Na}).

MANAGEMENT OF ATN

Initial management of ATN includes treating the precipitating cause and any accompanying hyperkalemia or metabolic acidosis. Maintain normovolemia, adequate blood pressure, and nutritional support (which decreases catabolism). Discontinue nephrotoxins, including ACEIs/ARBs and NSAIDs. Avoid contrast exposure.

Oliguric ATN usually resolves in 1–4 weeks. Note that oliguria is **not** required for the diagnosis of ATN. However, patients with oliguric ATN are more prone to hyperkalemia and volume overload, so dialysis is often needed earlier.

TUBULOINTERSTITIAL NEPHRITIS

PREVIEW | REVIEW

- Characterize the clinical presentation of acute interstitial nephritis (AIN).
- What glomerular pathologic lesion is seen in patients with NSAID-induced AIN?

OVERVIEW

Interstitial nephritis is characterized by inflammation of the interstitium. Tubular and interstitial diseases have only low-grade proteinuria (< 1–1.5 g/day), and they can cause a NAGMA.

ACUTE INTERSTITIAL NEPHRITIS

Acute (or allergic) interstitial nephritis (AIN) is most often a drug-induced **hypersensitivity** reaction that can cause fever, eosinophilia, and rash. Only 10% of patients have all 3. More often, presentation is unexplained AKI.

The drugs most frequently implicated in AIN include NSAIDs, antibiotics, proton pump inhibitors (e.g., pantoprazole), thiazides, allopurinol, and cimetidine. AIN is an idiosyncratic response to the drug and generally is not related to cumulative dose.

These are the most common antibiotic culprits:

- β -lactams (especially nafcillin or oxacillin)
- Trimethoprim/sulfamethoxazole (TMP/SMX)
- Rifampin
- Ciprofloxacin and, less often, other fluoroquinolones

Remember: Proton pump inhibitors are a major cause of interstitial nephritis.

AIN also can be caused by sarcoidosis, systemic lupus erythematosus (SLE), Sjögren syndrome, transplant rejection, and infection (e.g., pyelonephritis, *Legionella*, streptococci).

The urine sediment in AIN contains few RBCs, WBCs, +/- WBC casts. There is mild proteinuria (< 1 g/day, if quantified). RBC casts are generally not seen. Urinary eosinophils may be present, but this finding is nonspecific; routine testing for urinary eosinophils is no longer recommended. Peripheral blood eosinophilia is sometimes observed in severe cases. FE_{Na} is typically > 1%. NAGMA and Fanconi syndrome can occur if there is proximal tubular damage. Diagnosis of AIN is by renal biopsy, but often patients are treated empirically.

NSAID-induced AIN is different in that the NSAIDs are typically ingested for **months** before symptoms occur. Rash, fever, and eosinophilia are frequently absent. **Contrary** to all other types of AIN, NSAID-induced AIN commonly causes **nephrotic-range proteinuria**, and biopsy shows glomerular changes of **minimal change disease**.

Treatment includes discontinuing the offending drug and observing the patient. Consider steroids in severe cases (usually after biopsy confirmation). Steroids are beneficial if started within the first 2 weeks of the injury.

TINU syndrome (a.k.a. acute tubulointestinal nephritis and uveitis) was first described in 1975. Younger females are usually affected. An elevated modified C-reactive protein (mCRP) and renal biopsy help with the diagnosis. Treat with systemic steroids.

CHRONIC INTERSTITIAL NEPHRITIS

Chronic interstitial nephritis is caused by:

- Drugs—analgesics, cyclosporine, tacrolimus, lithium, cisplatin, proton pump inhibitors, and aristolochic acid
- Heavy metals—especially lead and cadmium
- Chronic obstruction
- Infections—chronic pyelonephritis, reflux nephropathy, tuberculosis
- Sarcoidosis
- Autoimmune diseases—systemic lupus erythematosus, Sjögren syndrome
- Sickle cell disease
- Multiple myeloma

Historically, chronic use of analgesic combinations containing phenacetin (a prodrug of acetaminophen), aspirin (acetylsalicylic acid), and caffeine or codeine was an important cause of chronic interstitial nephritis, papillary necrosis, and CKD—a syndrome called analgesic nephropathy. The incidence of analgesic nephropathy fell dramatically after phenacetin was withdrawn from the market and combination analgesics were restricted to prescription use. Avoid long-term use of analgesic combinations containing acetaminophen, aspirin, and/or caffeine or codeine.

Whether chronic use of individual analgesics (acetaminophen or NSAIDs) can cause CKD in previously healthy individuals is controversial. However, chronic use of NSAIDs may worsen renal function (both acutely and chronically) in patients with underlying CKD and should be avoided in these patients.

Rarely, patients may be exposed to lead via their **occupation** (working with batteries, solder, cabling, ceramics, tin, mining; construction workers may be exposed to lead-based paint), drinking **moonshine** (lead in moonshine is very rare), taking alternative **herbal medications** from India and China, using **lead-glazed plates** or **cookware**, and smoking **marijuana**. Nephropathy usually develops after years of chronic lead exposure and presents as azotemia, a tiny bit of proteinuria, hyperuricemia, and a bland

urine sediment. ~ 50% of patients develop gouty arthritis, termed “**saturnine gout**.” The serum lead level is often normal in this condition; lead chelation testing (e.g., with EDTA) is required to establish the diagnosis.

Remember: Lithium can cause both chronic interstitial nephritis and nephrogenic diabetes insipidus (DI). Sometimes, both are seen in the same patient!

Herbs containing **aristolochic acid**, ingested as weight-loss agents, can also cause kidney failure from chronic interstitial nephritis.

GLOMERULAR DISORDERS

PREVIEW | REVIEW

- What are the systemic manifestations of nephrotic syndrome?
- Rapidly progressive glomerulonephritis (RPGN) has which hallmark finding on renal biopsy?
- What are the 3 major causes of RPGN?
- What is the empiric treatment for RPGN?
- In addition to anti-glomerular basement membrane (anti-GBM) antibodies, which pathologic feature defines Goodpasture syndrome?
- What are the most common sites of primary infection in patients with poststreptococcal glomerulonephritis (GN)?
- How long after the original infection does renal failure from poststreptococcal GN start?
- What are the complement levels in patients with infection-related GN?
- Which infections are associated with development of immune complex-mediated membranoproliferative glomerulonephritis?
- What are the findings on renal biopsy in patients with IgA nephropathy?
- What are the 3 key features of nephrotic syndrome?
- What drugs and diseases are associated with minimal change disease (MCD)?
- Under polarized light, “Maltese crosses” are seen in the urine sediment of patients with which syndrome?
- What is the treatment of MCD?
- What racial group has the highest incidence of focal segmental glomerulosclerosis (FSGS)?
- What is the treatment of primary FSGS?
- Solid tumors are associated with which glomerular disease?
- Which renal tubular acidosis is associated with diabetic nephropathy?
- What is the classic finding seen on kidney biopsy in a patient with diabetic nephropathy?

OVERVIEW

Glomerular diseases can be divided into 2 categories, based on clinical presentation and mechanism of disease:

- 1) **Glomerulonephritis (GN)** is an **inflammatory process** that presents with proteinuria (commonly < 2 g/day) and an active urine sediment: always RBCs (often dysmorphic RBCs; A in [Figure 7-1 on page 7-2](#)), with or without WBCs, **RBC casts** (B in [Figure 7-1 on page 7-2](#)), and WBC casts. Disease can be mild and indolent (hematuria and proteinuria with normal or slowly decreasing renal function) or acute and severe (rapidly progressive renal failure, HTN, and edema).
- 2) **Nephrotic syndrome** is a noninflammatory process that presents with heavy proteinuria (> 3.5 g/day) and edema. The glomerulus is leaky to both protein and fat, and urine fat appears in the form of fatty casts or oval fat bodies (D and E in [Figure 7-1 on page 7-2](#)), which appear as Maltese crosses under polarized light. Hematuria is usually absent; renal function may be normal or decreased. Hypoalbuminemia, edema, hypercholesterolemia, and hypercoagulability are classic features of nephrotic syndrome.

Know that some glomerular diseases (e.g., antineutrophil cytoplasmic antibody [ANCA]-associated vasculitis) usually cause GN, while others (e.g., minimal change disease) usually cause nephrotic syndrome. However, some glomerular diseases (e.g., SLE, membranoproliferative glomerulonephritis [MPGN]) can have either presentation.

The causes of glomerular disease can be either primary renal (usually idiopathic) or secondary to a systemic disease.

For patients with suspected glomerular disease, start with a good H&P and targeted serologic workup. Renal biopsy is required for definitive diagnosis of most glomerular diseases except diabetic nephropathy, which is usually diagnosed clinically.

A strategy that helps classify the glomerular diseases:

- 1) Is the clinical picture suggestive of **glomerulonephritis** or **nephrotic syndrome**?
- 2) If you suspect glomerulonephritis, are the complement levels **low** or **normal**?
- 3) Does the patient have **systemic** findings by history and physical exam, or is the presentation limited to the **kidneys**? (Note: Edema and HTN are kidney, not systemic, manifestations.)

As soon as you see a **nephritic** picture, do serologic testing. Serologies for GN should always include complements (C3 and C4). Even if the patient presents with a history of classic infection-related GN, measure complement levels! Depending on the patient's age, gender, and other features on H&P, other useful serologic tests may include ANA, anti-double-stranded DNA (anti-dsDNA), ASO, ANCA, anti-GBM antibody, HBV, HCV, and HIV testing.

Refer to [Table 7-4](#), [Table 7-5](#), and [Table 7-6 on page 7-24](#) as you go through the glomerular disorders.

GLOMERULONEPHRITIS (GN)

Rapidly Progressive GN (RPGN)

The most aggressive syndrome of acute GN is RPGN. RPGN is a **clinical syndrome of acute GN** with rapidly worsening eGFR (over days to weeks). Kidney biopsy usually shows glomerular **crescents** (**extracapillary proliferation**) inside Bowman capsule ([Figure 7-7 on page 7-20](#)).

Table 7-4: Classification of Glomerulonephritis According to Complement Levels

Complement Level	Renal-Limited GN	Systemic Causes of GN
Low	Complement-mediated MPGN	Immune complex-mediated MPGN Lupus nephritis Infection-related GN (including endocarditis) Cryoglobulinemia
Normal	Renal-limited vasculitis (usually ANCA+)	ANCA-associated vasculitis (3 systemic forms): • Granulomatosis with polyangiitis • Microscopic polyangiitis • Eosinophilic granulomatosis with polyangiitis
	Renal-limited anti-GBM disease	Systemic anti-GBM disease ("Goodpasture syndrome")
	IgA nephropathy	IgA vasculitis
	Alport syndrome (can occur without ear and eye manifestations)	Alport syndrome (with sensorineural hearing loss, anterior lenticonus)

ANCA = antineutrophil cytoplasmic antibody
GBM = glomerular basement membrane
MPGN = membranoproliferative glomerulonephritis

Table 7-5: Glomerulonephritis — Detailed Summary

Classification	Complement Level	Cause	Presentation	Treatment	Notes
Renal-limited presentation	Low	Complement-mediated MPGN	Hematuria, proteinuria (sometimes nephrotic-range), and progressive renal insufficiency	Not well established; plasma exchange, rituximab, and cyclophosphamide have been used	Complements stay low > 3 months. Types include dense deposit disease, C3 glomerulopathy, and C4 glomerulopathy.
	Normal	Renal-limited vasculitis	RPGN HTN	High-dose steroids + cyclophosphamide or rituximab Plasmapheresis if renal failure is severe	Pathology is identical to GPA and MPA (crescentic GN with negative IF). Usually ANCA+
		Anti-GBM disease (renal-limited)	RPGN HTN	Plasmapheresis + high-dose steroids + cyclophosphamide	30–50% of patients with anti-GBM disease have no pulmonary manifestations.
		IgA nephropathy	Gross hematuria after viral illness (no latent period) or persistent microscopic hematuria	ACEIs/ARBs if proteinuria is present Steroids if proteinuria is heavy Cyclophosphamide if RPGN and crescents on biopsy	Best prognosis for patients with intermittent hematuria; may progress in patients with proteinuria
		Alport syndrome	Hematuria Hearing loss Lens abnormalities Family history of kidney disease	ACEIs/ARBs	X-linked (recessive) is most common
Systemic presentation	Low	Immune complex-mediated MPGN (e.g., due to hepatitis C or monoclonal gammopathy) Lupus nephritis Cryoglobulinemia	Systemic features, including fever, skin lesions, arthritis Presents with variable proteinuria—sometimes in nephrotic range	Varies by underlying cause Treat any underlying infection, autoimmune, or lymphoproliferative disorder. Proliferative lupus nephritis treated with cyclophosphamide or mycophenolate + steroids	Serologic testing can help determine etiology: HCV/ HBV, SPEP/UPEP (to identify a monoclonal gammopathy), ANA and anti-dsDNA (for SLE), ASO and blood cultures (for endocarditis), cryoglobulins. Immune complex deposits seen on kidney biopsy (EM)
		IRGN	Abrupt onset weeks after strep or staph infection (especially skin or oropharynx) Insidious onset in the setting of endocarditis or other chronic infections.	Treat the infection, supportive care	Latent period between infection and symptoms Check for antibodies of antecedent strep infection.
	Normal	ANCA-associated vasculitis (MPA, GPA, and eosinophilic granulomatosis with polyangiitis)	RPGN Constitutional symptoms Sinusitis Cough Dyspnea Hemoptysis Purpura	High-dose steroids + cyclophosphamide or rituximab + Plasmapheresis if severe renal failure or pulmonary hemorrhage is present	Requires urgent renal biopsy: crescentic GN with negative IF
		Anti-GBM antibody disease (Goodpasture syndrome)	RPGN and pulmonary hemorrhage (shortness of breath, cough, hemoptysis) Severe respiratory failure and death can occur.	Plasmapheresis + high-dose steroids + cyclophosphamide	Requires urgent renal biopsy: crescentic GN with linear staining on IF

ANCA = antineutrophil cytoplasmic antibody
ASO = antistreptolysin O
C3, C4 = complements
dsDNA = double-stranded DNA
EM = electron microscope
GBM = glomerular basement membrane

GN = glomerulonephritis
GPA = granulomatosis with polyangiitis
HTN = hypertension
IF = immunofluorescence
IRGN = infection-related glomerulonephritis
MPA = microscopic polyangiitis

MPGN = membranoproliferative glomerulonephritis
RPGN = rapidly progressive glomerulonephritis
S_C = serum creatinine
SPEP = serum protein electrophoresis
UPEP = urine protein electrophoresis

Figure 7-7: Crescentic glomerulonephritis: Bowman space filled with inflammatory cells and fibrosis

In RPGN, creatinine is typically > 3 mg/dL. The urine has protein, red cells, and sometimes RBC casts. Other findings depend on the underlying disease causing the RPGN. There are 3 major causes of RPGN:

- 1) Anti-GBM antibody disease (Goodpasture syndrome)
- 2) ANCA-associated glomerulonephritis
- 3) Immune complex-mediated GN such as IgA nephropathy, lupus nephritis, immune complex-mediated MPGN (e.g., due to cryoglobulinemia in hepatitis C infection), and infection-related GN

Note that while anti-GBM antibody disease and ANCA-associated GN typically present with RPGN (including crescents on biopsy), the diseases that cause immune complex-mediated GN usually **do not** cause RPGN or glomerular crescents. More commonly, these diseases cause a more slowly progressive form of GN without crescents.

Always consider RPGN if a patient presents with severe and progressive renal failure of recent onset with an active urinary sediment. If RPGN is suspected, quickly obtain kidney biopsy and do serologic testing, including ANCA, anti-GBM antibodies, and complements.

Treat suspected RPGN empirically with high-dose IV methylprednisolone while waiting for results of the kidney biopsy and serologic testing. Once the diagnosis is confirmed, add specific therapy based on the underlying disease (e.g., cyclophosphamide + plasmapheresis for anti-GBM disease).

Summary of RPGN: **rapidly progressive** renal failure with **active** urine sediment; renal biopsy shows **crescents**; most common causes are anti-GBM antibody disease and ANCA-associated GN; treat empirically with steroids then focus treatment on underlying disease once diagnosis is confirmed.

Anti-Glomerular Basement Membrane (Anti-GBM) Antibody Disease

Anti-GBM antibody disease causes crescentic RPGN with positive anti-GBM antibodies in the serum, with or without pulmonary hemorrhage. When **pulmonary**

hemorrhage is present (50–70% of patients), the disease is called **Goodpasture syndrome**. Patients with Goodpasture syndrome present with an **active** urine sediment and **hemoptysis with dyspnea**. Younger male patients are more likely to present with Goodpasture syndrome and older females with renal-limited anti-GBM disease.

In anti-GBM disease, antibodies formed in response to an unknown stimulus attack the glomerular (and sometimes pulmonary) basement membrane(s).

Diagnosis is by renal biopsy, which shows crescentic GN (Figure 7-7) and linear IgG deposits along the GBM on immunofluorescence (IF). Linear IgG, along with positive serologic testing for anti-GBM antibodies, distinguishes anti-GBM disease from ANCA-associated vasculitis (where the IF is negative).

Treatment of anti-GBM disease, whether renal-limited or with pulmonary hemorrhage, is urgent plasma-pheresis (to remove the antibodies) and aggressive immunosuppression (steroids + cyclophosphamide). Prognosis depends on the severity of disease at presentation.

Antineutrophil Cytoplasmic Antibody (ANCA)-Associated Vasculitis

ANCA-associated vasculitis can cause crescentic RPGN. Subtypes include:

- Granulomatosis with polyangiitis (GPA)—distinguishing feature: granulomas. Clinical features include:
 - **Upper respiratory disease** (e.g., sinusitis, epistaxis)
 - Lower respiratory disease (e.g., hemoptysis, infiltrates, cavitary lesions, diffuse alveolar hemorrhage [DAH])
 - Usually proteinase-3 (PR3)-ANCA+
- Microscopic polyangiitis (MPA)—necrotizing vasculitis but no granulomas. Clinical features include:
 - DAH
 - **Mononeuritis multiplex**
 - Cutaneous small-vessel vasculitis (palpable purpura)
 - Usually myeloperoxidase (MPO)-ANCA+
- Eosinophilic granulomatosis with polyangiitis. These are variously discussed in the **Rheumatology** section and the **Pulmonary Medicine** section:
 - Asthma/Atopy
 - **Eosinophilia**
 - Crescentic GN/RPGN is less common.

Signs and symptoms of ANCA-associated vasculitis depend on the organs affected. With GPA and MPA, there is usually RPGN (hematuria, proteinuria, rapid deterioration in eGFR), along with the extrarenal findings listed above. Laboratory testing shows normal complements and positive ANCA (either PR3 or MPO). (See the **Rheumatology** section for a discussion of types of ANCAs.) Diagnosis is by kidney biopsy, which shows crescentic GN on light microscopy, but negative immunofluorescence.

Treat ANCA-associated glomerulonephritis aggressively and urgently with pulse intravenous solumedrol, and either cyclophosphamide or rituximab. Early treatment is critical to prevent irreversible loss of kidney function. When the diagnosis is suspected clinically, treatment with IV solumedrol should be started even before the kidney biopsy and ANCA results are available! Plasmapheresis is beneficial in severe disease (pulmonary hemorrhage or severe renal failure).

Infection-Related GN

The most common form of infection-related GN (IRGN; formerly known as postinfectious glomerulonephritis [PIGN]) is seen after Group A β -hemolytic streptococcal infection of the skin or throat. This entity had been called “poststreptococcal GN.” On renal pathology, there is an immune-complex GN. Other organisms such as *Staphylococcus* and sites (e.g., infectious endocarditis, atrioventricular shunt infection) also cause IRGN.

Signs and symptoms of IRGN include hematuria (gross or microscopic), elevated serum creatinine, HTN, and/or edema. With poststreptococcal GN, renal injury is seen 1–6 weeks after the initial illness (average 10 days after throat infections, 2–4 weeks after skin infections). The **latency period** is a diagnostic clue and differs from IgA nephropathy, which is **synpharyngitic**; that is, within 3 days of the pharyngitis episode. Throat cultures may grow β -hemolytic streptococci. Urine is often described as the color of cola. With other forms of IRGN (e.g., caused by endocarditis), the infection may be diagnosed at the same times that the renal injury is identified.

Antistreptolysin O (ASO) antibodies are usually elevated in IRGN due to *Streptococcus* and can be diagnostically useful.

Know that an ASO titer generally remains elevated for **several weeks** after a streptococcal infection. Again, complement levels remain low for 6–8 weeks.

IRGN is caused by an antibody-antigen reaction, with the source of the antigen being the infecting agent. Renal biopsy confirms the diagnosis and shows the presence of immune complexes in the glomerulus. In children, renal biopsies are rarely performed because the diagnosis typically can be made via the clinical history + measurement of complement levels and antistreptococcal antibodies. IRGN is less common in adults, so an adult with suspected IRGN usually gets a renal biopsy.

IRGN can cause severe renal failure, but most patients eventually improve with supportive care and treatment of the underlying infection with antibiotics. Most children recover completely in 6–8 weeks; however, adults may not have complete recovery.

Summary of IRGN: gross and/or microscopic hematuria, proteinuria, renal insufficiency, and low complements. With poststreptococcal GN, renal failure

occurs 1–6 weeks after infection. There is **low complement** for 6–8 weeks, variably positive **antistreptococcal antibody titers** (with group A strep infection), and subendothelial and subepithelial immune “humps” on renal biopsy. Most patients show good response to treatment of the infection.

Membranoproliferative Glomerulonephritis (MPGN)

Complement-Mediated MPGN

MPGN (a biopsy diagnosis) is classified based on etiology into 2 major types: complement-mediated MPGN and immune complex-mediated MPGN. These 2 types are distinguished by kidney biopsy. In complement-mediated MPGN, immune fluorescence is positive for complement but negative for immunoglobulin components (IgG, IgA, IgM, kappa, and lambda light chains); this is because no immune complexes are deposited—only complement. In immune complex-mediated MPGN, immune fluorescence is positive for complement (C3), but also 1 or more of the immunoglobulin components listed above.

Complement-mediated MPGN is due to dysregulation of the alternative pathway. The disease is caused by either a genetic mutation in, or autoantibodies to, complement regulatory proteins. This results in overactivity of the alternative complement pathway and complement deposition in the glomeruli. Regulatory proteins affected by gene mutations include Factors H, I, and B. In antibody-mediated disease, the antibodies can simply be against these same proteins or can be against C3 convertase (the autoantibody to C3 convertase is called C3 nephritic factor).

Low C3 and normal C4 levels are common in complement-mediated MPGN. The low C3 stays **low indefinitely**. This is useful: If you initially suspected IRGN but C3 stays low for > 3 months, suspect MPGN instead, and get a renal biopsy! If biopsy shows complement-mediated MPGN, test for genetic mutations and autoantibodies to alternative complement pathway proteins.

Treatment of complement-mediated MPGN is controversial. For antibody-mediated disease, plasma exchange, immunosuppression, and eculizumab have been used. For disease due to a genetic deficiency, intermittent infusions of fresh frozen plasma to replace the missing factor have been used.

Remember: MPGN is 1 of the diseases that can present with either a nephritic or nephrotic clinical picture.

Immune Complex-Mediated MPGN

Immune complex-mediated MPGN usually is due to an underlying systemic disease.

Immune complex-mediated MPGN is caused by immune complexes deposited within or adjacent to the glomerular basement membrane. Immune complexes form in chronic infections (e.g., **hepatitis B and hepatitis C**, shunt nephritis, abscess), autoimmune disease

(e.g., SLE, Sjögren syndrome), or monoclonal gammopathy. Low complement levels are common in immune complex-mediated MPGN.

Hepatitis C is the most common cause of immune complex-mediated MPGN. It is treated with antiviral therapy. For more on hepatitis C, see the [Gastroenterology](#) section.

If cryoglobulinemia and other severe features are present (i.e., progressive loss of renal function, systemic vasculitis), treat with steroids + plasmapheresis, rituximab, or cyclophosphamide.

Lupus Nephritis

Lupus nephritis is glomerular disease caused by SLE. It is divided into 6 patterns of glomerular injury:

- Class 1—normal/minimal mesangial
- Class 2—mesangial proliferative
- Class 3—focal proliferative (< 50% of glomeruli involved)
- Class 4—diffuse proliferative (> 50% of glomeruli involved)
- Class 5—membranous
- Class 6—advanced-stage lupus nephritis (> 90% global glomerulosclerosis)

Clinically, the most important categories of lupus nephritis are Classes 3, 4, and 5. Classes 3 and 4 typically present with a decline in renal function (can be chronic, subacute, or acute) and glomerulonephritis (i.e., active sediment, low-grade proteinuria). Class 5 can present similarly or with a more nephrotic picture (bland sediment, heavy proteinuria, edema). Sometimes, there are pathologic features of both Class 5 and Class 3 or 4. Complements are usually low, and ANA and anti-dsDNA titers are elevated. Commonly, patients have other clinical symptoms of lupus at the time of renal disease diagnosis; occasionally, renal disease is the only presenting symptom. Perform a renal biopsy on all lupus patients with active urine sediment, regardless of GFR.

Without treatment, lupus nephritis can quickly progress to ESRD. Treat Classes 3, 4, and 5 aggressively with steroids + either mycophenolate mofetil or cyclophosphamide. Use maintenance therapy with mycophenolate or azathioprine to prevent relapses. Classes 1 and 2 are not usually biopsied, have a good prognosis, and immunosuppressive therapy is not needed unless they evolve into Class 3, 4, or 5 (suspect this if there is worsening renal function or worsening proteinuria). Class 6 is end-stage disease, and treatment is not recommended.

For more information on lupus nephritis during pregnancy, see the [Women's and Men's Health](#) section.

IgA Nephropathy

IgA nephropathy is the most common GN worldwide. It is more common in Asians and males 20–40 years of age.

IgA nephropathy has a wide range of presentations, including gross hematuria, microscopic hematuria with or without proteinuria (the most common presentation), and RPGN (more under [Rapidly Progressive GN \(RPGN\)](#) on page 7-18). Gross hematuria in IgA nephropathy commonly occurs either during or immediately following an upper respiratory infection or after strenuous exercise. Unlike infection-related GN, there is no latent period between infection and appearance of hematuria. This is an important distinguishing feature!

In IgA nephropathy, there is immune complex deposition of IgA and C3 in the glomerular mesangium. Although C3 is deposited, serum complement levels are normal.

Diagnosis is with renal biopsy, which shows mesangial proliferation on light microscopy (crescents in severe disease), and deposits of IgA and complement in the mesangium and in the glomerular capillaries on immunofluorescence staining ([Figure 7-8](#)).

Figure 7-8: IgA nephropathy: mesangial IgA deposits on immunofluorescence

Source: Sriram S. Narsipur, MD

Some illnesses are associated with mesangial IgA deposition but without obvious glomerular injury (e.g., HIV/AIDS, celiac disease, end-stage liver disease). These presentations are called **secondary** IgA nephropathy.

Prognosis for IgA nephropathy is tied to serum creatinine, blood pressure, and amount of proteinuria. Prognosis is good if these values are normal. Prognosis is much worse if any of these are elevated. Up to 50% of patients with proteinuria > 1 g/day may progress to ESRD. Patients with recurrent gross hematuria without proteinuria are at low risk for progression.

Observe patients who maintain normal renal function with no proteinuria. Use ACEIs/ARBs for proteinuria (> 0.5 g/day). Corticosteroid therapy is sometimes used for persistent proteinuria (> 1 g/day) despite 6 months on an ACEI/ARB, or a progressive decline in eGFR. However, the 2015 STOP-IgAN trial showed no improvement in rate of eGFR decline, and an increased risk of adverse events, with immunosuppression. Data are inconclusive on the benefit of statins and fish oil for the treatment of IgA nephropathy.

IgA vasculitis is a systemic vasculitis due to IgA deposition in the kidneys, skin, and other organs. IgA vasculitis is seen mostly in children; however, it can occur in adults. Patients present with abdominal pain, joint pain, lower extremity palpable purpura, and hematuria. Renal insufficiency (elevated creatinine) sometimes occurs. As with IgA nephropathy, complement levels are usually normal. Diagnosis is clinical, or by kidney or skin biopsy which shows IgA deposition in the mesangium (kidney) or venules (skin; leukocytoclastic vasculitis). The disease typically resolves spontaneously; treatment is supportive.

NEPHROTIC SYNDROMES

Nephrotic urine reflects defects in the selectivity of the glomerular filtration barrier, in the absence of inflammation. **Nephrotic-range proteinuria** is defined as urine protein excretion > 3.5 g/day. **Nephrotic syndrome** is nephrotic-range proteinuria, plus hypoalbuminemia and edema. Frequently, hyperlipidemia also is present. Nephrotic syndrome of any type causes urinary loss of immunoglobulins and antithrombin III. This results in both an increased risk of infections (particularly with encapsulated organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*) and a hypercoagulable state. Loss of thyroid and iron-binding globulins also occurs (so, low total thyroxine and iron levels).

Table 7-6 on page 7-24 describes the most important causes of nephrotic syndrome.

Nephrotic syndrome is classified according to the pathologic pattern seen on kidney biopsy. These pathologic patterns can be primary (idiopathic), or secondary to a systemic illness. Pathologic patterns in nephrotic syndrome include:

- Minimal change disease
- Focal segmental glomerulosclerosis
- Membranous nephropathy

For each of these 3 main pathologic patterns, disease can be primary (idiopathic), or secondary to a systemic disease (e.g., SLE Class 5 = membranous lupus). Amyloidosis and diabetes mellitus are systemic diseases which cause nephrotic syndrome and produce unique changes on kidney biopsy that do not fit into these 3 classic pathologic patterns. We will discuss these 5 categories of nephrotic syndrome in detail next.

Minimal Change Disease (MCD)

MCD is the most common cause of primary nephrotic syndrome in children and is the cause of 10–15% of nephrotic syndrome in adults. The pathogenesis of MCD is not yet known. It appears to be related to T-cell dysfunction. Pathologically, there is fusion or effacement of the podocyte foot processes in the glomerular capillary walls. This makes for a leaky glomerular filtration barrier and heavy proteinuria.

The **vast majority** of MCD is **idiopathic**, but it is sometimes caused by drugs or systemic diseases.

Know these secondary causes of MCD:

- **Drugs**—NSAIDs; rarely other drugs such as lithium
- **Lymphoma**—both Hodgkin lymphoma and non-Hodgkin lymphoma

Patients present with **anasarca** or severe peripheral **edema** that develops over days to weeks usually **without** HTN. Adults can have renal failure that usually improves with treatment.

As with any cause of nephrotic syndrome, urine sediment may show fatty casts or oval fat bodies (see D and E in Figure 7-1 on page 7-2), which appear as Maltese crosses under polarized light.

MCD diagnosis is made by renal biopsy, which shows **normal** histology on light microscopy and absence of immune deposits on immunofluorescence. Electron microscopy shows fusion or effacement of epithelial (podocyte) foot processes.

Treat MCD initially with steroids. Remission typically occurs within 3–4 months. Steroid-dependent and steroid-resistant disease may be treated with cyclophosphamide or cyclosporine.

The prognosis of MCD is very good; however, relapses are common.

Summary of MCD: **nephrotic-range** proteinuria, fusion of podocyte foot processes, fatty casts or oval fat bodies; secondary causes are **NSAIDs** and **lymphoma**; treat with steroids; **generally very good** prognosis.

Focal Segmental Glomerulosclerosis (FSGS)

FSGS has become the most common cause of idiopathic nephrotic syndrome in African Americans and is the most common primary glomerular disease causing ESRD in the U.S. Although FSGS is most often a primary (idiopathic) disease, it can be familial or secondary. Therefore, consider secondary FSGS if there is a history of HIV/AIDS, heroin use, obesity, sickle cell disease, reduced renal mass, or chronic vesicoureteral reflux.

The hallmark pathology in FSGS is glomerulosclerosis (glomerular scarring) that is **focal** (< 50% of glomeruli are affected) and **segmental** (for affected glomeruli, < 50% of the tuft is involved). This is different from global glomerulosclerosis (100% of the tuft is sclerosed), which is nonspecific scarring that is the end stage of many forms of kidney disease. Like MCD, FSGS has diffuse **foot process fusion** on EM. Unlike MCD, these patients often present as hypertensive as well as nephrotic.

50% have a reduction in kidney function at diagnosis. These patients have slowly progressive renal failure. Those **not** responding to treatment **require dialysis** within ~ 5–10 years. Those with severe proteinuria and reduction in GFR at diagnosis have a worse prognosis.

Table 7-6: Nephrotic Syndrome — Detailed Summary

Pathologic Pattern	Etiology	Presentation	Treatment	Notes
Minimal change disease: Fusion of podocyte foot processes; otherwise, path is normal! Secondary to: • NSAIDs • Hodgkin lymphoma • Lithium	Primary (idiopathic)	Sudden onset of severe nephrotic syndrome	Primary: • Steroids = 1 st line • CNI or cyclophosphamide = 2 nd line	10–15% of nephrotic syndrome in adults
	Look for clues to secondary causes.	Treat the underlying cause.		
Focal segmental glomerulosclerosis Secondary to: • HIV/AIDS • Reflux nephropathy • Obesity	Primary: • Idiopathic (common in African Americans) • Familial	Can be similar to MCD or have more gradual onset	ACEIs/ARBs Steroids +/- CNI (Patients who respond to steroids have the best prognosis.)	Associated with the APOL1 gene variant in African Americans Can recur after kidney transplantation
	Look for clues to secondary causes.	Treat the underlying cause.	FSGS due to HIV is usually with untreated/uncontrolled disease.	
Membranous: Thickening of glomerular basement membrane; subepithelial deposits on EM Secondary to: • Malignancy (especially solid tumors) • SLE ("Class 5") • Drugs (e.g., NSAIDs) • HBV and other chronic infections	Idiopathic: anti-PLA2R antibodies	Acute or subacute onset of nephrotic syndrome Hematuria is sometimes present.	Mild cases: ACEIs/ARBs Persistent and/or severe proteinuria: steroids + cyclophosphamide or rituximab	Anti-PLA2R antibodies are present in 70% of cases.
	Clues are often present on history and physical examination.	Treat the underlying cause.	Look for malignancy, especially in older adults. Screen for lupus, hepatitis B, and hepatitis C.	
Diabetic nephropathy: Nodular glomerulosclerosis	Type 1 or Type 2 diabetes mellitus (usually after 15+ years of disease)	Long-term Type 1 or Type 2 diabetes mellitus Begins with moderately increased albuminuria, with gradual progression to overt proteinuria and chronic kidney disease	ACEIs/ARBs Control of blood glucose, blood pressure, and lipids	Most common cause of nephrotic syndrome Retinopathy typically precedes kidney disease.
Amyloidosis: Apple-green birefringence with Congo-red stain; 8- to 12-nm fibrils on EM	AL amyloidosis: deposition of immunoglobulin light chain fragments Multiple myeloma (most common) Waldenström macroglobulinemia Non-Hodgkin lymphoma	Proteinuria (often, though not always, nephrotic-range) +/- progressive renal insufficiency	Treat underlying hematologic malignancy.	Look for clues to myeloma (low anion gap, hypercalcemia, anemia).
	AA amyloidosis: chronic inflammatory disorders Can be seen in rheumatoid arthritis and chronic infections	Nephrotic syndrome +/- cardiomyopathy	Treat underlying infection or inflammatory process.	Check SPEP, UPEP, and serum free light chains.

Nephrotic syndrome definition is heavy proteinuria (> 3.5 g/day), hypoalbuminemia (< 3.0 g/dL), edema, and hypercholesterolemia. Lipiduria (i.e., oval fat droplets or fatty casts) and a hypercoagulable state may occur.

Complications: DVT and bacterial infections

AA amyloidosis = amyloid A amyloidosis
 AL amyloidosis = immunoglobulin light-chain amyloidosis
 APOL1 = apolipoprotein L1 gene
 CNI = calcineurin inhibitor (cyclosporine, tacrolimus)
 EM = electron microscopy

FSGS = focal segmental glomerulosclerosis
 MCD = minimal change disease
 PLA2R = phospholipase A2 receptor
 SPEP = serum protein electrophoresis
 UPEP = urine protein electrophoresis

It is important to distinguish between primary and secondary FSGS because the treatment differs. Treat primary FSGS with steroids. For secondary FSGS, treat the underlying disease.

Initial treatment of primary FSGS includes ACEIs/ARBs and high-dose steroids for up to 6 months to induce remission. Patients without remission have a poorer prognosis. Treatment can improve prognosis and prevent or delay progression to ESRD.

Treat secondary FSGS with ACEIs/ARBs and therapy directed at the underlying cause, if possible. Initiate antiretroviral therapy in all patients with HIV-associated nephropathy, regardless of CD4 count, because treatment can lead to regression of the renal disease.

HIV patients with nephrotic syndrome usually have the collapsing variant of FSGS, also known as **HIV-associated nephropathy (HIVAN)**. Untreated, HIVAN progresses rapidly to ESRD. Be sure to consider **tenofovir** nephrotoxicity (which causes ATN, not nephrotic syndrome or FSGS) in patients with HIV and renal failure.

Summary of FSGS: **nephrotic-range** proteinuria, **African Americans**, hypertensive; secondary causes are **HIV/AIDS** (the collapsing variant), **reflux nephropathy**, obesity; treat primary disease with steroids.

Membranous Nephropathy

Idiopathic (primary) membranous nephropathy is a common cause of nephrotic syndrome in adults, especially in Caucasian males > 40 years of age. The most important secondary cause of membranous nephropathy is malignancy, particularly solid tumors such as breast, colon, lung, prostate, and bladder cancer. The cancer is usually obvious at the time of renal presentation, but if not, do age-appropriate malignancy screening. **Other secondary** causes include:

- Chronic **infections** (primarily chronic HBV, but also malaria)
- **Drugs**
- **Autoimmune** diseases (e.g., thyroiditis, rheumatoid arthritis, SLE [consider if membranous nephropathy presents in a young female])

Patients with membranous nephropathy present with subacute onset of nephrotic syndrome, and 50% of patients have red cells in the urinary sediment (without RBC casts). Most patients have normal blood pressure and renal function at diagnosis.

Renal biopsies should be done in all cases of nephrotic syndrome when the underlying cause is not obvious (e.g., diabetic nephropathy). In membranous nephropathy, renal biopsy shows thickened capillary walls and GBM "spikes" on **light microscopy** and granular IgG and C3 deposits on **immunofluorescence**. Electron microscopy shows subepithelial electron-dense deposits. The GBM is thickened because new matrix is laid down between the subepithelial deposits.

The majority (70%) of patients with **primary** membranous nephropathy have positive antiphospholipase A2 receptor (**anti-PLA2R**) antibodies. This test can be useful in distinguishing primary from secondary membranous nephropathy, which can guide therapy.

Up to 30% of patients spontaneously improve over a period of 3–5 years, while others improve partially or completely with treatment. ~ 15% of patients progress to ESRD despite treatment. Patients with more severe proteinuria and/or reduced GFR have a worse prognosis, as do men > 50 years old.

Secondary membranous nephropathy often improves with treatment of the underlying disease or discontinuation of any offending drugs.

Because some patients with idiopathic membranous nephropathy can have spontaneous remission, not all patients need to be treated immediately. Aggressively treat only those who have persistent high-grade proteinuria (> 4 g/day) despite at least 6 months of conservative management with ACEI or ARB and HTN control. Treatment is with corticosteroids + either cyclophosphamide or rituximab.

Membranous nephropathy has the highest prevalence of renal vein thrombosis compared with other causes of nephrotic syndrome. If a patient with known membranous nephropathy develops flank pain, hematuria, and high LDH, think about renal infarction secondary to renal vein thrombosis.

Summary of membranous nephropathy: **nephrotic-range** proteinuria; secondary causes are **HBV**, gold, penicillamine, **solid tumors**, **SLE**; aggressively treat primary form with corticosteroids + a cytotoxic agent if proteinuria is > 4 g/day and not responsive to conservative treatment; prognosis is worse in older men.

Diabetic Nephropathy

Diabetic nephropathy is the most common cause of ESRD in the U.S. and worldwide. It is also the most common systemic cause of nephrotic syndrome in adults. Diabetes mellitus also can cause **Type 4 RTA** (i.e., hyporeninemic hypoaldosteronism). The risk of diabetic nephropathy is the same, regardless of whether patients have Type 1 or 2 diabetes mellitus. In most cases, **retinopathy precedes nephropathy** (weaker association in Type 2 diabetes mellitus).

Not all patients with diabetes develop diabetic nephropathy. Know the following risk factors:

- Family history of ESRD
- African American, Hispanic, Pima Native American
- Uncontrolled HTN (systolic blood pressure > 140 mmHg)
- GFR (hyperfiltration in the first 5 years after diagnosis = higher risk)
- Poor glycemic control
- Obesity
- Smoking

The diagnostic finding on renal biopsy is glomerular enlargement, mesangial sclerosis, and nodular accumulations of mesangial matrix (**Kimmelstiel-Wilson nodules**). However, if the clinical picture is “classic” (i.e., proteinuria and slowly rising serum creatinine in the setting of long-standing diabetes mellitus with retinopathy and neuropathy), kidney biopsy is not usually necessary. In patients with atypical presentations, kidney biopsy is sometimes done to exclude other glomerular causes of nephrotic syndrome.

Diabetic nephropathy occurs in 2 phases. In the **silent, or preclinical, phase**, the only detectable abnormality is **moderately increased albuminuria**, which is urinary albumin between 30 and 300 mg/day—an amount often too low to be detected on dipstick. It can be detected by measuring a random urine albumin:creatinine ratio; > 30 mg albumin/g creatinine (or > 0.03 mg/mg) represents moderately increased albuminuria. Test all diabetic patients yearly for albuminuria using the spot albumin:creatinine ratio. Albuminuria screening should start 5 years after diagnosis of Type 1 diabetes mellitus and at the time of diagnosis of Type 2 diabetes mellitus. If moderately increased albuminuria is found, treat with an ACEI or ARB **even if normotensive**.

The **clinical phase** (overt diabetic nephropathy) is characterized by overt proteinuria (> 300 mg/day), HTN, and progressive loss of kidney function.

Control of **HTN** (to $< 130/80$ mmHg, per the 2017 American College of Cardiology/American Heart Association Guidelines for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults, with ACEI/ARB as the 1st line drug) and **hyperglycemia** (HbA1c target $< 7\%$) **slow** the rate of progression of diabetic nephropathy. ACEI/ARB use has been shown in randomized controlled trials to reduce progression from moderately increased albuminuria to overt diabetic nephropathy, and to delay loss of renal function in patients with overt diabetic nephropathy, in both Type 1 and Type 2 diabetes mellitus. However, avoid using ACEIs and ARBs together, as the combination use can increase risk of AKI and hyperkalemia. The sodium glucose cotransporter 2 (SGLT2) inhibitors (e.g., canagliflozin) slow progression of diabetic nephropathy and are recommended by the American Diabetes Association (ADA) guidelines in patients with albumin:creatinine ratio > 300 mg/g and eGFR > 30 mL/minute/1.73 m². However, SGLT2 inhibitors should not be used in patients with eGFR < 30 mL/minute/1.73 m².

Weight reduction and treatment of hyperlipidemia also appear to decrease risk. The ADA guidelines recommend dietary protein intake of 0.8 g/kg body weight/day (the recommended daily allowance) in patients with diabetic CKD who are not yet on dialysis. Very-low-protein diet (< 0.6 g/kg/day) is not recommended, either in diabetic or nondiabetic CKD.

Know: As renal function decreases, insulin requirements decrease (secondary to decreased metabolism by the kidneys).

Multiple Myeloma and Amyloidosis

Multiple myeloma can cause several different renal lesions:

- **Cast nephropathy** (myeloma kidney) is the most common renal lesion with multiple myeloma. Immunoglobulin light chains precipitate in the tubules, leading to acute kidney injury. A **clue** to myeloma cast nephropathy is **negative urinary dipstick for protein** but abnormal **proteinuria on lab quantification** (urine protein:creatinine ratio, 24-hour urine protein, and urine protein electrophoresis). This occurs because the dipstick reacts to albumin but not to the nonalbumin light chains.
- **Hypercalcemia**, which can cause AKI and nephrogenic DI
- **Primary amyloidosis** (a.k.a. immunoglobulin light-chain [AL] amyloidosis) is a multisystem disease that can include nephrotic syndrome and renal failure (**Figure 7-9**; Congo red stain shows deposits with apple-green birefringence under polarized light). AL amyloidosis can occur alone or with multiple myeloma.
- **Mixed immunoglobulin deposition disease (MIDD)** presents with a nephritic picture. On renal biopsy, monoclonal immunoglobulin light chains or heavy chains (or both) are deposited in the glomeruli.

Secondary amyloidosis (a.k.a. amyloid A [AA] amyloidosis) is seen in chronic inflammatory states such as rheumatoid arthritis and familial Mediterranean fever. AA amyloid nephropathy also can be caused by recurrent skin and soft tissue infections such as those caused by chronic injection drug use. Clues to amyloidosis include carpal tunnel syndrome and new-onset HF associated with nephrotic syndrome. AA amyloidosis in the kidney causes nephrotic syndrome.

Enlarged kidney size, as seen on imaging studies, can be caused by **multiple myeloma**, **amyloidosis**, and **HIV-associated nephropathy**.

Secondary Causes of Nephrotic Syndrome

To review, secondary/systemic causes of nephrotic syndrome include:

- **Drugs:** Lithium and NSAIDs can cause MCD. NSAIDs, penicillamine, gold, and anti-TNF agents (e.g. infliximab) can cause membranous nephropathy. Bisphosphonates, anabolic steroids, and interferon can cause FSGS.
- **Malignancy:** Hodgkin lymphoma and non-Hodgkin lymphoma can cause MCD. Solid tumors can cause membranous nephropathy.
- **Infections:** HIV/AIDS can cause collapsing FSGS. HVB, HCV, and syphilis can cause membranous nephropathy.
- **Autoimmune:** SLE (Class 5) and IgG4-related disease can cause membranous nephropathy.
- **Miscellaneous:** Obesity, vesicoureteral reflux, sickle cell anemia, and reduced renal mass can cause FSGS.

Figure 7-9: Renal pathology in amyloidosis. (A) PAS stain shows mesangial expansion with amorphous, pale, eosinophilic material. (B) Congo red stain and polarized light show apple-green birefringence.

Treatment of Nephrotic Syndrome

General principles: Treat any underlying systemic disease. Use ACEIs/ARBs to decrease intraglomerular pressure and reduce proteinuria. Diuretics, usually loop diuretics, are needed because edema can be severe. Note that immunosuppression (glucocorticoids +/- cyclophosphamide, calcineurin inhibitors, or rituximab) are used in most primary causes of nephrotic syndrome and nephrotic syndrome due to autoimmune disease (e.g., SLE), but not in nephrotic syndrome secondary to most systemic diseases (e.g., amyloidosis, diabetes, obesity, infection). Consider anticoagulation if there is a significant risk of thrombosis, particularly in severe hypoalbuminemia in membranous nephropathy. Be cognizant of the significantly increased rate of infections and vaccinate accordingly.

THROMBOTIC MICROANGIOPATHIES

Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS) are forms of thrombotic microangiopathy (TMA). TMA is a pathologic pattern of microvascular thrombosis of the arterioles and capillaries. Clinically, you see microangiopathic hemolytic anemia (anemia, high LDH, low haptoglobin, high indirect bilirubin, and schistocytes on the peripheral blood smear), and thrombocytopenia. TMA can be caused by TTP (acquired or genetic), drugs, Shiga toxin, and complement disorders.

Acquired TTP is caused by a severe deficiency of the ADAMTS13 enzyme (defined as activity < 10%), which leads to large von Willebrand factor multimers and platelet aggregation. TTP usually has mild or no renal dysfunction. Often, the only renal manifestation is a U/A dipstick positive for heme but with no RBCs on the urine sediment exam—this is due to hemoglobinuria from the hemolysis. Patients present with progressive weakness,

fatigue, and purpura. This syndrome is often suspected only after the discovery of anemia and thrombocytopenia. ~ 2/3 of patients have some neurological involvement. Diagnose TTP by measuring the ADAMTS13 level; however, do not wait for the result to start treatment if your suspicion is high! TTP is a medical emergency—untreated, mortality approaches 100%. Diagnosis and treatment with plasmapheresis should occur within hours of suspecting the diagnosis.

Certain drugs can cause TMA, with the classic findings of microangiopathic hemolytic anemia and thrombocytopenia, with or without renal failure. Drugs known to cause TMA include quinine (present in tonic water), calcineurin inhibitors (i.e., cyclosporine, tacrolimus), gemcitabine, and VEGF inhibitors (e.g., bevacizumab).

Shiga toxin-mediated hemolytic uremic syndrome (ST-HUS) initially presents with abdominal pain, nausea, vomiting, and bloody diarrhea, followed by AKI, microangiopathic hemolytic anemia, and low platelets. Treatment for ST-HUS is supportive; plasmapheresis is sometimes used.

Complement-mediated HUS (i.e., atypical HUS) is due to complement dysregulation. It can be caused by complement gene mutations or by antibodies to complement proteins (especially complement Factor H). Note that in complement-mediated HUS, low C3 levels are common (though not universal). Patients typically present with microangiopathic hemolytic anemia, low platelets, and renal failure. Kidney biopsy reveals a thrombotic microangiopathy (identical to TTP). ADAMTS13 levels are normal. Genetic testing is not yet widely available, so often the diagnosis is by exclusion of other causes of TMA. Treat with eculizumab.

TTP and HUS also are discussed in the Hematology section.

OTHER DRUG-INDUCED NEPHROPATHIES

NSAIDs have several potentially adverse effects on the kidneys. Renal effects of NSAIDs are seen equally with both nonselective NSAIDs (e.g., ibuprofen, ketorolac, naproxen) and COX-2 inhibitors (e.g., celecoxib).

NSAIDs inhibit prostaglandin (PG) production. This prevents PG-induced **dilation** of the **afferent** arterioles, which is needed to maintain GFR in patients with decreased renal perfusion. By this mechanism, NSAIDs can lead to or exacerbate **acute prerenal failure** in patients with low effective circulating volume (e.g., low cardiac output, hypovolemia). Note that ACEIs/ARBs have a similar effect (exacerbation of acute prerenal failure), in this case due to blockade of AT II-mediated constriction of the efferent arteriole.

NSAIDs can cause Na^+ retention, HTN, and hyperkalemia. Additionally, they can cause acute or chronic interstitial nephritis, with nephrotic-range proteinuria (common) and papillary necrosis (rare).

Chronic injection-drug (e.g., heroin) users are at risk for several types of kidney problems:

- Acute bacterial endocarditis can cause **IRGN** (with low complement).
- Endocarditis can cause septic **emboli** that can result in renal infarction and hematuria.
- Injection drug users are at risk for **HIV** infection and subsequent HIV-associated nephropathy (collapsing FSGS).

KIDNEY INJURY IN CANCER

Renal disease secondary to cancer can be grouped into several categories:

- **Direct infiltration** by lymphoma, leukemia, or myeloma
- **Extrinsic obstruction** at the level of the ureters or urethra, particularly from pelvic and abdominal tumors
- **Intrinsic obstruction** by intratubular precipitation of uric acid (seen in tumor lysis syndrome), methotrexate crystals, or immunoglobulin light chains (i.e., myeloma cast nephropathy)
- **Glomerular disease**—minimal change disease (from Hodgkin lymphoma), membranous GN (from solid tumors), amyloidosis (from multiple myeloma), glomerulonephritis (e.g., mixed immunoglobulin deposition disease, seen in monoclonal gammopathies)
- **Chemotherapy drug toxicity**—including mitomycin C-induced **hemolytic uremic syndrome**; cisplatin and ifosfamide-induced acute tubular injury;

bevacizumab-induced thrombotic microangiopathy; and checkpoint inhibitor-induced interstitial nephritis (e.g., due to pembrolizumab)

- **Hypercalcemia** of malignancy (can lead to AKI due to vasoconstriction and hypovolemia)

Patients with very high WBCs (e.g., acute monocytic leukemia, acute lymphoblastic leukemia) and lymphoma with high tumor burden being treated with antimetabolites are at high risk for tumor lysis syndrome (acute urate nephropathy). Give prophylaxis with aggressive IV fluid hydration (hypotonic or isotonic saline) and either **allopurinol** or **rasburicase**. Alkalinization of the urine is no longer recommended; HCO_3^- is given only in the setting of metabolic acidosis. Watch for hyperphosphatemia and hyperkalemia. For more on tumor lysis syndrome, see the **Oncology** section.

Rasburicase is an enzyme that catalyzes the oxidation of uric acid and is highly effective for both prevention and treatment of hyperuricemia. Know that rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Aside from nephrotoxicity due to chemotherapy, treat cancer-associated kidney disease by treating the underlying malignancy.

HEREDITARY AND CYSTIC KIDNEY DISEASES

PREVIEW | REVIEW

- What are the common presenting symptoms of polycystic kidney disease?
- When are renal cysts considered benign?

POLYCYSTIC KIDNEY DISEASE (PKD)

Autosomal dominant PKD is the most common genetic disease of the kidney. Affected patients get cysts in the kidneys, liver, and pancreas, and eventually develop ESRD (**Figure 7-10**). Autosomal recessive PKD is much less common, and usually presents with renal failure and hepatic fibrosis in infancy or early childhood.

Figure 7-10: Autosomal dominant polycystic kidney disease

Gross hematuria is the most common presenting symptom, while microscopic hematuria is a common laboratory finding. Patients also can present with flank pain, chronic kidney disease, HTN, and cyst infections. Progressive renal failure and HTN are the norm. Associated liver cysts cause hepatomegaly but rarely liver dysfunction.

Cerebral aneurysms occur in 1–5% of patients. Screening for aneurysms is recommended only if the patient with PKD has a family history of subarachnoid hemorrhage or a known cerebral aneurysm. Some experts also recommend that patients with PKD be screened if they have an occupation that places their own life or the lives of others at risk should the patient lose consciousness (e.g., airplane pilots, railroad engineers). Screen for cerebral aneurysms with an MRA.

The diagnosis of autosomal dominant PKD is generally established when polycystic kidneys are identified by imaging (U/S or CT). Renal U/S is used for screening in patients > 18 years of age with a family history of PKD. Genetic testing is available when the diagnosis is in question.

Treatment of PKD is generally supportive. Tight blood pressure control delays loss of renal function. Tolvaptan (a vasopressin antagonist) is used to slow renal function decline in adults with PKD; LFTs must be monitored with this drug as fulminant hepatitis can occur with long-term use.

MEDULLARY DISEASE

There are 2 main inherited medullary kidney diseases:

- 1) **Medullary sponge kidney** is a generally benign disease; however, it is associated with nephrolithiasis and urinary tract infections.
- 2) **Medullary cystic disease** can cause renal failure and presents in childhood. This is 1 of the few chronic kidney diseases in which U/A is usually normal.

ALPORT SYNDROME

Alport syndrome (a.k.a. hereditary nephritis) can be either X-linked (most cases), autosomal recessive (15%), or autosomal dominant (5%) with variable expression. For X-linked disease, men are affected much more severely than women. For autosomal recessive and autosomal dominant disease, severity is the same in men and women.

Alport syndrome results from a mutation in genes encoding Type 4 collagen, affecting the basement membrane (the same target area attacked by the Goodpasture's anti-GBM antibodies) in the glomerulus, cochlea, and lens. Hearing loss is common. The female X-linked carriers have microscopic hematuria only. The affected males usually have renal failure by the time they are adults.

Consider Alport syndrome in any patient with persistent microscopic hematuria (onset at birth) that worsens after an infection (i.e., include this in the differential

diagnosis of infection-related GN and IgA nephropathy). Additionally, especially consider Alport syndrome in a woman with microscopic hematuria when there is a family history of males with advanced kidney disease. Diagnose with a kidney biopsy in both men and women. The hallmark finding is splitting (lamination) of the GBM, visible on EM. Genetic testing detects mutations in the COL4A3, COL4A4, and COL4A5 genes. Thinning of the GBM occurs in both early Alport syndrome and the related (though benign) thin basement membrane disease, which typically presents with isolated microscopic hematuria.

Treat Alport syndrome with an ACEI or ARB. Transplant is the optimal treatment, but patients with Alport syndrome who get a kidney transplant can develop anti-GBM disease in the transplanted kidney because their immune system has not been exposed previously to normal Type 4 collagen.

RENAL CYSTS

Renal cysts are very common. 50% of people > 50 years of age have them. They are considered benign if they are simple on U/S and the patient is asymptomatic. Simple cysts have well-defined margins, dense (compressed) surrounding tissues, and no solid component. Complex cysts (thickened walls, septa, calcifications, or solid component) have malignant potential. Management of complex cysts may include periodic imaging, fine needle aspiration, or surgical excision (partial or radical nephrectomy).

CHRONIC KIDNEY DISEASE (CKD)

PREVIEW | REVIEW

- What is the definition of chronic kidney disease (CKD), and what are its stages?
- How is osteitis fibrosa cystica different from adynamic bone disease?
- List 4 signs or symptoms of uremia.
- How is anemia of CKD treated?
- What rare complication can occur after gadolinium in patients with end-stage renal disease?

OVERVIEW

CKD is defined as either of the following:

- Kidney damage for > 3 months, with or without decreased GFR. Kidney damage can include any of the following: albuminuria, active urine sediment, abnormal imaging (cystic kidneys, hydronephrosis), or abnormal pathology.
- Estimated glomerular filtration rate (eGFR) < 60 mL/minute/1.73 m² for > 3 months, with or without kidney damage

CKD is divided into stages:

- Stage 1—GFR > 90 mL/minute/1.73 m² with evidence of kidney damage (e.g., proteinuria, hematuria, cystic kidney disease)
- Stage 2—GFR 60–89 mL/minute/1.73 m²
- Stage 3—GFR 45–59 mL/minute/1.73 m²
- Stage 3b—GFR 30–44 mL/minute/1.73 m²
- Stage 4—GFR 15–29 mL/minute/1.73 m²
- Stage 5—GFR < 15 mL/minute/1.73 m² or on dialysis

These stages provide a framework for managing the expected complications of anemia, bone disease, HTN, salt and water retention, and uremia. The Kidney Disease Outcomes Quality Initiative (KDOQI) and Kidney Disease: Improving Global Outcomes (KDIGO) provide the best evidence-based guidelines for diagnosis and management of CKD and its complications.

While CKD can be multifactorial, the most common causes of ESRD (CKD Stage 5) are diabetes mellitus and HTN.

Patients with CKD have an increased risk of heart disease because of their comorbidities and because CKD itself is an independent risk factor. Heart disease is the number 1 cause of death.

All patients with CKD should be screened for hepatitis C infection. If positive, they should be evaluated for antiviral therapy per the 2018 KDIGO guidelines. It is particularly important to diagnose and treat hepatitis C infection prior to kidney transplantation.

SMOKING CESSATION

Smoking accelerates the progression of CKD and increases risk of cardiovascular events. Counsel patients regarding smoking cessation and offer resources to aid in their efforts.

BLOOD PRESSURE CONTROL

Hypertension is both a cause and a consequence of CKD. It is present in the majority of patients with CKD, and blood pressure control is 1 of the most important modifiable risk factors for CKD progression.

Rigorous blood pressure control slows the progression of CKD. The American College of Cardiology/American Heart Association (ACA/AHA) guidelines recommend a blood pressure treatment goal of < 130/80 mmHg in patients with CKD.

ACEIs and ARBs decrease proteinuria. In patients with proteinuria, ACEIs/ARBs slow progression of CKD above and beyond their antihypertensive effect. Keep in mind that although they provide long-term improvement in renal outcomes, ACEIs/ARBs can cause hyperkalemia and an acute decrease in eGFR. Monitor for this by checking labs after adding or increasing the dosage of these medications.

GLYCEMIC CONTROL

Diabetes mellitus remains the number 1 cause of ESRD. Chronic hyperglycemia leads to diabetic nephropathy, and good glycemic control can prevent or slow progression of diabetic nephropathy.

The 2020 American Diabetes Association (ADA) guidelines recommend:

- Optimize glycemic control (HbA1c < 7% in most nonpregnant adults).
- Screen for albuminuria annually.
- Treat HTN and albuminuria (urine albumin:creatinine ratio > 30 mg/g) with an ACEI or ARB.
- Consider use of an SGLT2 inhibitor in patients with an eGFR ≥ 30 mL/min/1.73 m² and urinary albumin > 30 mg/g Cr, particularly in those with urinary albumin > 300 mg/g Cr, to reduce risk of CKD progression, CV events, or both (more under [Diabetic Nephropathy](#) on page 7-25).

TREATMENT OF DYSLIPIDEMIA

Lowering lipids appears to slow progression of renal failure. Remember: Dyslipidemia also leads to an increase in cardiovascular mortality in patients with CKD.

The 2013 KDIGO Guidelines for Lipid Management in Chronic Kidney Disease suggest the following:

- Screen all adults with CKD with a lipid panel.
- Treat adults > 50 years of age with eGFR < 60 mL/minute/1.73 m² with a statin or statin/ezetimibe combination.
- Treat adults 18–49 years of age with CKD and another cardiovascular risk factor (i.e., known coronary artery disease, diabetes, prior stroke, or estimated 10-year cardiovascular disease risk > 10%) with a statin.
- Do not initiate statins in patients with ESRD who are on dialysis (large, randomized, controlled trials have failed to show a benefit of statins in this population).
- In patients with CKD and high triglycerides, treat with lifestyle modification.

The KDIGO guidelines, like the 2018 ACC/AHA Guidelines on the Management of Blood Cholesterol, do not specify a particular LDL treatment target.

Fibrates lower triglycerides, but because there is risk of rhabdomyolysis, they should not be used in patients with eGFR < 30 mL/minute/1.73 m².

DIETARY MODIFICATIONS

Moderately restricting dietary protein intake may slow loss of renal function in patients with CKD. The KDIGO and ADA guidelines recommend lowering protein intake for adults with CKD to 0.8 g/kg/day. A moderately low protein diet also may improve uremic symptoms in patients with advanced (Stage 5) CKD not yet on dialysis. A very low protein diet (< 0.6 g/kg/day) is not recommended; it can lead to malnutrition.

Na⁺ restriction improves blood pressure and volume overload (edema), and it may improve cardiovascular outcomes and slow CKD progression. Limiting dietary Na⁺ intake to < 2 g/day is recommended by the 2013 KDIGO CKD Guidelines.

PROGRESSION OF CKD

In patients with CKD, the ultimate result of progressive loss of kidney function (eGFR) is ESRD, which usually requires dialysis or kidney transplant. Strategies to prevent progression of CKD include:

- Smoking cessation
- Blood pressure control (goal < 130/80 mmHg)
- ACEIs or ARBs (in diabetics and patients with proteinuria)
- Glycemic control and use of SGLT-2 inhibitors (in diabetics)
- Treatment of hyperlipidemia
- Avoiding nephrotoxins (e.g., iodinated contrast, NSAIDs, aminoglycosides)
- Treatment of metabolic acidosis with oral sodium bicarbonate

CKD — MINERAL AND BONE DISORDERS (MBDs)

Pathogenesis

Advanced kidney disease causes abnormalities in Ca²⁺ and phosphate homeostasis, which result in a spectrum of adverse consequences. The term “chronic kidney disease-mineral and bone disorder” (CKD-MBD) was adapted to reflect these abnormalities.

Phosphate, Ca²⁺, calcitriol, and parathyroid hormone (PTH) are tightly interdependent. As you read the following, make sure you understand each concept as you encounter it.

Secondary hyperparathyroidism is 1 of the earliest findings in CKD-MBD. PTH release is stimulated by:

- Hyperphosphatemia
- Hypocalcemia
- Low calcitriol (i.e., 1,25-(OH)₂-D, the active form of vitamin D)

These 3 changes develop with decreasing GFR by the following mechanisms:

- High phosphate
 - Lower GFR = less phosphate excreted in the urine
- Low Ca²⁺
 - Low calcitriol
 - Excess phosphate complexes with free Ca²⁺
- Low calcitriol
 - Dietary (25-OH-D) vitamin D deficiency (usually in diet and sunlight; deficiency = common in CKD patients)

- Decreased conversion 25-OH-D (the storage form) to 1,25-(OH)₂-D (calcitriol, the active form) by the kidneys

Management of CKD-MBD

The following recommendations are based on the 2017 KDIGO CKD-MBD guidelines. The goals of therapy are to maintain Ca²⁺ and phosphate levels at or close to the normal range to avoid severe secondary hyperparathyroidism.

Screen all CKD patients for nutritional vitamin D (25-OH-D) deficiency, and supplement as needed (e.g., with ergocalciferol or cholecalciferol) to maintain normal levels.

Serum phosphate levels remain normal until ~ **Stage 3-4** CKD, after which hyperphosphatemia develops. As the phosphate levels rise, treat with low-phosphate diet and phosphate binders.

Phosphate binders are either **Ca²⁺ based** (e.g., calcium carbonate, calcium acetate) or **non-Ca²⁺ based** (e.g., sevelamer, lanthanum). Iron-based phosphate binders (sucroferric oxyhydroxide and ferric citrate) are also available. Use of Ca²⁺-containing phosphate binders should be avoided, especially in patients with hypercalcemia. They may contribute to vascular calcification. Aluminum-containing phosphate binders cause dementia and other toxicity; they should not be used.

Monitor intact PTH (iPTH) levels regularly. Correction of hyperphosphatemia with dietary phosphate restriction and phosphate binders, and correction of 25-OH-D deficiency (if present), usually leads to a fall in the iPTH. If there is severe and progressive secondary hyperparathyroidism, consider adding 1,25-(OH)₂-D (calcitriol) or an active vitamin D analog (e.g., doxercalciferol, paricalcitol). However, do **not** lower the PTH all the way to the normal range because adynamic bone disease can result. The optimal PTH level is not known, but in patients with ESRD on dialysis, the KDIGO guidelines recommend targeting iPTH to 2-9× the upper limit of normal.

Calcimimetics (e.g., cinacalcet) increase PTH receptor sensitivity to Ca²⁺ and reduce PTH levels, while decreasing serum Ca²⁺ levels. Use of calcimimetics should be limited to patients with ESRD on dialysis due to lack of data and the risk of hypocalcemia in patients with CKD who are not yet on dialysis.

Putting it all together, prevention and treatment of CKD-MBD includes controlling iPTH, Ca²⁺, and phosphate levels using the following strategies:

- Low phosphate diet and phosphate binders
- 25-(OH)-D (ergocalciferol, cholecalciferol) if deficient

If hyperparathyroidism is severe and progressive despite these measures, consider:

- 1,25-(OH)₂-D (calcitriol) or vitamin D analogs (e.g., paricalcitol, doxercalciferol)
- Calcimimetics (cinacalcet)—only in patients with ESRD

Renal Osteodystrophy

Renal osteodystrophy refers to the **skeletal** complications caused by CKD that can result in bone pain or fractures.

Patients with CKD can have 3 types of bone disorders:

- 1) **Osteitis fibrosa cystica** due to secondary **hyperparathyroidism** (**high** bone-turnover disorder)
- 2) **Adynamic bone** disease due to oversuppression of PTH release (**low** bone-turnover disorder); often a result of overtreatment of secondary hyperparathyroidism
- 3) **Osteomalacia** (**low** bone-turnover disorder associated with unmineralized bone)

Osteitis Fibrosa Cystica

Osteitis fibrosa cystica is **high-turnover bone disease** resulting from persistent secondary hyperparathyroidism.

Clinical findings of osteitis fibrosa cystica: It is usually asymptomatic but can develop bone pain and fractures. Alkaline phosphatase levels are high. Radiographs classically show subperiosteal bone resorption especially in the distal clavicle and the phalanges (Figure 7-11).

Treat osteitis fibrosa cystica by maintaining serum Ca^{2+} and phosphate levels in the normal range and treating severe, persistent secondary hyperparathyroidism, using the strategies summarized in [Management of CKD-MBD on page 7-31](#).

Figure 7-11: Osteitis fibrosa cystica

Adynamic Bone Disease

Adynamic bone disease is a **low bone-turnover state** with reduced bone formation. The cause is **oversuppression of PTH** by overzealous treatment of secondary hyperparathyroidism. For this reason, closely follow iPTH levels in CKD and ESRD patients, and do not lower PTH levels to the normal range.

Consider adynamic bone disease in a CKD patient with persistently low iPTH (< 100 pg/mL). Most affected patients are asymptomatic, but they can have fractures and **hypercalcemia** (especially if on vitamin D analogs and Ca^{2+} -based binders).

Bone biopsy is the gold standard for diagnosis of adynamic bone disease but is rarely indicated. Alkaline phosphatase levels are usually normal.

Treat by reducing or stopping active vitamin D, vitamin D analogs, and Ca^{2+} -based phosphate binders (i.e., substituting with non- Ca^{2+} -based binders). Adynamic bone disease can be exacerbated by the use of bisphosphonates, which inhibit resorption of bone by osteoclasts.

Osteomalacia

Osteomalacia is now uncommon in CKD. Historically, it was due to the use of aluminum-containing phosphate binders that caused aluminum toxicity. Osteomalacia can still occur from vitamin D deficiency.

UREMIA IN CKD

Uremia is a constellation of signs and symptoms associated with a $\text{GFR} < 15$ mL/minute/1.73 m^2 and can include:

- Anorexia, weight loss
- Nausea/Vomiting
- Pericardial and pleural effusions
- Pericarditis
- Platelet dysfunction, bleeding
- Pruritus
- Sensory neuropathies
- Cognitive dysfunction (e.g., confusion, difficulty concentrating, encephalopathy, coma)

The presence of uremic symptoms is an indication for dialysis.

ENDOCRINE PROBLEMS IN CKD

CKD can cause decreased glucose tolerance, decreased gonadal hormone production (with impotence or amenorrhea/infertility), and a low T_3 with a normal thyroid-stimulating hormone.

ANEMIA OF CKD

Advanced CKD causes a **normochromic, normocytic anemia** due to decreased kidney production of erythropoietin. When a CKD patient develops anemia, first exclude other causes of anemia, especially iron deficiency (common in patients with CKD). If iron, B_{12} , and folate stores are adequate and there are no other apparent causes, the anemia can be attributed to CKD.

Anemia of CKD responds dramatically to erythropoiesis-stimulating agents (ESAs).

A trial of PO or IV iron should be given before starting ESAs if there is evidence of iron deficiency (transferrin saturation $< 30\%$ and ferritin < 500 ng/mL).

ESAs can increase risk of cancer progression and stroke, so use of these agents is usually avoided in patients with active malignancy. Use only with caution in patients with a history of malignancy or stroke.

The 2012 KDIGO guidelines explain:

- In **dialysis** patients, initiate ESA when Hgb is 9–10 g/dL (100 g/L).
- For patients with CKD not yet on dialysis, do not start ESAs if Hgb is ≥ 10 g/dL.
- For patients with CKD not yet on dialysis and Hgb < 10 g/dL (100 g/L), the decision to start ESAs should be individualized based upon presence of symptoms,

the rate of fall in Hgb concentration, prior response to iron therapy, risk of needing a transfusion, and the risks related to ESA therapy.

- For both dialysis and nondialysis patients, do not use ESAs to achieve a Hgb > 13 g/dL.

The target Hgb in most patients with anemia of CKD treated with ESAs is 10–11 g/dL.

GOUT IN CKD

CKD is a major risk factor for gout. Glucocorticoids (e.g., prednisone) are the treatment of choice for acute gout in most patients with CKD. Colchicine and NSAIDs are usually avoided whenever possible in patients with significant renal dysfunction. For gout affecting a single joint, treat with an intraarticular steroid injection.

Use allopurinol or febuxostat to prevent recurrent gout flares in patients with CKD and hyperuricemia. These medications decrease the production of uric acid; chronic use often is necessary. Probenecid is **contraindicated** in patients with uric acid stones and is unlikely to be effective in patients with advanced CKD because it works by increasing renal excretion of uric acid.

DRUG METABOLISM IN CKD

Decreased renal function increases the half-lives of many drugs.

As renal function deteriorates, many drugs require dosing reductions, including:

- Vancomycin
- Gentamicin
- Digoxin
- Glyburide
- Procainamide
- Colchicine
- Low-molecular-weight heparin (LMWH)
- Gabapentin
- Insulin

Many antibiotics are cleared by dialysis; therefore, they should be dosed (or redosed) after each dialysis. The common ones include:

- Vancomycin
- Aminoglycosides
- Most β -lactams
- Daptomycin
- Metronidazole
- Ciprofloxacin
- Levofloxacin

IMAGING IN CKD

Avoid older forms of gadolinium contrast (e.g., gadodiamide) in patients with CKD Stages 4 and 5, especially those especially those with ESRD on dialysis.

Gadolinium, a contrast material used in MRIs, can cause **nephrogenic systemic fibrosis (NSF)** in patients with advanced CKD and ESRD.

NSF presents as a thickening of the skin with symmetrical plaques, papules, or nodules. Systemic involvement can include pulmonary fibrosis, myocardial fibrosis, and joint contractures.

Diagnosis of NSF is based upon histopathologic examination of a biopsy (deep incisional or punch biopsy) of an involved site. The course is progressive, sometimes **fulminant**. NSF has not been reported with newer forms of gadolinium (e.g., gadobutrol), so these are considered safe to use in patients with advanced CKD and ESRD (2020 American College of Radiology Manual on Contrast Media).

IV **iodinated** contrast such as that utilized for CT studies and angiograms (including cardiac catheterization) can cause **contrast-induced nephropathy** (more under **AKI – Evaluation and Treatment** on page 7-10).

RENAL REPLACEMENT THERAPY

PREVIEW | REVIEW

- What are the indications for dialysis initiation in CKD?
- What is the most common cause of death in dialysis patients?
- Which organisms are the most common pathogens in peritoneal dialysis peritonitis?
- Which immunosuppressive agents are used in renal transplant patients?

When CKD progresses to ESRD, typically at an eGFR of 8–10 mL/min/1.73 m², renal replacement therapy is usually needed. Forms of renal replacement therapy include:

- Hemodialysis—in-center and home
- Peritoneal dialysis
- Kidney transplantation—deceased donor and living donor

Conservative care of ESRD is an alternative to renal replacement therapy in which supportive care is provided without dialysis or transplant. Conservative care is an option that should be offered to all patients and is preferred in some patients with severe comorbidities or poor functional status (e.g., terminal cancer, advanced HF) in whom dialysis is unlikely to provide benefit. Dialysis in these high-morbidity patients, especially those of advanced age, is associated with loss of functional status, increase in hospitalizations, high burden on patients and families of the dialysis procedure, and a high mortality rate. Conservative care may include:

- Medical management of CKD, including diuretics, anemia management, blood pressure management, and interventions to slow decline in eGFR (more under **Chronic Kidney Disease (CKD)** on page 7-29)

- Psychosocial and spiritual support
- Management of uremic symptoms such as anorexia, fatigue, pruritus
- Pain management, if needed, often with a palliative approach
- Advanced care planning (more in the [General Internal Medicine](#) section)

DIALYSIS

Dialysis: When to start? Answer: When the patient has CKD Stage 5 (eGFR < 15 mL/min/1.73m²) and **symptoms of uremia** (more under [Uremia in CKD on page 7-32](#)). Starting at a specific BUN or creatinine value is of **no** proven benefit.

Other indications for the initiation of dialysis in a CKD (or AKI) patient:

- Refractory metabolic acidosis
- Refractory hyperkalemia
- Fluid overload that is resistant to diuretics

Note: Acute toxin ingestion (e.g., methanol, ethylene glycol, salicylates, lithium) also can be an indication for dialysis, sometimes even when renal function is intact.

Hemodialysis: An upper extremity arteriovenous (AV) fistula lasts the longest but needs to be created at least 3 months before dialysis initiation; otherwise, a tunneled dialysis catheter or AV graft is needed. Refer patients when they develop Stage 4 CKD (eGFR < 30 mL/minute/1.73 m²).

Know that the most common cause of **death** in dialysis patients is **cardiovascular** disease. Infection is next.

Dialysis patients frequently have anemia, high triglycerides, and a low HDL. They usually have a metabolic acidosis just before dialysis and a respiratory alkalosis just after dialysis.

Maintaining **adequate nutrition** in these patients is one of the key factors in reducing morbidity and mortality. Vitamin supplements are important, especially the water-soluble ones. These vitamins are not stored in fat; they must be replenished each day. The main water-soluble vitamins are B-complex, C, and folate.

Peritoneal dialysis: Patients do **not** need AV access, but instead require a tunneled peritoneal dialysis catheter and the ability to manage their dialysis at home. Pay close attention to nutritional status—a **high protein intake** is necessary. Fluid shifts are more gradual, so peritoneal dialysis causes less strain on the heart than hemodialysis.

Many patients receive their peritoneal dialysis exchanges at night using an automated cyclor.

Peritonitis is the main complication of peritoneal dialysis. Presenting symptoms include cloudy fluid, abdominal pain, and fever. It is usually caused by gram-positive skin flora (e.g., *Staphylococcus epidermidis*, *Staphylococcus aureus*), or gram-negative organisms.

Initiate empiric antibiotics while awaiting confirmatory testing with agents effective against both these classes of organisms. The diagnosis of peritonitis is confirmed by a peritoneal dialysis fluid WBC count > 100 WBCs/μL with > 50% PMNs, or a positive culture. Intraperitoneal antibiotics are preferred; use PO or IV only when the IP route is not available, such as where the catheter has been removed. Other complications include hernias, hydrothorax, high protein loss (12 g/day), and loss of water-soluble vitamins (especially folic acid).

KIDNEY TRANSPLANT

Kidney transplant can improve quality of life and life expectancy in ESRD patients, as compared to dialysis. Renal transplant reverses the platelet dysfunction, renal osteodystrophy, and sensory/cognitive dysfunction of CKD. Sometimes, transplant can even reverse late manifestations of small-vessel calcification and motor neuropathy of advanced CKD. The main downside to kidney transplantation is the need for life-long immunosuppression to prevent acute and chronic rejection.

Some kidney diseases tend to recur after transplant in the transplanted kidney: FSGS, MPGN, IgA nephropathy, and even diabetes. The main cause of death after kidney transplant is **cardiovascular disease**.

Before Transplant

There are 2 ways to get a kidney transplant: via a living donor (usually a family member, spouse, or friend) or a deceased donor (usually requiring years on a waiting list). Generally, donor and recipient must have compatible ABO blood types. Some centers are now doing ABO-incompatible kidney transplants.

Major contraindications to kidney transplantation are active and recurrent infections, recent or active malignancy, severe cardiovascular disease (untreated coronary artery disease, cerebrovascular disease, or clinical HF), and history of noncompliance.

Controlled HTN and diabetes are not contraindications, nor is age alone.

In appropriate candidates, a preemptive transplant can be performed before dialysis is initiated.

After Transplant

Kidney Rejection

Anytime renal function deteriorates in a patient with a kidney transplant, think of the AKI in the usual terms. Is it prerenal, intrinsic renal, or postrenal? Intrinsic causes include acute rejection, drug toxicity (calcineurin inhibitor toxicity, AIN), infection (cytomegalovirus or BK virus), and recurrence of the primary disease (primary FSGS can recur almost immediately).

Acute rejection should always be considered, as this is a common cause of AKI in transplant recipients. It is most

likely to occur **in the first 6 months** after transplant and can be either cellular, vascular, or antibody mediated. Renal biopsy is needed to establish the diagnosis.

Hyperacute rejection of the transplanted kidney is now exceedingly rare, due to the widespread use of cross-match testing prior to transplant. This rejection is caused by preformed donor antibodies that acutely damage the kidney, and it occurs within minutes to hours of transplant. Cellular rejection is mediated by T-cells and is treated with high dose intravenous steroids. Antibody-mediated rejection is caused by antibodies to the allograft ("donor-specific antibodies"); treatment can include IV steroids, plasmapheresis, intravenous immunoglobulin, and/or rituximab.

Start workup by checking the transplant using U/S with doppler (to rule out obstruction or venous/arterial thrombosis), FE_{Na} (to assess for prerenal failure), and levels of **immunosuppressant** drugs (e.g., **cyclosporine**, **tacrolimus**, **sirolimus**). Screen for CMV and BK virus. If these are normal and the patient's renal function is not improving with empiric IV fluids, renal biopsy is indicated.

Immunosuppressive Therapy

Immunosuppression in transplant recipients consists of induction therapy followed by maintenance therapy. Induction therapy is intensive immunosuppression early after kidney transplant, when the risk of acute rejection is greatest. Maintenance therapy is long-term, less intensive immunosuppression to prevent acute and chronic rejection.

Induction typically consists of antibodies to lymphocytes (e.g., antithymocyte globulin) or the IL-2 receptor (e.g. basiliximab) and high-dose, IV steroids. Maintenance therapy (started immediately after transplant) usually includes:

- 1) a calcineurin inhibitor (e.g., cyclosporine, tacrolimus),
- 2) mycophenolate mofetil or mycophenolic acid, and
- 3) corticosteroids.

Sometimes, sirolimus is also used.

Cyclosporine and **tacrolimus** are calcineurin inhibitors with a similar mechanism of action. They decrease T-cell proliferation (but **not** function!) **without** affecting the bone marrow. **Sirolimus** (a.k.a. rapamycin) is an mTOR (mechanistic target of rapamycin) kinase inhibitor and has T-cell antiproliferative properties.

All 3 drugs are metabolized by the cytochrome P450 system, so **blood levels** of all 3 are **increased** by erythromycin, ketoconazole, voriconazole, and diltiazem and **decreased** by phenytoin, caspofungin, carbamazepine, rifampin, and phenobarbital.

All 3 drugs cause dose-related nephrotoxicity and carry FDA black box warnings for increased risk of death from infections. Side effects of cyclosporine include tremors,

hepatotoxicity, CNS toxicity, and gum hypertrophy. Tacrolimus is the most diabetogenic. Sirolimus is associated with wound dehiscence/impaired healing and development of lymphoma and hyperlipidemia.

Mycophenolic acid and **mycophenolate mofetil** are "antimetabolites." They have largely **replaced** a similar, older agent, **azathioprine**. Main side effects are nausea, vomiting, diarrhea, and bone marrow suppression, and there may be increased risk for lymphoproliferative disorders. **Know that allopurinol increases serum levels of azathioprine but not mycophenolate mofetil or mycophenolic acid.**

Prednisone is the 3rd component of maintenance immunosuppression. Doses are high immediately after transplant but are tapered rapidly and maintained at a low dose long-term in most patients. Toxicities of long-term steroid use include impaired wound healing, osteoporosis, and hyperlipidemia. Glucocorticoids also can make worse glycemic control in patients with diabetes. To avoid these side effects, strategies to withdraw or completely avoid glucocorticoids after kidney transplant have been explored. Outcomes have been mixed, with a small but significant increase in acute rejection and chronic allograft nephropathy in patients treated with early steroid withdrawal. Most transplant centers continue to use long-term low-dose prednisone as part of their standard immunosuppressive regimen.

Immunosuppression increases susceptibility to urinary tract infections, pneumonia, and sepsis. These are common events after renal transplant. Patients are given primary prophylaxis against *Pneumocystis* and CMV in the early posttransplant period.

KIDNEY STONES

PREVIEW | REVIEW

- Name the factors that promote Ca^{2+} stone formation.
- What systemic diseases are associated with Ca^{2+} stones?
- Which bacteria cause staghorn calculi?
- Which antiretroviral drug causes renal stones?
- Name 1 of the most important general recommendations for patients with kidney stones, regardless of the type of stones.

OVERVIEW

Kidney stones are common: 10–15% of people have at least 1 symptomatic kidney stone during their lifetime.

2/3 of renal stones are calcium phosphate or calcium oxalate; the other 1/3 are struvite or uric acid. Multiple crystal types can coexist in the same stone in a single patient.

Kidney stones are usually asymptomatic until they pass from the renal pelvis into the ureter. Classic symptoms of kidney stone passage are renal “colic” (severe, acute flank pain) with or without gross hematuria. Workup of acute renal colic includes:

- **Renal imaging:** CT of abdomen and pelvis without contrast is the test of choice. Renal ultrasound is an alternative which can exclude obstruction and is 1st choice in pregnant women (for more information on renal stones during pregnancy, see the [Women's and Men's Health](#) section). Abdominal plain film is less sensitive, missing uric acid stones (which are radiolucent) and smaller calcium stones. Imaging confirms the diagnosis, excludes obstruction, and stone size helps predict the likelihood of spontaneous passage. Stones > 1 cm are unlikely to pass spontaneously and usually require urologic intervention.
- **Labs:** Check electrolytes, BUN, and creatinine to exclude acute kidney injury from obstruction.
- **Pain control:** NSAIDs are 1st line; use opioids if needed.

Most stones pass spontaneously, and most patients with acute renal colic from stones can be managed as outpatients. Hospitalization and urgent urologic intervention are indicated if there is evidence of infection (fever, leukocytosis), obstruction (hydronephrosis on imaging), or acute kidney injury. Patients should strain their urine, as laboratory analysis of the stone can guide future preventive strategies. Hydration with oral fluids and α -blockers (e.g., tamsulosin) can facilitate stone passage.

If the stone is > 1 cm or the stone does not pass on its own after a trial of conservative management, refer to a urologist for intervention. Options for mechanical stone removal include:

- Ureteroscopy (middle and distal ureteral stones)
- Percutaneous nephrostolithotomy (best for large or staghorn stones)
- Extracorporeal shock wave lithotripsy (best for smaller stones)

In the remainder of this topic, we discuss evaluation and management of patients with kidney stones after the episode of acute renal colic has resolved (stone passage).

DIAGNOSIS

Workup following the 1st kidney stone includes:

- Imaging, if not previously done
- Measure serum Ca^{2+} and, if hypercalcemia is present, iPTH (exclude hyperparathyroidism).
- Measure serum electrolytes and urine pH (exclude Type 1 [distal] RTA).
- U/A and urine culture (Exclude stone-forming urinary pathogens such as *Proteus*; clue = urine pH > 7.5.)
- Chemical analysis of the stone (when available)

If the above results are normal, no specific treatment is needed aside from encouraging fluid intake (high fluid intake reduces recurrence risk for all stone types).

Although some patients only have a single episode, 50% of patients develop recurrent kidney stones. For **recurrent stones**, perform 24-hour urine collection, measuring urine volume, Ca^{2+} , Na^+ , urea, uric acid, citrate, oxalate, cystine, and creatinine.

The 24-hour urine stone profile has 2 purposes. First, it helps to determine the likely stone type in patients without a stone available for analysis (these are most patients). Second, it identifies individual risk factors for stone formation, which helps to guide targeted prevention of recurrent stones.

Several factors **inhibit** or **promote** stone formation. Urinary citrate, Mg^{2+} , and pyrophosphate inhibit Ca^{2+} stone formation.

Promoters of stone formation:

- Crystals (e.g., uric acid, calcium oxalate), which act as a nidus for stone formation
- Hypercalciuria
- Hypocitraturia
- Metabolic acidosis (causes hypocitraturia and also leaches Ca^{2+} from the bones, resulting in hypercalciuria)
- Hyperoxaluria
- Concentrated urine (low urine volume)
- Hyperuricosuria (high urinary uric acid)

Ca^{2+} stones are composed of calcium oxalate (most common), calcium phosphate, or a combination of the 2.

Almost all patients with **calcium phosphate** kidney stones have hypercalciuria. Hypercalciuria may be idiopathic (50%) or caused by excess vitamin D, Type 1 (distal) RTA, sarcoidosis, primary hyperparathyroidism, or medullary sponge kidney.

High urinary **oxalate** is the most important factor in **calcium oxalate** stone formation. (See A in [Figure 7-2 on page 7-2](#) for calcium oxalate crystals in the urine.) **Vitamin C** is an oxalate precursor and can cause stones if taken in large amounts.

Steatorrhea (e.g., patients with gastric bypass, short bowel syndrome, Crohn disease) also can lead to calcium oxalate stones, in a condition called enteric hyperoxaluria. Unabsorbed free fatty acids in the bowel chelate Ca^{2+} . This prevents Ca^{2+} from binding to oxalate, allowing the oxalate to be absorbed and then excreted in the urine.

High urinary uric acid is a predisposing factor for oxalate stones because **uric acid crystals** can act as a nidus for calcium oxalate stone formation.

TREATMENT

Prevent recurrent Ca^{2+} stones by **pushing fluids** (urine output should be > 2 L/day) and **decreasing dietary protein and Na^+ intake**. If dietary modification and increased fluid intake fail to prevent recurrent stones, options depend on the results of the 24-hour stone profile. Give **potassium citrate** to patients with low urinary citrate or low urinary pH. Treat patients with hypercalciuria with a **thiazide diuretic** (which reduces urinary Ca^{2+} excretion). Treat patients with hyperuricemia

and high urinary uric acid excretion with **allopurinol** or another uric acid-lowering drug. Remember: Uric acid can act as a nidus for Ca^{2+} stone formation!

Note: Do **not** instruct patients to reduce dietary Ca^{2+} intake; this only **increases** oxaluria! In fact, increasing dietary Ca^{2+} (e.g., dairy products) can reduce stone formation by decreasing oxalate absorption in the gut, hence decreasing urinary oxalate. However, Ca^{2+} supplements should be avoided.

Uric acid stones are radiolucent and are not seen on plain film x-ray. (See C in [Figure 7-2 on page 7-2](#) for uric acid crystals in the urine.) Uric acid stones are usually seen in patients with acidic urine ($\text{pH} < 5.5$) and/or high serum uric acid (sometimes with gout). Myeloproliferative syndromes, chemotherapy, and Lesch-Nyhan syndrome can cause a hyperuricosuria in which there is stone formation even at normal urine pH. Treat with urinary alkalinization (e.g., potassium citrate) +/- allopurinol.

Struvite stones are also called “triple-phosphate,” as they are composed of calcium, ammonium, and magnesium phosphates. Struvite stones grow quickly from struvite crystals (D in [Figure 7-2 on page 7-2](#)) and often become **staghorn calculi** ([Figure 7-12](#)). Think chronic UTI when you see staghorn calculi. The **ammonium** needed to make these stones forms only when **urease** breaks down the urea. The most common urease producers are *Proteus* and *Klebsiella*. Treatment consists of removal of the stone(s), acidification of the urine (this and calcium phosphate are the only stones that are **more likely** with alkaline urine), and antibiotics. If the stones cannot be surgically removed, patients require antibiotics indefinitely.

Figure 7-12: Staghorn calculi

Cystine stones are rare and only seen in patients with cystinuria. This is an autosomal recessive disorder usually diagnosed in childhood. Look for clear, **hexagonal** crystals in the urine (E in [Figure 7-2 on page 7-2](#)). Treat by **increasing fluid intake** and **alkalinizing** the urine (like uric acid, cystine solubility increases at high urine pH).

Some **medications** can cause kidney stones and crystal-induced nephropathy. HIV/AIDS patients on indinavir as part of an antiretroviral regimen can get **indinavir** stones. Sulfa drugs and ciprofloxacin can cause stones via crystallization in the urine. Loop diuretics and carbonic anhydrase inhibitors (e.g., acetazolamide) can increase the risk of Ca^{2+} stone formation.

Keypoints to remember about kidney stone management:

- All kidney stone patients should increase oral fluid intake to produce at least **2 L/day** of urine, regardless of stone type.
- Urinary **alkalinization** is appropriate for all stone-formers **except** in struvite and calcium phosphate stones. Potassium citrate, given orally, both alkalinizes the urine and increases urinary citrate (which decreases calcium oxalate stone formation).
- Remember the difference between cystine and citrate: **Cystine** is an amino acid that precipitates into stones; **citrate** chelates Ca^{2+} in the urine, thereby preventing stones.

INTERSTITIAL CYSTITIS

Interstitial cystitis is a chronic pain syndrome that presents with bladder pain but no identifiable infection or other pathology. Diagnosis of interstitial cystitis is based on symptoms of bladder pain, usually relieved by voiding, and exclusion of UTI and bladder dysfunction. U/A, urine culture, and postvoid residual are usually normal. As with other chronic pain syndromes, treatment is challenging. Behavior modification including education, symptom management, fluid management, identification and avoidance of dietary triggers, and bladder training may help. Use of analgesics should be limited to short-term rescue therapy.

ACID-BASE DISORDERS

PREVIEW | REVIEW

- What are the common causes of a normal anion gap metabolic acidosis (NAGMA)? High anion gap metabolic acidosis (HAGMA)?
- How is the osmol gap (OG) calculated?
- Which poisonings cause an increased OG and a normal anion gap (AG)?
- Which poisonings cause both an increased AG and an increased OG?
- Why is isopropyl alcohol different from the other toxic alcohols?
- What is the 4-step method for solving acid-base disorders?
- List the 4 primary acid-base disorders and explain the expected compensatory response of each one.
- What are the causes of HAGMA?
- What urine abnormality is seen in patients who have ingested ethylene glycol?
- What are the classic symptoms in a patient who has ingested methanol?

- What is the treatment for methanol and ethylene glycol ingestions?
- What is the most common cause of NAGMA?
- Which cause of NAGMA also causes hyperkalemia?
- What are 2 causes of NAGMA and hypokalemia?
- Which renal tubular acidosis (RTA) can cause renal stones?
- Multiple myeloma is associated with which RTA?
- What is the serum K^+ level in Type 4 RTA?
- Diabetic nephropathy causes which RTA?
- Answer all of the RTA questions associated with Table 7-10 on page 7-47.

RESPIRATORY vs. METABOLIC DISORDERS

First, let's go over some definitions of terms we use over and over again when discussing acid-base disorders:

- Acidemia is an arterial pH < 7.35; alkalemia is a pH > 7.45.
- Acidosis is a disorder that decreases the pH of extracellular fluid (ECF); alkalosis is a disorder that increases ECF pH. Either of these disorders can be respiratory or metabolic in origin:
 - Respiratory acid-base disorders either retain CO_2 (increasing pCO_2 and decreasing pH) or blow it off (decreasing pCO_2 and increasing pH).
 - Metabolic acid-base disorders are due to an increase of acids or bases in the body, causing a decrease or increase in HCO_3^- and a respective decrease or increase of pH.
- Primary disorder: In a **simple** acid-base disorder, there is an initial shift in acid-base balance that is caused by the "primary" disorder.
- Compensatory response: The change in pH caused by the primary disorder is decreased by a compensatory response of the other system. Metabolic compensatory responses are slow (12–24 hours). Pulmonary responses are immediate:
 - Metabolic acidosis immediately induces a respiratory alkalosis; metabolic alkalosis immediately induces a compensatory respiratory acidosis.
 - Respiratory acidosis slowly induces a metabolic alkalosis; respiratory alkalosis slowly induces a compensatory metabolic acidosis.
- Simple acid-base disorders are, as the ones discussed above, a primary disorder with an opposing compensatory response. Mixed disorders are more than one primary disorder occurring concurrently. The classic example is salicylate poisoning, where there is a metabolic acidosis with a respiratory alkalosis.

In this topic, we use pCO_2 for P_aCO_2 . We also drop the brackets to indicate concentration of a substance. For instance, we use HCO_3^- instead of $[HCO_3^-]$. We use **AG** for serum anion gap, **UAG** for urine anion gap, and **OG** for osmol gap.

MECHANISMS

Understanding acid-base disorders depends on understanding the relationship between bicarbonate (HCO_3^-), carbonic acid (H_2CO_3), and carbon dioxide (CO_2). These substances are in equilibrium with each other and form the **bicarbonate buffer system**:

Eq. 5 is used to derive the Henderson-Hasselbalch (H-H) equation:

$$pH = 6.10 + \log (HCO_3^- / (0.03 \times pCO_2)) \quad (\text{Eq. 6})$$

The H-H equation illustrates the 2 ways the body controls the serum pH:

- 1) Regulation of the respiratory rate and tidal volume, which controls the pCO_2 **or**
- 2) Regulation of the kidney's reabsorption of HCO_3^- or excretion of acids/acid equivalents (phosphoric, sulfuric, and ammonium)

Note that it is the ratio of HCO_3^- to pCO_2 —not the absolute levels—that determines pH.

Also note that you can plug pH and pCO_2 values into the H-H equation and calculate the HCO_3^- . This is how the lab calculates the HCO_3^- for an arterial blood gas (ABG) report.

Soon, we will go over a very cool method of assessing acid-base status, but first let's discuss anion gaps and osmol gap.

ANION GAPS

Serum Anion Gap (AG)

Note: We call serum anion gap, simply, anion gap (AG). We always call urine anion gap (UAG) by its name.

Always calculate the AG when there is any possibility of a metabolic acidosis. To see why, let's first see how AG is calculated:

$$AG = Na^+ - (HCO_3^- + Cl^-) \quad (\text{Eq. 7a})$$

Alternatively, you can use:

$$AG = Na^+ - HCO_3^- - Cl^- \quad (\text{Eq. 7b})$$

These are the **same** formula. Regardless of which way you use it, be very certain about your order of operations so you get the correct value. Note that K^+ is usually left out. This is because it does not change enough to significantly affect the gap.

You are probably wondering why the H^+ cations are not included in this equation. Most of the H^+ cations are buffered out. It only takes a very tiny fraction to change the pH and this tiny bit would not add significantly to the Na^+ level. But the anions do stay around and affect the Cl^- and HCO_3^- levels. Which is what AG is all about.

Normal AG is 3–11 mEq/L (3–11 mmol/L), with an average of 6 mEq/L. We use these values in this section.

Note that a few clinical labs do use K^+ in their AG formula. This boosts their reference range up by ~ 4 mEq/L. In your calculations, always take into account the reference range used by your lab.

The AG is an estimate of the number of anions other than HCO_3^- and Cl^- . These are called the **unmeasured anions** and calculating the AG helps us determine the cause of a metabolic acidosis:

- If the AG is normal, the acidosis is being caused by a process that either decreases HCO_3^- (usually severe **diarrhea**) or increases H^+ (**CKD**, **RTA**; large infusions of **normal saline** given during surgery or when treating diabetic ketoacidosis [DKA] with subsequent removal of Na^+ by the kidney). There is a 1:1 increase in Cl^- with the decrease in HCO_3^- . This is termed a normal AG metabolic acidosis (NAGMA).
- If the AG is elevated but the Cl^- is normal, the required increase in anions (again, the ECF is always neutral) is due to the unmeasured anions. This is called a high AG metabolic acidosis (**HAGMA**) and is caused by **ketoacids** (DKA or alcoholic ketoacidosis), **lactic acid** (from impaired tissue oxygenation), and salicylic acid or metabolites of **ethylene glycol** or **methanol** (poisoning). There is normally a 1:1 increase in AG with the decrease in HCO_3^- except with lactic acidosis where it is 1.5:1.

Under normal conditions, negatively charged albumin is the main contributor to the AG. Therefore, **hypoalbuminemia** results in a lower AG. To correct this falsely low AG, add 2.5 mEq/L to the AG for each 1 g/dL decrease in albumin. The converse is also true; correct the AG downward for patients with an elevated serum albumin.

You can tell a lot from a glance at the electrolyte results after examining a patient. Is Na^+ normal? Great! Then look at HCO_3^- . If it is low, think metabolic acidosis and check the Cl^- . If Cl^- is elevated, bang! it is a probably a NAGMA. If Cl^- is normal, zing! it is probably a HAGMA. Remember the causes! And with a metabolic acidosis, expect somewhat faster or deeper breathing, indicating respiratory compensation. Don't be fooled. With a high-normal Na^+

and low-normal HCO_3^- , you can have a high anion gap! If all this doesn't make perfect sense, review this topic. Read even more on AG in **Metabolic Acidosis** on page 7-43.

Urine AG (UAG)

The **UAG** is used to evaluate the cause of a NAGMA. The UAG can help differentiate between gastrointestinal (GI) loss of HCO_3^- (diarrhea) and renal tubular acidosis (RTA; see RTAs on page 7-45). In the setting of NAGMA due to extrarenal (e.g., GI) HCO_3^- losses, renal H^+ excretion is increased, and this H^+ is excreted in the form of ammonium (NH_4^+). In RTA, there is a renal defect in H^+ excretion, so urine NH_4^+ is low. We do not measure urine NH_4^+ directly; we estimate it indirectly using the UAG.

UAG is calculated from the measured ions in the urine: Na^+ , K^+ , and Cl^- , expressed in mEq/L:

$$UAG = Na^+ + K^+ - Cl^- \quad (\text{Eq. 8})$$

UAG is an estimate of the unmeasured anions in the urine. NH_4^+ is a cation (not an anion), so when the urine NH_4^+ is high (as in metabolic acidosis due to GI losses of bicarbonate), the UAG will be **negative**. A **positive** UAG means there is not much NH_4^+ in the urine. In the setting of a NAGMA, a positive UAG usually indicates an RTA.

Note: K^+ is used in calculating UAG but not serum AG.

In summary:

- A normal/positive UAG value suggests low urinary NH_4^+ (e.g., **RTA Type 4**).
- A negative UAG value suggests high renal excretion of H^+ in the form of NH_4^+ (seen in NAGMA due to HCO_3^- loss from **diarrhea**). Remember **neGUTive** UAG in cases of diarrhea (i.e., **GUT**).

OSMOL GAP (OG)

The osmolality of the blood is normally determined mainly by concentrations of sodium ($[Na^+]$), glucose, and urea.

The OG is elevated when there are unmeasured osmotically active substances (particles or osmoles) in the blood (and possibly causing an acidosis). The OG is the difference between the measured serum osmolality (from the lab) and a calculated estimation of what the osmolality ought to be—if the only effective osmoles present are the normal ones (Na^+ , glucose, and urea). Use the following formula to calculate the serum osmolality:

$$Osm_{calc} = 2[Na^+] + (BUN/2.8) + (glucose/18) \quad (\text{Eq. 9})$$

Subtract this value from the lab-measured serum osmolality to get the OG:

$$\text{OG} = \text{Osm}_{\text{meas}} - \text{Osm}_{\text{calc}} \quad (\text{Eq. 10})$$

$$\text{OG} = \text{Osm}_{\text{meas}} - (2[\text{Na}^+] + \text{BUN}/2.8 + \text{glucose}/18) \quad (\text{Eq. 11})$$

A normal OG is < 10 mOsm/kg.

The main use of the OG is in the workup of an obtunded patient with possible toxic alcohol ingestion. An **extremely high OG** (> 25 mOsm/kg) is almost always due to toxic alcohol poisoning from:

- methanol,
- ethylene glycol,
- propylene glycol, or
- isopropyl alcohol.

Chronic kidney disease, lactic acidosis, and ketoacidosis cause a high OG from retention of small solutes.

Nontoxic causes of a high OG and a **normal AG** are mannitol, sorbitol, and glycerol ingestion.

Toxic causes of a high OG and **normal AG** are isopropyl alcohol, ethanol, and acetone ingestion. These are not metabolized to acids; hence, metabolic acidosis is not usually seen.

Toxic causes of both a high OG and a **high AG**:

- Ethylene glycol, a common ingredient in radiator **anti-freeze** solutions. Toxic acid metabolite = glycolic acid.
- Methanol, a common ingredient in **paint thinners** and **deicing** solutions (e.g., windshield washer fluids). Rarely, methanol is an inadvertent contaminant of **moonshine**. Toxic acid metabolite = formic acid.
- Propylene glycol (rarely; low toxicity). Toxic acid metabolite = lactic acid.

These 3 toxic alcohols directly increase the plasma osmolality, causing a high OG. Toxic alcohols are metabolized by **alcohol dehydrogenase** to their toxic acid metabolites; the OG falls and the HAGMA develops. So, early after ingestion, the elevated OG dominates and later the OG resolves as the HAGMA worsens.

In low doses, **propylene glycol** is generally considered safe and is even an approved food additive. But propylene glycol is metabolized to lactic acid, and excessive absorption can cause lactic acidosis. It is a solvent used in IV lorazepam, and a few cases of severe lactic acidosis have resulted from lorazepam given as a continuous infusion.

Isopropyl alcohol is metabolized to acetone, which, unlike the others, is not an acid and is less toxic than the original alcohol. Hence, isopropyl alcohol intoxication does not cause metabolic acidosis. Still, about 8 oz of isopropyl alcohol can be fatal.

Patients with toxic alcohol poisoning can develop stupor, coma, and hypotension (for more treatment details, see

HAGMA on page 7-43). Treat with dialysis +/- fomepizole, folate, and supportive care, including ventilatory support, IV fluids, and vasopressors.

Table 7-7 lists disorders that cause a high or normal AG and OG.

Table 7-7: Anion Gap (AG) and Osmol Gap (OG) in the Obtunded Patient

AG	OG	Consider...
High	High-very high	Methanol and ethylene glycol Ketoacidosis and lactic acidosis Chronic kidney disease Propylene glycol
	Normal	Salicylate poisoning Methanol or ethylene glycol ingestion after substrates have been converted to acid metabolites
Normal	High	Isopropyl alcohol, acetone, or ethanol ingestion
	Normal	Carbon monoxide poisoning—before lactic acidosis develops

ANALYSIS OF ACID-BASE PROBLEMS

Introduction

The goal of acid-base analysis is to identify simple and mixed acid-base disorder(s) based on labs alone (i.e., ABGs and electrolytes). Here we give you a good method to quickly crank out accurate acid-base diagnoses—even mixed ones.

The MedStudy 4-Step Method of Acid-Base Analysis

Overview of the Method

The process is simple and quick. This method can easily handle multiple, concurrent acid-base disorders. Always remember to take into account the patient's clinical presentation while interpreting the ABG results.

The information required to determine exactly what the acid-base status is:

- From ABGs: pH and pCO₂
- From electrolyte panel: Na⁺, HCO₃⁻, and Cl⁻

The 4 Steps

Prepare: Get the ABG and electrolytes results. Write down: pH, pCO₂, and HCO₃⁻.

Step 1: Check pH. Does the patient have acidemia (pH < 7.35) or alkalemia (pH > 7.45)?

Step 2: Check pCO₂ and HCO₃⁻ to see what disorder is causing the acidemia/alkalemia. The body never fully compensates for the primary disorder. So with an acidemia, the primary disorder must be a metabolic or respiratory acidosis; with an alkalemia, the primary disorder must be a metabolic or respiratory alkalosis.

If patient has acidemia (**low pH**), the primary disorder can **only** be an acidosis caused by:

- metabolic acidosis if HCO_3^- is **low** or
- respiratory acidosis if pCO_2 is **high**.

If patient has alkalemia (**high pH**), the primary disorder can **only** be an alkalosis caused by:

- metabolic alkalosis if HCO_3^- is **high** or
- respiratory alkalosis if pCO_2 is **low**.

Use this very common-sense way to figure out the initial disorder. With a little practice, you'll see some interesting correlations. One very cool and commonly taught one is, if the direction of the HCO_3^- follows the pH (i.e., high pH, high HCO_3^- ; low pH, low HCO_3^-), the primary disorder is metabolic. If pCO_2 follows the pH, the primary disorder is respiratory. But remember the logic as presented above, so if you get confused with the high/high, low/low and what follows what, you can still easily figure out the primary disorder.

Step 3: Now you know which of the 4 disorders is primary. What we do now is calculate the body's automatic compensatory response to this primary disorder using accepted formulas as listed in Table 16.1 of Brenner and Rector's *The Kidney 11th Ed. 2020*. A metabolic primary disorder automatically initiates a respiratory response to move the pH back toward normal, and vice-versa for a pulmonary primary disorder. We illustrate these 2 physiologic reactions in Figure 7-13 and Figure 7-14.

Resp ($1^\circ = \text{pCO}_2$): pH **pCO_2** HCO_3^- 

Figure 7-13: Acid-base equation (respiratory primary disorder)

Metab ($1^\circ = \text{HCO}_3^-$): pH pCO_2 **HCO_3^-** ...AG 

Figure 7-14: Acid-base equation (metabolic primary disorder)

In Figure 7-13, the pCO_2 is in bold, showing that we have a respiratory primary disorder and the change in pCO_2 is driving the compensatory response (indicated by the red arrow). Beside the red arrow is the magic [1,2,4,5] square you use to calculate how much HCO_3^- will be changing based on the initial change in the pCO_2 . Remember that one mEq/L change in HCO_3^- occurs per 10 mmHg change in pCO_2 . Because it takes kidneys awhile to respond, the square is divided into acute and chronic values (acute = 1,2; chronic_{1-3days} = 4,5). Also, the kidney response is not quite as high for respiratory acidosis vs. alkalosis (1 vs. 2 acute; 4 vs. 5 chronic).

In Figure 7-14, the HCO_3^- is in bold, showing that we have a metabolic primary disorder and the change in HCO_3^- is driving the compensatory response (indicated by the red arrow). Beside the red arrow is the magic (+15) circle that reminds you of the simplified Winter's formula (expected $\text{pCO}_2 = \text{HCO}_3^- + 15$) that can be used to determine the respiratory response for both metabolic acidosis and alkalosis! When the HCO_3^- is < 10, you must use the complete Winter's formula (expected $\text{pCO}_2 = 1.5 \times \text{HCO}_3^- + 8$; think bicarb + half bicarb + 8).

You'll probably need to dredge up this info immediately after you've figured out the primary disorder. Let's restate it in that context. Here are the 4 primary disorders, along with how to calculate their expected compensatory responses:

- **Metabolic acidosis:** The body's response is to **immediately** hyperventilate (blow off CO_2), causing a compensatory respiratory alkalosis. The expected $\text{pCO}_2 = \text{HCO}_3^- + 15$. Remember (+15) from the magic circle. Again, if HCO_3^- is < 10, use the full Winter's formula (expected $\text{pCO}_2 = \text{bicarb} + \text{half bicarb} + 8$).
- **Metabolic alkalosis:** The body's response is to **immediately** hypoventilate (retain CO_2), causing a compensatory respiratory acidosis. The expected $\text{pCO}_2 = \text{HCO}_3^- + 15$. Remember (+15) from the magic circle. Note: Several other formulas can be used. This is the easiest one and it is used for metabolic acidosis, too. So, really easy to remember!
- **Respiratory acidosis:** The body's response is to retain HCO_3^- in the kidney, **slowly** causing a compensatory metabolic alkalosis. Remember [1 and 4] from the magic square. The expected $\text{HCO}_3^- = \text{change in } \text{pCO}_2 / 10 \times 1$ (if acute) or $\times 4$ (if chronic).
- **Respiratory alkalosis:** The body's response is to excrete HCO_3^- in the kidney, **slowly** causing a compensatory metabolic acidosis. Remember [2 and 5] from the magic square. The expected $\text{HCO}_3^- = \text{change in } \text{pCO}_2 / 10 \times 2$ (if acute) or $\times 5$ (if chronic).

Simple vs. mixed: So you've determined the primary disorder and its expected compensation. If the expected response is pretty close to the actual value, the patient has a simple acid-base disorder and you are done. If not, the patient has a mixed disorder. If the pCO_2 is higher than expected, there is an additional respiratory acidosis. If lower, a respiratory alkalosis. If the HCO_3^- is higher than expected, there is an additional metabolic alkalosis. If lower, a metabolic acidosis. Hey, easier than you thought it would be, right?

Step 4: If there is a metabolic acidosis, even if it is part of a mixed disorder, calculate the anion gap to see if the patient has a HAGMA or NAGMA. $\text{AG} = \text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$; see Eq. 7a and **Serum Anion Gap (AG)** on page 7-38.

That's all there is to the analysis, but you also need all the data gained from a thorough evaluation of the patient to make the proper diagnosis.

Caveats

Key points to keep in mind:

- ABGs and chemistries must be drawn at the same time.
- Always be sure the diagnosis makes sense given the clinical history.
- Again, remember that **"+15" does not work** in determining expected pCO_2 when $\text{HCO}_3^- < 10 \text{ mEq/L}$; use the **full** Winter's formula instead: $1.5 \times (\text{HCO}_3^-) + 8$ (bicarb + half bicarb + 8)

- For primary **metabolic alkalosis**, there is another accepted and more accurate alternative: Expected $p\text{CO}_2$ increases by ~ 0.7 mmHg for every 1 mEq/L increase in the HCO_3^- . It's just not as friendly for bedside calculations.
- Regarding the AG: Although low HCO_3^- with a high Cl^- signals a probable NAGMA, and a low HCO_3^- with a low Cl^- suggests a HAGMA, the Na^+ has a wide normal variation, so you can be fooled. Always do the actual calculation!
- If hypoalbuminemia is present, be sure to use the corrected AG: AG decreases by 2.5 mEq/L for every 1 g/dL decrease in albumin (from 4 g/dL).
- Few patients tolerate a $p\text{CO}_2 > 55$ mmHg in response to a metabolic acidosis. Also, in response to a severe metabolic acidosis, only young healthy patients can blow off CO_2 to a $p\text{CO}_2$ of 10 mmHg; weaker, older patients have a lower limit of 20+ mmHg. When patients reach this limit of respiratory compensation and the serum HCO_3^- keeps dropping, the pH drops at a much faster rate.

METABOLIC ALKALOSIS

Metabolic alkalosis always involves a generation phase (initial H^+ loss or HCO_3^- gain) and maintenance phase (failure of the kidney to excrete HCO_3^- to correct the alkalosis). The most common cause of metabolic alkalosis is **volume contraction** caused by diuretics or vomiting/nasogastric suction.

Generation Phase

Metabolic alkalosis is generated when H^+ is lost or excess HCO_3^- is administered or generated. Clinical situations where this occurs include:

- With vomiting and nasogastric (NG) suction, H^+ (and Cl^-) is lost via **gastric** secretions.
- With primary aldosteronism, there is acid loss (as NH_4^+) via the **kidneys**.
- With diuretic-induced “contraction” alkalosis, there is **renal loss of bicarb-free fluid**, which increases the relative concentration of extracellular HCO_3^- . The volume contraction prevents the excess HCO_3^- from being excreted by the kidneys.

Remember: H^+ loss leads to an increase in the serum HCO_3^- concentration (see Eq. 5 under **Mechanisms** on page 7-38).

Maintenance Phase

Normally, patients with good renal function and normal volume status rapidly excrete excess HCO_3^- in the urine, avoiding the development of metabolic alkalosis. An alkalosis persists only when there is failure of the kidney to excrete the excess HCO_3^- (maintenance phase). The most common cause of inability of the kidneys to excrete HCO_3^- is **volume depletion**.

This makes intuitive sense: HCO_3^- cannot be excreted alone; it must be accompanied by a cation (+), and the options for the kidney are Na^+ and K^+ . If the patient is volume depleted, the kidney will “want” to hold on to Na^+ , as Na^+ loss will worsen volume depletion. If the patient is also hypokalemic (as they often are), the kidneys similarly will “want” to hold on to K^+ . The cost of holding on to Na^+ and K^+ is persistent metabolic alkalosis—an inability to excrete all the excess HCO_3^- . This is a small price to pay, as metabolic alkalosis is much less dangerous than hypovolemic shock or severe hypokalemia.

Here is why this happens mechanistically. With volume depletion, there is:

- Decreased distal Cl^- delivery
- High aldosterone levels

Aldosterone enhances distal Na^+ reabsorption and H^+/K^+ excretion by activating distal tubular Na^+/H^+ and Na^+/K^+ pumps, thereby leading to H^+ loss (alkalosis) and K^+ loss (hypokalemia). This can result in **paradoxical aciduria**, a low urine pH in the setting of metabolic alkalosis. Metabolic alkalosis often is seen together with hypokalemia. This occurs because high aldosterone causes renal loss of K^+ , in addition to H^+ . Also in alkalemia, H^+ shifts from the intracellular space to the extracellular space in exchange for K^+ , thus exacerbating hypokalemia.

Types of Metabolic Alkalosis

The 2 types of metabolic alkalosis are **Cl^- -responsive** and **Cl^- -resistant**. Cl^- -responsive metabolic alkalosis is maintained by volume depletion. With Cl^- -resistant metabolic alkalosis, there is some other defect at play (usually high aldosterone). These 2 types are distinguished based on the urinary Cl^- measurement (Figure 7-15). The urine Na^+ concentration and fractional excretion of Na^+ can be elevated during metabolic alkalosis, even with volume depletion, because urinary HCO_3^- excretion (some is excreted, just not enough) must be accompanied by Na^+ excretion. In volume depletion, urinary Cl^- is < 10 mEq/L (10 mmol/L) because NaCl is avidly reabsorbed to maintain intravascular volume.

Figure 7-15: Causes of metabolic alkalosis

If urinary Cl^- is $> 10 \text{ mEq/L}$, you have a Cl^- -resistant alkalosis. The 1 exception to this rule is active diuretic use, which is a Cl^- -responsive alkalosis with a high urinary Cl^- due to the direct effect of the diuretic to increase urinary chloride. Bartter syndrome, Gitelman syndrome, severe hypokalemia, surreptitious use of diuretics, and increased intake of HCO_3^- (i.e., milk-alkali syndrome) present with normal blood pressure (BP).

In Cl^- -responsive alkalosis (when urinary $\text{Cl}^- < 10 \text{ mEq/L}$), aim treatment at **restoration of intravascular volume** with IV fluids (with NaCl and/or KCl). Volume resuscitation restores the kidney's ability to excrete HCO_3^- and correct the alkalosis. **K^+ correction** is integral to resolving the alkalosis, as well. Both interventions will lower aldosterone production.

The carbonic anhydrase inhibitor acetazolamide increases sodium bicarbonate excretion and can be used to treat metabolic alkalosis in the setting of volume overload (e.g., edematous states, such as decompensated HF).

Remember: Significant alkalemia of any etiology can cause the diffuse paresthesias/numbness and muscle spasms typically associated with acute hyperventilation; the high pH increases the fraction of bound Ca^{2+} . The resulting decrease in ionized Ca^{2+} produces these symptoms of hypocalcemia. There is no change in total serum Ca^{2+} (ionized + bound). This effect can also be induced by rapid infusion of IV HCO_3^- or citrate (massive blood transfusion).

On the other hand, patients with both metabolic acidosis and hypocalcemia are protected from the hypocalcemia because acidosis decreases the fraction of bound Ca^{2+} and increases the ionized Ca^{2+} . In this situation, **always correct the hypocalcemia before giving bicarbonate to treat the metabolic acidosis!** Correction of acidosis before correction of hypocalcemia removes the protective effect of the acidosis and can precipitate seizures.

METABOLIC ACIDOSIS

Etiology

Metabolic acidosis is divided into 2 categories:

- High anion gap metabolic acidosis (**HAGMA**); caused by 1 of the following:
 - Overproduction of lactic acid or ketoacids
 - Ingestion of agents that are acids (e.g., salicylates) or are metabolized to acids (e.g., methanol, ethylene glycol, propylene glycol, propofol) or cause a lactic/ketoacidosis (e.g., salicylates, isoniazid, metformin, cyanide, iron)
 - Renal failure
- Normal anion (a.k.a. non-AG) metabolic acidosis (**NAGMA**); caused by one of the following:
 - HCO_3^- losses by the kidney: proximal (Type 2) RTA
 - HCO_3^- losses by the gut: diarrhea

- Large infusions of **normal saline** given during surgery or when treating DKA with subsequent removal of Na^+ by the kidney
- Increased organic acids: Total parenteral nutrition can increase the generation of NH_4^+ as a breakdown product of amino acids.
- Inability of the kidney to excrete H^+ : CKD, renal failure, distal (Type 1) RTA, Type 4 RTA

HAGMA

With HAGMA, the fall in HCO_3^- is matched by an increase in unmeasured anions. There is no change in $[\text{Cl}^-]$.

Perform these tests immediately on a patient with unexplained HAGMA:

- Serum glucose
- Urine and serum ketones
- Lactic acid level
- Serum osmolality with calculation of the OG (high in methanol and ethylene glycol ingestions)
- Toxicology screen (if OG is elevated and/or toxic ingestion is suspected clinically)
- U/A to assess for calcium oxalate crystals (seen in ethylene glycol ingestion)

Table 7-8 on page 7-44 lists the causes of HAGMA. The 4 common categories of HAGMA include:

- 1) **Ketoacidosis**: There are 3 main causes of ketoacidosis—uncontrolled Type 1 diabetes, alcohol intoxication, and starvation. Check β -hydroxybutyrate and urine ketones:
 - Diabetic ketoacidosis (DKA): Classic findings include volume depletion, a normal Cl^- , hyperglycemia, and HAGMA in a known diabetic patient. DKA responds to restoration of intravascular volume, replacement of electrolytes, and IV insulin. Note that DKA with normal blood sugar has been reported with SGLT2 inhibitors (e.g., canagliflozin). DKA is discussed in the **Endocrinology** section.
 - Alcoholic ketoacidosis: A key clue is an alcoholic who presents with HAGMA. Classic findings include HAGMA, high OG (from ethanol and acetone, not from the ketones), and hyper- or hypoglycemia in a patient with alcohol use disorder. Alcoholic ketoacidosis responds well to dextrose infusion but be sure to treat any hypophosphatemia first and watch for development of hypophosphatemia during the dextrose infusion!
 - Starvation ketosis typically causes only mild metabolic acidosis. Consider this in a patient with ketoacidosis, normal blood sugar, and no history of alcohol use.

2) **Lactic acidosis:** Lactic acid has 2 isomers—L-lactate and D-lactate. Lactic acidosis presents with a **HAGMA** and can also cause a high OG:

- **L-lactic acidosis:**
 - Type A is due to impairment in tissue oxygenation during shock, cardiac failure, or sepsis. This is a medical emergency that requires immediate treatment.
 - Type B has no impaired tissue oxygenation and can be caused by drug-induced mitochondrial dysfunction (e.g., zidovudine, metformin, propofol), tumors (e.g., leukemia, lymphomas), and alcoholism. It can also be seen in hereditary metabolic myopathies, including glycogen storage diseases.
- **D-lactic acidosis:**
 - Can occur in patients with short bowel syndrome and other malabsorption disorders. They present with typical neurologic abnormalities, from slurred speech to obtundation.
 - The D-lactate isomer is not physiologically active and takes much longer to break down; it therefore accumulates more quickly and persists longer than L-lactate.
 - These patients have HAGMA with a **normal** lactate level because standard lab assays measure only L-lactate, not D-lactate.

3) **Uremia** causes an accumulation of anions (including **sulfate**, **phosphate**, and **urate**), resulting in a HAGMA. Check BUN and creatinine.

4) **Toxins:** Ethylene glycol, methanol, propofol, and propylene glycol are the classic toxic alcohols that present with a HAGMA and a high OG. Salicylate overdose and chronic acetaminophen are causes of HAGMA with a normal OG. Here are some facts on each:

- **Ethylene glycol**—key clues are a **HAGMA** and **calcium oxalate crystals** in the urine. Ethylene glycol metabolizes to toxic acids (1st to glycolic acid, and then to oxalic acid).
- **Methanol**—key clues are a **HAGMA** and **visual symptoms**. Methanol metabolizes to formic acid, a very toxic substance. Patients present with nausea, vomiting, and abdominal pain, and they can have visual complaints described as “walking through a snowstorm.” Formic acid, a metabolite, is directly toxic to the optic nerve.
- **Propofol-related infusion syndrome**—propofol is an IV sedative/hypnotic used for general anesthesia induction. If given in high doses for > 48 hours, it can cause a Type B lactic acidosis and a syndrome featuring renal failure, rhabdomyolysis, hyperlipidemia, J-point elevation on ECG, refractory bradycardia, and various arrhythmias.

- **Propylene glycol**—propylene glycol is used as a solvent for **IV lorazepam** (and numerous other drugs), and it is an FDA-approved food sweetener (!). Propylene glycol is metabolized to L- and D-lactate. Continuous infusion or repeated large IV doses of lorazepam or sustained intestinal absorption of propylene glycol can cause **severe lactic acidosis**. Patients have a HAGMA and a high OG.
- **Salicylate overdose**—key clue is **HAGMA** plus a **respiratory alkalosis**. Salicylate intoxication causes nausea, vomiting, diaphoresis, and **tinnitus**. Respiratory alkalosis is the first effect, followed by the HAGMA. Especially suspect this in elderly patients with these symptoms who are taking OTC medications for arthritis.
- **Chronic acetaminophen use**—at risk are malnourished women who chronically ingest acetaminophen. HAGMA due to chronic acetaminophen use occurs at therapeutic doses rather than in the setting of an overdose. This disorder is distinct from acute acetaminophen overdose, treated with *N*-acetylcysteine (NAC), which blocks the hepatotoxic effects caused by acetaminophen. The accumulating acid is **pyroglutamic acid** (also called 5-oxoproline).

Table 7-8: Common Causes of HAGMAs and NAGMAs

HAGMA: Remember GOLDMARK

- **Glycols:** propylene glycol, ethylene glycol
- **Oxoproline:** acetaminophen
- **L-lactic acidosis:** shock, tissue ischemia
- **D-lactic acidosis:** short gut, malabsorption syndromes
- **Methanol**
- **Aspirin (salicylates)**
- **Renal failure (uremia):** sulfates, phosphates, urate
- **Ketoacidosis:** diabetes, alcohol, starvation

NAGMA

- **Chronic kidney disease**
- **Renal tubular acidosis**
- **Diarrhea**
- **Large infusions of normal saline** given during surgery or when treating DKA with subsequent removal of Na⁺ by the kidney
- **Drugs:** carbonic anhydrase inhibitors (e.g., acetazolamide), amphotericin, toluene

Treatment notes on toxins:

- **Methanol** and **ethylene glycol** are toxic because of their metabolites, formic acid and oxalic acid. Like ethanol, methanol and ethylene glycol are metabolized by alcohol dehydrogenase. Fomepizole inhibits alcohol dehydrogenase and prevents this reaction. Fomepizole + dialysis is the standard of care for both of these ingestions. IV folate, which accelerates the metabolism of formic acid (the toxic metabolite of methanol), should also be given.

- Treat **propofol**-related infusion syndrome by stopping the propofol. Use hemodialysis if there is AKI or severe acidosis.
- Treat **salicylate** poisoning with aggressive IV sodium bicarbonate: Alkalemia prevents salicylate from entering the CNS, and alkalinization of the urine promotes salicylate excretion by the kidneys. Do **not** use acetazolamide to alkalinize the urine—it lowers blood pH, promotes movement of salicylate into the CNS, and worsens neurotoxicity.
- Treat **DKA** with HCO_3^- only if the pH is < 7.0 or there is hemodynamic instability (severe acidemia impairs cardiac contractility).
- Treat **lactic acidosis** with HCO_3^- only if the pH is < 7.1 .

NAGMA

NAGMA (a.k.a. **hyperchloremic acidosis**) has a commensurate increase in Cl^- with the decrease in HCO_3^- . The Cl^- is increased to maintain electrical neutrality.

Table 7-8 summarizes common causes of NAGMAs and HAGMAs. The most common cause of NAGMA is chronic kidney disease, so check the S_{Cr} first. If CKD Stage 3 or higher is present, no further workup is needed.

If renal function is normal, the most likely cause is either GI losses of HCO_3^- or renal tubular acidosis (RTA). The K^+ can be very helpful:

- For NAGMA plus **hyperkalemia**, think Type 4 RTA (hypoaldosteronism).
- NAGMA plus **hypokalemia** is caused by either:
 - GI loss, or
 - RTA Types 1 (distal) and 2 (proximal). See RTAs.

When RTA is suspected, calculate the UAG (see **Urine AG (UAG)** on page 7-39):

- UAG is **positive** with NAGMA due to **RTA**.
 - UAG is **negative** with NAGMA due to **GI** losses.
- Remember, **neGUT**ive—negative UAG with GI loss.

Toluene, a solvent in glues and paints, can cause NAGMA. Suspect toluene exposure in patients with a history of glue sniffing, use of oil-based paints, and use of varnishes in a poorly ventilated area. Other drugs that can cause NAGMA include **acetazolamide** (which inhibits proximal tubular HCO_3^- reabsorption, thus causing a proximal RTA) and **amphotericin** (which causes proximal tubular toxicity).

Treat NAGMA with replacement of HCO_3^- losses, whether due to GI losses or RTA. Depending on the clinical situation and presence of other electrolyte abnormalities, replace with sodium bicarbonate IV fluid or sodium bicarbonate tablets.

RTAs

All renal tubular acidoses (RTAs) are NAGMAs caused by specific defects in tubular acid-base handling. Remember

that NAGMAs have a normal AG (i.e., are **hyperchloremic acidoses**). RTAs are categorized as distal (Type 1), proximal (Type 2), and hypoaldosteronism (Type 4). (Type 3 RTA was originally described in the 1960s but is no longer observed or considered an important clinical syndrome.) Refer to Table 7-9 on page 7-46 as you read through this topic.

Type 1 (Distal) RTA

Type 1 (distal) RTA is a problem in the H^+ ATPase of the intercalated cells in the late distal tubule and cortical collecting duct that results in failure to acidify the urine. It causes **hypokalemia** (mechanism not completely understood) and hypercalciuria +/- nephrocalcinosis and kidney stones. Urine is alkaline.

The most common causes of Type 1 RTA:

- Autoimmune disease (e.g., Sjögren's, SLE, RA)—most common cause in adults
- Genetic (+/- hearing loss)—most common cause in children
- Hereditary hypercalciuria
- Drugs (commonly amphotericin B and lithium)

Treatment is alkali therapy (i.e., sodium bicarbonate—low doses are usually sufficient), K^+ replacement, and addressing the cause.

Type 2 (Proximal) RTA

The proximal tubule is the nephron segment where most HCO_3^- is reabsorbed. Type 2 RTA occurs when there is impaired proximal tubular HCO_3^- reabsorption (review **Proximal Tubule** on page 7-5), resulting in **HCO_3^- wasting**.

In Type 2 RTA, there are 2 proximal tubule defects:

- HCO_3^- reabsorption
- Reabsorption of Na^+ with glucose, amino acids, Cl^- , and K^+

Most common causes of Type 2 RTA:

- Monoclonal gammopathy (i.e., multiple myeloma [MM]) with accumulation of light chains that damage the tubular cells (Note that MM can sometimes also cause a **low** AG.)
- Carbonic anhydrase inhibitors (e.g., acetazolamide)

Type 2 RTA is often seen together with **Fanconi syndrome** (glucosuria, aminoaciduria, and wasting of other solutes, including Mg^{2+} , uric acid, and phosphorus). Urine pH varies. In untreated Type 2 RTA, the urine pH may be acidic (pH < 5.5) because distal acidification is intact. When Type 2 RTA is being treated (with sodium bicarbonate), the urine pH is basic (pH > 5.5) because the exogenous HCO_3^- is being dumped in the urine.

Treatment is HCO_3^- (often very large doses are needed), K^+ replacement, and vitamin D supplementation.

Table 7-9: Renal Tubular Acidosis — Diagnostic Features

	Urine pH	Serum K ⁺	Mechanism	Clinical Features	Main Causes
Type 1 Distal RTA	> 5.5	Low-normal	Decreased H ⁺ secretion by late distal tubule and cortical collecting duct	Stones Hypercalciuria +/- nephrocalcinosis Hearing loss	Autoimmune (SLE, Sjögren's, RA) Hereditary hypercalciuria Drugs (amphotericin B, lithium) In children: Type 1 RTA is usually a primary genetic disorder.
Type 2 Proximal RTA	< 5.5 when untreated > 5.5 when treated with bicarb	Low-normal	Decreased resorption of HCO ₃ ⁻ by proximal tubule	Fanconi syndrome (glucosuria, phosphaturia, aminoaciduria)	Multiple myeloma Acetazolamide, topiramate Heavy metals Amyloidosis
Type 4 RTA (Hypoaldosteronism)	Varies	High	Decreased Na ⁺ /K ⁺ exchange in late distal tubule and cortical collecting duct; reduced NH ₃ generation and NH ₄ ⁺ excretion	Hyperkalemia	Diabetic nephropathy Obstructive uropathy Chronic interstitial nephritis Drugs (NSAIDs, ACEIs/ARBs) Spironolactone Acute glomerulonephritis

Type 4 RTA

Type 4 RTA (hypoaldosteronism) is a result of **low renin**, **reduced aldosterone production**, or **aldosterone resistance** in the principal cells of the late distal tubule and cortical collecting duct. These cause decreased Na⁺ reabsorption with some Na⁺ loss and significant K⁺ retention. Other factors (norepinephrine and angiotensin II) minimize the Na⁺ loss. Because of either insufficient aldosterone or resistance to aldosterone, the epithelial Na⁺ channels do not open. Type 4 RTA causes **hyperkalemia** and a mild NAGMA.

The most common cause of Type 4 RTA is diabetic nephropathy.

Causes of reduced aldosterone **production**:

- With low renin:
 - Diabetic nephropathy
 - Chronic kidney disease
 - Obstructive uropathy
 - Acute glomerulonephritis
 - Drugs: NSAIDs, cyclosporine, tacrolimus
- Primary adrenal insufficiency (decreased cortisol and aldosterone)
- Severe illness
- Drugs: heparin, ACEIs/ARBs

Causes of aldosterone **resistance**:

- K⁺-sparing diuretics (e.g., spironolactone)
- Antibiotics (trimethoprim, pentamidine)

Treatment for Type 4 RTA is usually indicated based on the degree of hyperkalemia. Primary therapy should always be a low-K⁺ diet, often the administration of HCO₃⁻ therapy, and, if necessary, furosemide. Fludrocortisone (a synthetic adrenal corticosteroid with very potent mineralocorticoid effects) can be considered in patients with refractory hyperkalemia, but this therapy often causes HTN and edema.

Review of RTAs

Clues to analyzing possible RTA:

- All types of RTA cause a NAGMA.
- Positive UAG is seen primarily in those with impaired distal acidification: distal (Type 2) and Type 4 RTA.
- **Proximal (Type 1)** RTA can cause **hypercalciuria** +/- nephrocalcinosis or stones; always elevated urine pH; and **hypokalemia**.
- **Distal (Type 2)** is characterized by HCO₃⁻ wasting. Especially consider **MM** and **Fanconi** syndrome. With Fanconi syndrome, the patient can present with metabolic acidosis, hypoglycemia, hypophosphatemia, hypokalemia, and **hyperchloremia**.
- **Type 4** is caused by **aldosterone deficiency** or **resistance** and is marked by mild acidosis and **hyperkalemia**. Consider causes of hyporeninemic hypoaldosteronism (chronic obstructive uropathy, diabetic nephropathy, and NSAIDs).

Exam questions concerning RTA may not even mention the term "RTA." For example, a question presents a patient with a history of nephrocalcinosis, diabetes, or signs/symptoms suggestive of myeloma; you then are asked to select the most likely serum and urine chemistry or the best treatment based on your interpretation of the given labs.

RTA Questions

Okay, now is a great time to do some review. We've gone over the causes of metabolic acidosis. Let's look at some sets of lab results and figure out the cause of each. After reviewing [Table 7-9](#), try to analyze the chemistry profiles presented in [Table 7-10](#). Let's get started!

Table 7-10: Metabolic Acidosis Problems

Scenario	Serum				Urine		
	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	Cl ⁻ (mEq/L)	HCO ₃ ⁻ (mEq/L)	pH	K ⁺ (mEq/L)	Na ⁺ (mEq/L)
Normal	135–145	3.5–5	95–105	22–30	Variable	25–100	100–260
A	140	3.0	113	17	7.9	50	100
B	140	5.5	117	13	6	50	100
C	140	2.9	115	15	6	50	100
D	140	4.0	105	15	6	50	100
E	140	3.3	115	15	6	10	10

Match each chemistry profile (A through E in Table 7-10) with the most likely clinical scenario:

- Patient with DKA
- Patient with diabetes and chronic kidney disease
- Patient with myeloma
- Woman with nephrolithiasis
- Patient with chronic diarrhea

If you're not sure where to start, here is one approach to decoding this table:

- 1) First, look at the HCO₃⁻. All of these are low, so they are all metabolic acidoses.
- 2) Calculate the AG for each scenario, and label the ones with an increased AG as "HAGMA" and the others as "NAGMA." AGs = 10, 10, 10, 20, 10. Only D is a HAGMA; the rest are NAGMAs. The only diagnosis on the list that causes a HAGMA is DKA.
- 3) Look at the NAGMAs to see if any have an alkaline urine (pH > 6.0), despite the low HCO₃⁻. Check to see if the serum K⁺ is also low to normal. If yes, you've found a Type 1 (distal) RTA. Hmm. That's A. Of the diagnoses listed, nephrolithiasis is the one associated with distal RTA.
- 4) Look for a NAGMA with high serum K⁺, and label it "hyperkalemic RTA (Type 4)." Looks like that is B. Type 4 RTA is associated with diabetes and chronic kidney disease.
- 5) A NAGMA with a low urine Na⁺ is probably diarrhea-induced volume contraction—E. You might also be given the urine Cl⁻, in which case you should calculate the urine AG. The urine AG is negative in diarrhea-induced NAGMA but is positive in RTA.
- 6) Proximal (Type 2) RTA, in this case, is the answer of exclusion—the last NAGMA with low K⁺ left on the list—C. Proximal RTA is associated with MM from the diagnosis list.
- 7) And what if you see a low AG? This usually means that either albumin (an anion) is low or immunoglobulins (cations) are high (e.g., MM, Type 2 RTA).

Correct matches:

- A: Woman with nephrolithiasis—distal (Type 1) RTA
 B: Patient with diabetes and chronic kidney disease—Type 4 RTA
 C: Patient with myeloma—proximal (Type 2) RTA
 D: Patient with DKA—HAGMA
 E: Patient with chronic diarrhea—NAGMA due to GI loss
- Questions may ask what disease each scenario could represent, so go over the causes of each type of metabolic acidosis.

Clinical Pearl

Look at the AG formula $AG = Na^+ - (HCO_3^- + Cl^-)$. Usually a HAGMA has a normal Cl⁻ and a NAGMA has a high Cl⁻. This gives you quick way to tell at a glance at the electrolytes **1**) if the patient has a metabolic acidosis (i.e., low HCO₃⁻) and **2**) if it is a NAGMA (i.e., high Cl⁻) or HAGMA (normal Cl⁻). Cool, huh?

DISORDERS OF WATER BALANCE

PREVIEW | REVIEW

- What are the most important regulators of antidiuretic hormone secretion from the posterior pituitary?
- Name 2 causes of hypertonic hyponatremia.
- How do you correct the serum Na⁺ in severe hyperglycemia?
- What causes hypovolemic hyponatremia?
- What causes hypervolemic hyponatremia?
- Which drugs cause the syndrome of inappropriate antidiuretic hormone secretion?
- Which endocrinopathies must be ruled out in all patients with hyponatremia?
- What is the suggested rate of correction for severe hyponatremia?

- When is osmotic demyelination syndrome most likely to occur?
- What is the most common cause of hyponatremia?
- What is the typical serum Na^+ in a patient with diabetes insipidus who has access to water?

OSMOLALITY AND VOLUME STATUS

Osmolality (mOsm/kg) is the number of particles per unit mass of solution (water). Osmolarity (mOsm/L) is the number of particles per unit volume of solution. For water, 1 kg = 1 liter, so osmolality and osmolarity are essentially equivalent. Here, we will use osmolality (mOsm/kg), but you may see osmolality around—there is essentially no difference between the 2. Also, 1 mOsm is equivalent to 1 mmol. Both osmoles and moles are the number of particles; osmolality is the total number of all different types of particles and can be used to predict how water will move across semipermeable membranes. Water will always want to move from an area of low osmolality to an area of high osmolality. In the body, osmolality is important because it affects fluid shifts between the intracellular and extracellular spaces.

Normal serum osmolality is 275–290 mOsm/kg H_2O . Osmolality is maintained within the normal range by changes in water intake (thirst) and renal water excretion. Renal water excretion is regulated by antidiuretic hormone (ADH). Tonicity is a measure of effective osmolality, and it is what is actually sensed by the body's osmoreceptors. The biggest difference between tonicity and osmolality—urea (BUN) does not count toward tonicity, because it can freely cross cell membranes.

ADH is the common term for arginine vasopressin (AVP), sometimes simply called vasopressin. ADH is the primary regulator of renal water excretion. It is a hormone, secreted by the posterior pituitary, that acts on the late distal tubule and cortical collecting duct to increase water permeability. This allows water reabsorption (from the collecting duct back into the circulation) and formation of a concentrated urine.

ADH release is regulated by several mechanisms. The 2 most important are:

- 1) **Osmoreceptors** in the hypothalamus—high osmolality triggers ADH release.
- 2) **Volume (stretch) receptors** in the left atrium (and possibly in the pulmonary veins) and blood vessels—low effective circulating volume triggers ADH release.

The **strongest** stimulant for ADH release is significant **volume loss** resulting in hypotension (e.g., hemorrhagic shock). This stimulates both the stretch receptors and baroreceptors. High serum osmolality is a weaker but more sensitive stimulus for ADH release. More on ADH is in the **Endocrinology** section.

The volume status of the patient with a Na^+ abnormality is **critical** in determining the diagnosis and treatment. In general, if the patient is **edematous**, there is volume **overload**. If the patient has the clinical signs of **volume loss**, there is volume **depletion**. If there is neither of these, the patient is considered euvolemic.

Remember these clinical clues to **hypovolemia**: history of decreased oral intake and/or GI losses (i.e., diarrhea), dry mucous membranes, decreased skin turgor, tachycardia, narrowed pulse pressure, orthostatic hypotension, and resting tachycardia with hypotension. Central venous pressure is low.

Edematous states can sometimes cause ADH release due to decreased effective circulating volume, even though the patient has total body fluid overload. This is seen in severe HF and severe hepatic cirrhosis.

ADH secretion can also be stimulated by nausea, vomiting, pain, medications, or pathology in the brain or lungs. This is called the syndrome of inappropriate ADH (SIADH) and causes euvolemic hyponatremia.

HYPONATREMIA

The clinical presentation of hyponatremia depends on several factors, including rate of onset (acute vs. chronic), underlying cause, and volume status. Begin with a detailed history, including fluid intake, recent illness, and medications. Initial lab evaluation includes serum and urine osmolality, urine Na^+ , and thyroid-stimulating hormone.

Isotonic and Hypertonic Hyponatremia

Hyponatremia is defined as a low serum Na^+ . Hyponatremia usually indicates low serum tonicity and osmolality, reflecting high total body water content relative to total body sodium content.

Usually, a patient with a low serum Na^+ can be assumed to have **hypotonic** hyponatremia and measuring the plasma osmolality (a surrogate for tonicity) is not necessary. But in some situations, the serum Na^+ is low, but the tonicity (and osmolality) is normal or high. Suspect **isotonic** or **hypertonic** hyponatremia (and measure the plasma osmolality) in the following situations:

- Severe hyperglycemia
- Recent transection of the prostate or hysterectomy (procedures that use mannitol)
- Recent exposure to hypertonic iodinated contrast
- Recent exposure to mannitol, glycerol, or IVIG

Hypertonic hyponatremia—both **hyperglycemia** and **mannitol** cause hypertonicity, leading to an osmotic shift of water out of cells. This dilutes serum Na^+ resulting in hypertonic hyponatremia. Remember: For each 100-mg/dL (5.55-mmol/L) increase in glucose over 100 mg/dL, the Na^+ concentration decreases by 1.6 mEq/L (1.6 mmol/L).

Isotonic hyponatremia—this is an artifactual decrease in the serum Na^+ caused by older lab instruments that miscalculated Na^+ in settings of high protein (e.g., myeloma) or lipid content of the blood. Modern laboratories use ion-specific electrodes; thus, this diagnosis is of historical interest only.

Hypotonic Hyponatremia

Classification by Volume Status

Most patients with hyponatremia have true hypotonicity. From here on out, we'll drop the “hypotonic” and refer to hypotonic hyponatremia as simply “hyponatremia.” Refer to [Figure 7-16](#) as you read along.

The low serum osmolality causes water movement into cells, leading to **intracellular swelling**, which can result in cerebral edema, neuromuscular excitability, seizures, and coma—usually when the Na^+ falls **acutely** and severely ($< 120 \text{ mEq/L}$ [120 mmol/L]). If the Na^+ level decreases slowly, the cells equilibrate and do not swell enough to cause these symptoms. Hypotonic hyponatremia is subdivided by **volume status**: hypovolemic, euvolemic, and hypervolemic.

Always think of the serum Na^+ concentration as the ratio of total body Na^+ (TBNa) to water, with increased total body water content (relative to the amount of sodium) as the key disorder in most cases of hyponatremia. In other words, hypotonic hyponatremia is caused by excess **water**, not insufficient sodium. Whenever the serum Na^+ is low, it means the patient has more water relative to TBNa , from either loss of Na^+ , true water excess, or TBNa excess that is exceeded by water excess.

In the patient with hypotonic hyponatremia, the **first** thing to do is to assess the volume status, which is done clinically (using history and physical exam). Volume status essentially reflects TBNa content.

Hypovolemic Hyponatremia

Hypovolemic patients have lost both water and Na^+ but more Na^+ than water. This has several causes:

- Diuretics
- GI losses (vomiting and diarrhea)
- 3rd spacing of fluid
- Primary adrenal insufficiency (Addison disease)
- Cerebral salt wasting (CSW)
- Inadequate solute intake

In primary adrenal insufficiency, both cortisol and aldosterone are deficient. The low aldosterone causes renal Na^+ wasting and decreased K^+ and H^+ excretion, resulting in hypovolemia (sometimes with hypotension), **hyperkalemia**, and **metabolic acidosis**. The low cortisol and the hypovolemia stimulate ADH production, resulting in hyponatremia. More information on hyponatremia is in the [Endocrinology](#) section.

CSW is typically seen in patients with CNS disease, particularly subarachnoid hemorrhage, and is characterized by significant urinary Na^+ losses. This must be differentiated from SIADH because both disorders cause hyponatremia in the setting of CNS insults and result in high urinary Na^+ concentration and low serum uric acid. Patients with CSW have hypovolemia (low extracellular fluid volume) and may have elevated fractional excretion of phosphate.

Hypervolemic Hyponatremia

Hypervolemic hyponatremia reflects increased total body sodium content and increased total body water content, but water excess exceeds Na^+ excess. These patients have **edema** and **jugular venous distention**.

Causes of hypervolemic hyponatremia:

- Edema-forming states: HF, cirrhosis
- Renal failure: acute or chronic

ARF = acute renal failure
CRF = chronic renal failure
HF = heart failure
RF = renal failure
TBNa = total body sodium

Figure 7-16: Causes of hypotonic hyponatremia

Treatment is restriction of **water** and **Na⁺** intake, and loop diuretics. **Avoid thiazide** diuretics because they impair urinary-diluting ability, worsening hyponatremia. **Loop** diuretics work by eradicating the interstitial hypertonicity in the renal medulla, which is the driving force for water reabsorption in the presence of ADH. With loop diuretics, the kidneys are no longer able to make a concentrated urine, so free water excretion increases, even if ADH levels are high.

Vasopressin antagonists (e.g., tolvaptan) are approved for the treatment of hypervolemic hyponatremia when other treatments have failed. However, because these agents are expensive and can cause liver toxicity, do not use them chronically.

Euvolemic Hyponatremia

Euvolemic patients usually have the syndrome of inappropriate antidiuretic hormone (SIADH) or are taking drugs that either mimic ADH or cause ADH release.

Again, recall that pain and nausea are potent natural stimulators of ADH release.

Euvolemic hyponatremia can also be caused by primary polydipsia. But keep in mind—in a patient with normal renal function and solute intake, it takes over 15 L/day of water intake to produce hyponatremia! Hypothyroidism, isolated glucocorticoid deficiency can also cause euvolemic hyponatremia.

SIADH

Causes of SIADH:

- CNS disease
- Lung disease (e.g., cavitary pneumonia)
- Neoplasms (especially small cell lung cancer)
- Intense exercise, pain, nausea
- Drugs, most commonly:
 - NSAIDs
 - SSRIs
 - Carbamazepine and oxcarbazepine
 - Psychotropic drugs: haloperidol, amitriptyline
 - IV cyclophosphamide
 - Vincristine/Vinblastine
 - Cisplatin
 - Chlorpropamide (rarely used)
 - Methylenedioxymethamphetamine (MDMA; Ecstasy)

Diagnose SIADH by a high urine osmolality with a high urine **Na⁺** (> 40 mEq/L) in a patient with euvolemic hyponatremia. A low serum uric acid level also supports the diagnosis of SIADH. The **normal** response to hyponatremia is to excrete free water in the urine (i.e., make a dilute urine, with an osmolality < 100 mOsm/kg). In SIADH, however, the urine is inappropriately concentrated (> 250 mOsm/kg) despite the presence of hyponatremia. Remember: This occurs because ADH

acts on the collecting duct to make it permeable to water, allowing water to be reabsorbed into the hypertonic medullary interstitium (and subsequently into the circulation). Patients cannot excrete free water, so the serum osmolality stays low and the hyponatremia persists and worsens.

Exercise-induced hyponatremia can occur in marathon and other endurance exercise participants. This is caused by both nonosmotic production of ADH and excessive intake of hypotonic fluids.

Primary Polydipsia

Primary polydipsia is a psychiatric disorder in which patients consume tremendous amounts of water (as much as 1 L/hour). If the urine is appropriately dilute (urine Osm < 100 mOsm/kg), it takes a huge amount of water (> 15 L/day) to cause hyponatremia. However, in some patients with polydipsia, plasma ADH may not be fully suppressed, and the patients are unable to fully dilute their urine and efficiently excrete the water. These patients can develop hyponatremia with more modest amounts of water intake. They have a urine osmolality that is lowish, but not maximally diluted (100–300 mOsm/kg).

Endocrinologic Causes

The mechanism for ADH release in moderate-to-severe hypothyroidism is decreased cardiac output, which stimulates the carotid baroreceptors. Rule out hypothyroidism and glucocorticoid deficiency before making a diagnosis of SIADH because both can have low serum osmolalities and high urine osmolalities—mimicking SIADH.

Thiazide Diuretics

Thiazides can also cause euvolemic hyponatremia. This occurs via at least 2 possible mechanisms: **1)** mild volume depletion directly stimulates ADH release; and **2)** thiazides impair urinary dilution in the early **distal** tubule, so the patient cannot maximally dilute their urine. Elderly patients are highly susceptible to this effect of thiazides.

Treatment of Hyponatremia

Only **hypotonic hyponatremia** (hyponatremia with low plasma osmolality) requires treatment. **Hypertonic** hyponatremia (e.g. due to hyperglycemia) resolves with treatment of the underlying process (e.g., insulin and IV fluids for DKA). **Isotonic** hyponatremia is a lab artifact and does not require any treatment. Treat hyponatremia due to hypothyroidism or adrenal insufficiency with appropriate hormone replacement. All other causes of hypotonic hyponatremia should be treated according to the recommendations that follow.

First, determine if the patient is **symptomatic** or **asymptomatic**.

If there are moderate or severe **symptoms** of hyponatremia—such as lethargy, confusion, coma, seizures—treat urgently with 3% saline. The goal is to increase the serum Na^+ concentration by 4–6 mEq/L (within 6 hours) to prevent neurologic deterioration and brain herniation from cerebral edema. Correction of hyponatremia should **never exceed 8 mEq/L over the first 24 hours** due to the risk of osmotic demyelination syndrome (see below).

For **severe** symptoms (seizure, coma), give a 100-mL bolus of 3% saline. If severe symptoms persist, up to 2 more boluses (100 mL each) can be given in 10-minute intervals. This should usually be followed by a hypertonic saline infusion. For **moderate** symptoms (e.g., confusion, lethargy), use either a 100-mL hypertonic saline bolus, or a hypertonic saline infusion. Hypertonic saline infusion should start at a rate of 0.5–1.0 mL/kg lean body weight/hour. Check the serum Na^+ frequently (every 4 hours) and adjust the rate to achieve the target correction of no more than 8 mEq/L over 24 hours. Watch for a water diuresis (high urine output, dilute urine), which can cause the serum Na^+ concentration to rise faster than expected. This is most common in patients with primary polydipsia, hypovolemic hyponatremia, and hyponatremia due to thiazide diuretics. If water diuresis with overcorrection occurs, treat with desmopressin (DDAVP).

Exercise-induced hyponatremia (e.g., in marathon runners) can cause cerebral edema with brain herniation, so promptly treat with 3% hypertonic saline when this disorder is suspected.

ADH antagonists (discussed below) are not recommended for **symptomatic** hyponatremia.

Remember: Isotonic saline worsens hyponatremia in patients with SIADH.

Treat **asymptomatic** hyponatremia (no neurologic symptoms) based on etiology:

- **Hypovolemic** hyponatremia—normal saline to replenish volume deficit (watch for a water diuresis, which can lead to overly rapid correction of hyponatremia!)
- **Hypervolemic** hyponatremia—oral fluid restriction (1.0–1.2 liters/day) +/- loop diuretics
- **Euvolemic** hyponatremia—this is usually caused by SIADH. The first line treatment is fluid restriction (1.0–1.2 liters/day). Salt tablets or urea and loop diuretics can be added if fluid restriction alone is not effective.

Refractory asymptomatic hypervolemic or euvolemic hyponatremia can be treated with an ADH receptor antagonist, such as conivaptan or tolvaptan. However, these agents are expensive, and can cause liver injury with chronic use. ADH antagonists can also cause overly rapid correction of hyponatremia, placing the patient at risk for osmotic demyelination syndrome, so monitor serum Na^+ very carefully.

Osmotic demyelination syndrome (ODS) is a rare but devastating neurologic complication that can occur with

rapid correction of chronic hyponatremia. When the plasma Na^+ concentration rises, the extracellular osmolality is transiently higher than the intracellular osmolality. Osmotic forces cause water to move out of cells into the extracellular fluid space, and the cells shrink. In the brain, this can cause permanent neurologic damage. ODS is more likely to occur in the patient with chronic, severe hyponatremia ($\text{Na}^+ < 115$ mEq/L [115 mmol/L] for > 2 days) whose Na^+ is corrected rapidly (> 10 mEq/L over 24 hours). Symptoms first occur 2–6 days after the rise in the Na^+ concentration and are usually irreversible. Symptoms include speech and swallowing difficulties, weakness or paralysis, cognitive deficits, and coma.

HYPERNATREMIA

Severe hypernatremia **always** represents a **water deficit**. It only occurs when the patient has decreased access to water (i.e., patient is debilitated or H_2O is unavailable) or the thirst mechanism is defective. Unlike hyponatremia, these patients are **always hypertonic**. The appropriate diagnosis and management of hypernatremia require the following steps (refer to [Figure 7-17 on page 7-52](#)):

- 1) Determine if the patient has had inadequate water intake. Determine why the patient has inadequate water intake. For example, does the patient have dementia with impaired thirst mechanism? Is the patient intubated and sedated?
- 2) Determine the volume status. Is the patient hypovolemic, euvolemic, or hypervolemic?
- 3) Assess the urine output. If there is polyuria, consider the possibility of diabetes insipidus (DI). Confirm the diagnosis by measuring the urine osmolality. A low urine osmolality ($\text{UOsm} < 200$ mOsm/kg) in a patient with hypernatremia is diagnostic of DI.

Hypovolemic Hypernatremia

Hypovolemic hypernatremia is the most common form of hypernatremia and is caused by unreplaced losses of water and Na^+ . These patients have both a water deficit and a total body Na^+ deficit, but they have lost more water than Na^+ .

Treat severe **hypovolemic hypernatremia** with **normal saline** first to correct the volume deficit and **then** with hypotonic fluids (e.g., oral water, IV D5W) to further replace the water deficit. Remember: Even normal saline has a lower osmolality than serum in a patient with hypernatremia.

The amount of free water needed in a hypernatremic patient is calculated by multiplying the total body water (60% of weight in kg) by the fractional difference between a patient's Na^+ and normal Na^+ :

$$\text{Vol}_{\text{water}} = (\text{total body water}) \times [(\text{Na}^+_{\text{serum}} - 140) / 140] \quad (\text{Eq. 12})$$

$$\text{Vol}_{\text{water}} = 0.6 \times (\text{body weight}) \times [(\text{Na}^+_{\text{serum}} - 140) / 140] \quad (\text{Eq. 13})$$

Figure 7-17: Causes of hypernatremia

If a 100-kg patient has a serum Na^+ of 156 mEq/L, the amount of free water needed to fully correct the hypernatremia is 6.9 L. This is usually given over 1–2 days to decrease the Na^+ concentration at a rate of 0.5 mEq/L/hour or 10–12 mEq/L/day.

Cellular swelling can occur from rapid correction of any severe hypertonic state, such as hypernatremia, nonketotic hyperglycemic coma, and severe uremia. (You may recognize these variables— Na^+ , glucose, and BUN—from the equation for calculated serum osmolality.) Cellular swelling can cause cerebral edema, seizures, and coma. So, be careful with the rate of correction, and measure serum Na^+ frequently.

Euvolemic Hypernatremia

Euvolemic hypernatremia occurs when there is unreplaced loss of water, but overall volume status is maintained. Euvolemic hyponatremia is sometimes seen in patients with DI and reduced access to water (who thus become hypernatremic) but have not yet developed frank volume depletion. DI is a disorder in which the kidneys cannot appropriately concentrate the urine, due to either a lack of ADH (central DI) or renal resistance to the effects of ADH (nephrogenic DI). The distinguishing feature of DI is polyuria with a low urine osmolality. Typical DI patients with normal access to water do not develop severe hypernatremia—they have **normal or borderline-high** serum Na^+ levels. This is because their thirst mechanism is intact, so they are constantly drinking water (mild hypernatremia causes thirst, leading to increased water intake, preventing severe hypernatremia). Their primary complaint is usually polyuria and polydipsia.

However, when access to free water is restricted in a DI patient (e.g., when the patient is NPO due to surgery), patients can rapidly develop severe hypernatremia.

A low urine osmolality in a patient with hypernatremia is consistent with DI. DI can be either central or nephrogenic. Diagnosis and determination of the type of DI

are done with the water restriction test. See more on DI in the [Endocrinology](#) section for a discussion on how to interpret results from water restriction testing. Central DI is treated with vasopressin (DDAVP). Nephrogenic DI is difficult to treat—a low-sodium diet, thiazide diuretics, and NSAIDs are sometimes used.

Hypervolemic Hypernatremia

Hypervolemic hypernatremia is uncommon. It most often occurs with administration of sodium bicarbonate during advanced cardiac life support. Treat with loop diuretics and then free water if needed.

POTASSIUM DISORDERS

PREVIEW | REVIEW

- Which K^+ derangement can be seen in Cushing syndrome (hypercortisolism)?
- Which K^+ derangement can be seen in Addison disease (primary adrenal insufficiency)?

- What is special about the treatment of hyperkalemia in patients taking digoxin?
- What urine test can help distinguish between Bartter and Gitelman syndromes?
- When hypokalemia occurs with hypertension and alkalosis, what is the probable cause?
- What are the differences between Bartter and Gitelman syndromes?

OVERVIEW

The potassium disorders are hyperkalemia and hypokalemia, diagnosed by a high or low serum K^+ level. Potassium disorders are caused by changes in potassium intake, excretion (by the kidneys or gut) or shifts between the intracellular and extracellular spaces. First, we will review the mechanisms of potassium balance, and then we will discuss each potassium disorder in depth.

ALDOSTERONE

Aldosterone regulates the K^+ level by increasing renal K^+ excretion. Recall from [Distal Tubule on page 7-7](#), K^+ secretion occurs in the late distal tubule and cortical collecting duct under the influence of aldosterone, linked with Na^+ reabsorption.

Any situation that increases aldosterone release (or mimics aldosterone) **lowers** the serum K^+ . These include:

- Increased renin as a result of decreased effective arterial blood volume:
 - Volume depletion (e.g., GI losses, diuretic therapy)
 - Decreased renal perfusion (e.g., HF, renovascular HTN)
- Increased renin as a result of inappropriate release:
 - Renin-secreting renal tumors
- Increased aldosterone as a result of inappropriate overproduction by the adrenal gland:
 - Bilateral adrenal hyperplasia
 - Aldosterone-producing adrenal adenoma
- Increased excretion of hormone with aldosterone-like effects:
 - Cushing syndrome (hypercortisolism)

Conversely, any situation that inhibits aldosterone release or aldosterone action **increases** the serum K^+ :

- Type 4 RTA (hyporeninemic hypoaldosteronism): seen in chronic interstitial nephritis and diabetic nephropathy, exacerbated by NSAIDs
- **Primary adrenal insufficiency (Addison's)** affects both the zona glomerulosa (outer layer; site of aldosterone production) and the zona fasciculata (middle layer; site of cortisol production)—but not secondary adrenal insufficiency because lack of adrenocorticotrophic hormone affects **only** the zona fasciculata.
- Drugs that block aldosterone production or action:
 - K^+ -sparing diuretics (Remember: Spironolactone blocks the aldosterone receptor; amiloride blocks aldosterone-sensitive Na^+ channel.)
 - ACEIs and angiotensin receptor antagonists
 - NSAIDs
 - Heparins (Both unfractionated and low molecular weight heparins can be toxic to the zona glomerulosa.)

Know: NSAIDs decrease renin, so they can make K^+ go up—but generally only if the patient has another factor predisposing to hyperkalemia (e.g., CKD, ACEI use). Basically, NSAIDs make hyporeninemic states worse than they already are—see [Other Drug-Induced Nephropathies on page 7-28](#) for more explanation.

CELLULAR SHIFTS

Shifts between the intracellular and extracellular spaces can also affect serum K^+ level:

- Alkalosis, β -agonists, and insulin increase K^+ uptake into cells → **hypokalemia**
- Acidosis, α -agonists, and β -blockers decrease K^+ uptake into cells → **hyperkalemia**

The relationship between alkalosis/acidosis and hypokalemia/hyperkalemia can get confusing. Keeping it simple:

- Metabolic alkalosis → hypokalemia. Mechanism: K^+ shifts into cells in exchange for H^+ .
- Metabolic acidosis → hyperkalemia. Mechanism: K^+ shifts out of cells in exchange for H^+ .
- Hypokalemia → metabolic alkalosis. Mechanism: Low K^+ stimulates renal H^+ secretion; see [Proximal Tubule on page 7-5](#).
- Hyperkalemia → metabolic acidosis. Mechanism: High K^+ inhibits renal H^+ secretion.

OTHER FACTORS AFFECTING K^+ LEVEL

K^+ excretion by the kidney is stimulated by increased tubular flow, increased distal Na^+ delivery, aldosterone, the presence of nonresorbable anions in the tubules, and metabolic alkalosis. The following factors also affect serum K^+ and are important to know:

- Increased cell turnover causes **hyperkalemia** (e.g., tumor lysis syndrome, rhabdomyolysis, intravascular hemolysis, acute leukemia).
- Trimethoprim in TMP/SMX interferes with K^+ secretion in the principal cells of the late distal tubule and cortical collecting duct, especially in patients with preexisting renal disease, causing **hyperkalemia**.
- Both Type 1 (distal) RTA and Type 2 (proximal) RTA can cause **hypokalemia** for complex reasons.
- Loop and thiazide diuretics block reabsorption of solutes and water. Thiazides increase distal delivery of Na^+ and Cl^- and cause mild hypovolemia, activating the renin-angiotensin-aldosterone system. The combination of high distal Na^+ delivery and high aldosterone leads to increased Na^+ reabsorption and K^+ secretion in the collecting tubule, causing **hypokalemia**.
- The penicillins, including piperacillin, act as nonresorbable anions and increase K^+ excretion. Cisplatin nephrotoxicity can result in K^+ wasting.
- There are 3 genetic syndromes associated with **hypokalemia**: Liddle's, Bartter's, and Gitelman's. We'll discuss these under [Causes of Hypokalemia on page 7-55](#).

HYPERKALEMIA

Causes of Hyperkalemia

"Spurious" hyperkalemia (a.k.a. pseudohyperkalemia) occurs in a hemolyzed specimen or when there is thrombocytosis $> 400,000/\mu\text{L}$ or leukocytosis $> 100,000/\mu\text{L}$. Always retest if an unexpected lab result is found.

There are 3 main mechanisms of hyperkalemia:

- 1) Transcellular shifts (from cells to the extracellular space)
- 2) Decreased renal K^+ excretion
- 3) Excess K^+ ingestion or administration

Transcellular shifts can be caused by rhabdomyolysis, hemolysis, metabolic acidosis, and drugs (e.g., β -blockers, α -agonists).

Decreased renal K^+ excretion can be seen in AKI, advanced CKD, primary adrenal insufficiency (Addison disease), and Type 4 RTA (hyporeninemic hypoaldosteronism). Several drugs can decrease renal K^+ excretion, including K^+ -sparing diuretics (e.g., spironolactone, amiloride), NSAIDs, ACEIs/ARBs, direct renin inhibitors, calcineurin inhibitors (e.g., cyclosporine, tacrolimus), and heparins (which reduce adrenal aldosterone production).

Excess K^+ ingestion or administration usually does not cause hyperkalemia if renal function is intact, unless the amount of K^+ given is extraordinarily high. Hyperkalemia can result when there is acute or chronic renal failure, which reduces the kidney's ability to excrete a K^+ load.

Hyperkalemia Manifestations

Most patients have no symptoms if the increase in the K^+ has been chronic, even with a level near 7 mEq/L. Symptoms can occur at lower serum levels when the increase is acute. Presentation can include weakness or paralysis, cardiac conduction abnormalities, or arrhythmias. Typically, if a patient is experiencing weakness, they also have ECG changes, although the opposite is not necessarily true.

Know the sequence of ECG changes that occur with progressive hyperkalemia (Figure 7-18):

- 1) Peaked T wave and short QT interval
- 2) Progressive lengthening of PR and QRS intervals
- 3) Loss of P wave and QRS widening into sine waves
- 4) Ventricular fibrillation or cardiac standstill

Hyperkalemia Treatment

Treatment is aimed at decreasing the serum K^+ concentration and stabilizing cardiac membranes. Most acute treatments work by shifting K^+ from the extracellular space to the intracellular space. Loop diuretics, dialysis, and GI cation exchangers (e.g., sodium polystyrene sulfonate, patiomer) are the only treatments that actually remove K^+ from the body.

Treatment of severe hyperkalemia with ECG changes:

- Note: Hypercalcemia worsens the cardiac toxicity of digoxin. If a patient with severe hyperkalemia is on digoxin and requires IV calcium, it needs to be given very slowly to avoid hypercalcemia.

Figure 7-18: ECGs with moderate and severe hyperkalemia

- **IV calcium gluconate** (okay for peripheral injection) or IV calcium chloride (requires central access)
- **Insulin with glucose infusion** (effect in minutes)
- **Sodium bicarbonate** injection or infusion, if acidosis is present (30 minutes for effect; minimal response in patients without acidosis). Avoid sodium bicarbonate in patients with HF or volume overload.
- **Albuterol** nebulization (90 minutes for effect) or injection (30 minutes for effect). Be careful in patients with heart disease.
- **Loop diuretics** (in patients who make urine) with IVF to maintain euolemia
- **Dialysis** (in patients with kidney failure or those who do not respond to the above therapies)

Sodium polystyrene sulfonate (SPS) is a cation-exchange resin given orally or as an enema that exchanges Na^+ for K^+ across the gut wall and induces an osmotic diarrhea full of K^+ . Know that SPS, especially SPS in sorbitol (the most common preparation), can cause colon necrosis. Risk is highest in patients who have had surgery within 1 week and in patients with ileus, large or small bowel obstruction, or underlying bowel disease (e.g., inflammatory bowel disease). Avoid SPS unless the patient has severe, life-threatening hyperkalemia that is refractory to other therapies and when dialysis and patiomer are not available.

Patiomer, like SPS, binds K^+ in the GI tract but does **not** cause intestinal necrosis. Patiomer is available as oral therapy and is most commonly used to treat chronic hyperkalemia in patients with CKD. If available, patiomer is a reasonable treatment option in patients with acute hyperkalemia when used in conjunction with other treatments.

Patients with hyperkalemia in the setting of severe CKD or ESRD may be treated as described above, but they may also need immediate dialysis.

Treat $\text{K}^+ \geq 6.5$ mEq/L without symptoms or ECG changes with insulin + glucose, β -agonists, and sodium bicarbonate (if acidosis), followed by loop diuretics, patiomer, or dialysis. $\text{K}^+ \leq 6.5$ mEq/L can be treated with loop diuretics and dietary restriction.

Know that sodium bicarbonate infusions can cause edema and may precipitate pulmonary edema in patients with HF.

Make sure you check the patient's medication list and discontinue all drugs that cause hyperkalemia, such as ACEIs/ARBs, K^+ -sparing diuretics, β -blockers, heparin, NSAIDs, and TMP/SMX.

HYPOKALEMIA

Causes of Hypokalemia

To determine the cause of hypokalemia, first look to the history and physical exam to see if there are obvious causes (e.g., vomiting, diarrhea, diuretic use).

Usually the cause is obvious, but if it is not, assess urinary K^+ excretion to determine if there is renal K^+ wasting (Figure 7-19 on page 7-56). This can be done with a 24-hour urine K^+ measurement or a spot urine potassium:creatinine (K:Cr) ratio. If urinary K^+ excretion is low (< 20 mEq/day or spot urine K:Cr ratio < 1 mEq/g), the kidney is responding appropriately: Look again for GI sources of K^+ loss (e.g., surreptitious vomiting, laxative use) or a reason for transcellular shifts (e.g., hypokalemic periodic paralysis). If urinary K^+ is high (> 20 mEq/day or spot urine K:Cr ratio > 1 mEq/g), this indicates renal K^+ wasting. In this case, the acid-base status and the BP can guide you to the correct diagnosis. See Figure 7-19 on page 7-56.

Bartter and **Gitelman** syndromes are genetic causes of hypokalemia where there is impaired Na^+ reabsorption in the thick ascending limb of the loop of Henle (Bartter's) and the distal tubule (Gitelman's).

In **Bartter syndrome**, Na^+ reabsorption in the loop of Henle is impaired, and patients look like they are taking a **loop diuretic**. In **Gitelman syndrome**, the defect is in the Na^+/Cl^- cotransporter in the distal tubule, and patients look like they are taking a **thiazide diuretic**. Characteristics of Bartter's and Gitelman's are summarized in Table 7-11.

Table 7-11: Comparison of Bartter and Gitelman Syndromes

	Bartter Syndrome	Gitelman Syndrome
Age of Onset	Infants, children	Early adults
Hypokalemia	+	+
Metabolic Alkalosis	+	+
Hypomagnesemia	+	+
Urinary Ca^{2+}	High	Low
Chondrocalcinosis	–	+
Site of Defect	Loop of Henle	Distal tubule
Looks like patient is taking a...	Loop diuretic	Thiazide diuretic

The easiest way to distinguish Bartter from Gitelman syndrome: Patients with Bartter's have hypercalciuria, and patients with Gitelman's have hypocalciuria. This is easy to remember if you recall loop diuretics are sometimes used to treat hypercalcemia (increase urinary Ca^{2+} excretion), and thiazide diuretics are sometimes used to treat Ca^{2+} -containing kidney stones (decrease urinary Ca^{2+} excretion).

Major causes of hypokalemia:

- Hypokalemia with **metabolic alkalosis** and **normal or low BP**:
 - Volume contraction: vomiting, NG suction, bleeding, or diuretics (thiazides and loops)
 - Bartter syndrome, Gitelman syndrome (See Table 7-11.)

- Hypokalemia with **metabolic alkalosis** and high BP:
 - Primary aldosteronism
 - Secondary aldosteronism: renovascular disease (i.e., renal artery stenosis, fibromuscular dysplasia), HF with diuretic use, cirrhosis
 - Renin-secreting tumor
 - Cushing syndrome
 - Liddle syndrome
- Hypokalemia with **metabolic acidosis**:
 - Distal (Type 1) and proximal (Type 2) RTA
 - Diarrhea
- Hypokalemia due to **shifting** of K^+ into cells:
 - β -agonists
 - Insulin
 - Metabolic alkalosis
 - Hypokalemic periodic paralysis
- Other causes of renal K^+ wasting:
 - Penicillins
 - Cisplatin
 - Mg^{2+} deficiency

Hypokalemia Manifestations

Symptoms generally begin when the serum K^+ level is ≤ 3.0 mEq/L and include muscle weakness, fatigue, and palpitations. Severe hypokalemia (< 2.5 mEq/L) can cause U waves on the ECG (Figure 7-20), decreased deep tendon reflexes, and rhabdomyolysis. Serum K^+ does not decrease to below normal until there is a net loss of 200–300 mEq of K^+ from the body. The consequence of this is that large amounts of KCl are usually required for replacement.

Figure 7-20: U wave in hypokalemia

Hypokalemia Treatment

Try to identify the underlying cause, and treat contributing factors, such as volume depletion and/or metabolic alkalosis. Replace K^+ orally when possible. Poor response generally means the deficit is large and the patient merely requires more K^+ . Comorbid Mg^{2+} deficiency causes renal K^+ wasting, so always check and replenish Mg^{2+} stores.

Figure 7-19: Evaluation of hypokalemia

CALCIUM, PHOSPHORUS, AND MAGNESIUM DISORDERS

PREVIEW | REVIEW

- What are the common causes of hypercalcemia?
- What are the effects of **hypomagnesemia** and **hypermagnesemia** on serum Ca^{2+} level?
- In addition to its effect on Ca^{2+} levels, **hypomagnesemia** causes which other electrolyte abnormality?
- What is refeeding hypophosphatemia?

CALCIUM

Ca^{2+} balance is regulated by PTH and active vitamin D (i.e., calcitriol or $1,25\text{-(OH)}_2\text{-D}$), which affect Ca^{2+} reabsorption by the kidneys, Ca^{2+} absorption by the gut, and Ca^{2+} exchange with the bones. Ca^{2+} derangements are discussed extensively in the [Endocrinology](#) section.

The measured serum Ca^{2+} concentration is a total of free/ionized Ca^{2+} (iCa^{2+} , about 45% of total calcium), Ca^{2+} bound to albumin (~40%), and Ca^{2+} bound to other substances (~15%). iCa^{2+} is the state available for immediate use by the body and correlates with symptoms of hyper- or hypocalcemia. Measure iCa^{2+} directly to get the most reliable assessment of a patient's Ca^{2+} status.

Routinely, however, we measure the total serum Ca^{2+} . If serum albumin is low, the measured total serum Ca^{2+} decreases, but the iCa^{2+} may be normal. In this case, either measure the iCa^{2+} directly, or correct the total serum Ca^{2+} for hypoalbuminemia: For each 1-g/dL (10-g/L) decrease in albumin, add 0.8 mg/dL (0.2 mmol/L) to the measured total serum Ca^{2+} .

In pregnancy, Ca^{2+} absorption and excretion are increased because the active form of vitamin D, $1,25\text{-(OH)}_2\text{-D}$, is $> 2\times$ normal.

Know:

- Acidosis: $\downarrow$ fraction of bound $\text{Ca}^{2+} \rightarrow \uparrow \text{iCa}^{2+}$
- Alkalosis: $\uparrow$ fraction of bound $\text{Ca}^{2+} \rightarrow \downarrow \text{iCa}^{2+}$

Hypercalcemia

These are common causes of **hypercalcemia**:

- **Malignancy**: multiple myeloma, solid tumors with bone metastases, or paraneoplastic (PTH-related protein mediated)
- **Primary hyperparathyroidism**: Neck irradiation is a risk factor.
- **Granulomatous diseases**: sarcoidosis, tuberculosis
- **Medications**: thiazide diuretics (most common), theophylline, lithium
- **Excess vitamin D**, vitamin A, or calcium carbonate (milk-alkali syndrome)
- **Endocrine disorders**: adrenal insufficiency, thyrotoxicosis

Mild hypercalcemia is asymptomatic. Severe or acute hypercalcemia can cause confusion, nausea, anorexia, polyuria/polydipsia, volume depletion, and acute kidney injury. ECG shows shortened QT intervals. Moderately high chronic hypercalcemia (e.g., from primary hyperparathyroidism) can lead to kidney stones, HTN, and chronic kidney disease.

Severe hypercalcemia ($\text{Ca}^{2+} > 14 \text{ mg/dL}$ [3.5 mmol/L]) is most often caused by malignancy. It requires urgent treatment with aggressive volume replacement (most are volume depleted) with IV normal saline or other isotonic fluid. Use calcitonin and bisphosphates when hypercalcemia is persistent or severe. Use loop diuretics only if overt volume overload (peripheral or pulmonary edema) develops.

Hypocalcemia

Common causes of **hypocalcemia**:

- Vitamin D deficiency
- Severe pancreatitis
- Rhabdomyolysis
- Sepsis
- Hypomagnesemia and hypermagnesemia (Always check Mg^{2+} level!)

Less common causes:

- Hungry bone syndrome following parathyroidectomy
- Hypoparathyroidism
- Pseudohypoparathyroidism (PTH resistance)
- Citrate (in blood products; citrate binds calcium, causing low iCa^{2+} with normal total Ca^{2+})
- Advanced CKD (from low $1,25\text{-(OH)}_2\text{-D}$ and high PO_4^-)

Mild hypocalcemia is asymptomatic. Severe or acute hypocalcemia causes paresthesias, muscle twitching, tetany, seizures, and prolonged QT interval. Workup begins with ECG and labs, including albumin, PTH, vitamin D, phosphorus, and Mg^{2+} . Treat symptomatic hypocalcemia with Ca^{2+} replacement (PO or IV). Mild, asymptomatic hypocalcemia does not require treatment. Never give IV Ca^{2+} to a patient with hyperphosphatemia: Calcium phosphate can precipitate in blood vessels and organs! Replace Mg^{2+} and vitamin D if levels are low.

More information on hypercalcemia and hypocalcemia can be found in the [Endocrinology](#) section.

MAGNESIUM

Hypomagnesemia

Hypomagnesemia is **very common**. Causes are:

- Small bowel disease, resection, or bypass (malabsorption)
- Chronic diarrhea
- Acute pancreatitis
- Diuretics: kidney loss
- Recovery phase of AKI (ATN or obstruction)

- Bartter and Gitelman syndromes
- Nephrotoxic drugs (aminoglycosides, amphotericin B, cisplatin, pentamidine, cyclosporine, tacrolimus)
- Miscellaneous causes: proton pump inhibitors (impaired GI Mg^{2+} absorption)
- Hungry bone syndrome (after parathyroidectomy)
- **Alcohol abuse**
- Postsurgical state
- Foscanet (due to chelation)
- Hypercalcemia (causes renal Mg^{2+} loss)

The relationship between Ca^{2+} , Mg^{2+} , and K^{+} can be difficult to remember. Here's the quick synopsis:

- **Hypercalcemia** causes **hypomagnesemia**.
- Both hyper- and hypomagnesemia cause **hypocalcemia**.
- **Hypomagnesemia** causes **hypokalemia**.

Always check Mg^{2+} in patients presenting with hypocalcemia and/or hypokalemia because Mg^{2+} deficiency leads to renal Ca^{2+} and K^{+} wasting, so they are not correctable until Mg^{2+} stores are replenished!

Clinical manifestations of hypomagnesemia most often occur concurrently with other electrolyte and/or mineral derangements, such as hypokalemia or hypocalcemia. Muscle weakness, spasms, and tetany are the more common neuromuscular manifestations. ECG abnormalities precede cardiac manifestations (wide QRS and peaked T waves). Refractory **cardiac arrhythmias** are more likely with depleted Mg^{2+} stores (even with a **normal** serum level).

Replace Mg^{2+} orally in patients without symptoms, using a sustained release preparation (e.g., magnesium chloride, magnesium lactate)—appreciating that the deficit is usually huge if the serum Mg^{2+} level is low. Treat severe or symptomatic hypomagnesemia with 1–2 g magnesium sulfate as a single IV dose, followed by a continuous infusion of 4–8 g magnesium sulfate over 8–24 hours. Note: Each gram of magnesium sulfate ($MgSO_4$) has 8.12 mEq (4.06 mmol) of Mg^{2+} .

Hypermagnesemia

Hypermagnesemia, on the other hand, is **rare** and occurs due to:

- The use of Mg^{2+} -containing laxatives, antacids, or enemas in patients with advanced CKD (All are contraindicated in this group of patients.)
- $MgSO_4$ infusion during preeclampsia treatment
- Less common, but noteworthy, causes: tumor lysis syndrome, milk-alkali syndrome, lithium overdose, and Epsom salts ingestion (even as a gargle)

Symptoms begin when the Mg^{2+} level is $> 4\text{--}6$ mEq/L (2 mmol/L). There is initial nausea, followed by sedation, muscle **weakness**, and a loss of deep tendon reflexes, progressing to paralysis (including heart and respiratory muscles).

Treat acute symptoms according to renal function:

- Normal renal function—stop Mg^{2+} -containing products. Use normal saline and loop diuretics if needed.
- Moderate renal impairment—use the same treatment as above but start treatment with normal saline and loop diuretics.
- Severe renal impairment—start hemodialysis. In addition to above, use IV Ca^{2+} as a Mg^{2+} antagonist.

Do not forget to look for hypocalcemia, which can develop as a result of increased Mg^{2+} concentrations.

PHOSPHATE

Hyperphosphatemia

Acute increase in serum phosphate can be from:

- AKI (especially in rhabdomyolysis)
- Rapid cell turnover (tumor lysis or acute leukemia)
- Phosphate-containing laxatives (especially in CKD patients)

Chronic hyperphosphatemia is seen in:

- CKD
- Hypoparathyroidism
- Vitamin D toxicity (with hypercalcemia)

Hyperphosphatemia is usually asymptomatic, but severe acute hyperphosphatemia can cause acute renal failure (acute phosphate nephropathy). Treat acute hyperphosphatemia with volume expansion (IV normal saline), keeping an eye on the Ca^{2+} . For a discussion of the treatment of chronic hyperphosphatemia in CKD (the most common situation), see [CKD – Mineral and Bone Disorders \(MBDs\)](#) on page 7-31.

Hypophosphatemia

Clinical manifestations of hypophosphatemia include irritability, muscle weakness, seizures, coma, and death. Severe hypophosphatemia ($PO_4^{3-} < 1$ mg/dL) can cause rhabdomyolysis (as can low K^{+}), cardiomyopathy, respiratory failure, and nervous system dysfunction.

Refeeding syndrome is an important cause of severe hypophosphatemia in patients with malnutrition and/or alcoholism. Refeeding of malnourished patients can cause severe hypophosphatemia by redistribution of phosphate into cells. Even if a malnourished patient has a normal phosphate level on admission, the patient can become severely hypophosphatemic a few days after a normal diet, tube feeding, or parenteral nutrition is established. This is due to the muscle cells becoming anabolic and taking up phosphate as the glycogen level returns to normal. Similarly, in the ICU, when a malnourished patient is started on TPN, the glucose load causes phosphate uptake by cells, resulting in severe hypophosphatemia. This form of refeeding hypophosphatemia is a common clinical scenario.

Alcoholic patients with hepatic encephalopathy often have a respiratory **alkalosis** and may receive **glucose** solutions, both of which cause phosphate to enter cells. This, in turn, causes severe **hypophosphatemia**, which can precipitate acute rhabdomyolysis.

A malnourished alcoholic presenting with **alcoholic ketoacidosis** is often treated glucose-containing IV fluids. This can result in severe hypophosphatemia and, subsequently, rhabdomyolysis.

Do not forget about the renal-wasting causes of hypophosphatemia:

- **Primary hyperparathyroidism** (causes renal phosphaturia)
- **Fanconi syndrome** (proximal tubular losses of phosphate, glucose, amino acids, and HCO_3^-)
- **Tumor-induced osteomalacia** (a.k.a. oncogenic osteomalacia)

Treatment of hypophosphatemia: Treat underlying cause of low phosphate, especially in renal phosphate wasting syndromes.

Give supplemental phosphate to patients with DKA or those having alcohol withdrawal; include it in hyperalimentation fluid.

Be cautious replacing phosphate in patients with CKD: They cannot excrete it, and aggressive phosphate supplementation can cause severe hyperphosphatemia.

VOLUME DEPLETION

Volume depletion is diagnosed based on history (see below) and physical exam findings of orthostatic hypotension, tachycardia, dry mucous membranes, and decreased skin turgor. The cause of volume depletion is usually evident from a history of:

- **Vomiting** can cause volume depletion with:
 - Metabolic **alkalosis**
 - Low serum Cl^- (losing stomach HCl in the emesis—makes sense)
 - Hypokalemia (from renal K^+ wasting mediated by aldosterone)
- **Diarrhea** can cause:
 - Metabolic **acidosis** (NAGMA; HCO_3^- is lost in the stool.)
 - An appropriately high serum Cl^- (Cl^- is avidly reabsorbed to increase intravascular volume.)
- **Loop diuretics and thiazide diuretics** can cause:
 - Metabolic **alkalosis** with low serum Cl^- (like vomiting)
 - Hypokalemia
 - These are both due to high distal Na^+ delivery in the setting of a high aldosterone state. Aldosterone stimulates Na^+ reabsorption, which is linked to H^+ and K^+ secretion.
 - High urinary Cl^- if the patient is actively taking the drug (unlike vomiting)

- **Osmotic diuresis** (e.g., hyperglycemia) can cause:
 - High urine output
 - Urine osmolality same as plasma (250–300 mOsm/kg)

These causes are summarized in Table 7-12. See the discussion of thiazides under **Thiazide-Type Diuretics** on page 7-63. Some diuretic-resistant patients with HF are on both loop and thiazide diuretics. This combination has the potential to cause severe volume depletion with prerenal AKI, so patients on both these drugs need to be monitored carefully. Treat volume depletion with isotonic IV fluids (e.g., normal saline, lactated Ringer's). Patients with metabolic acidosis due to diarrhea may benefit from HCO_3^- replacement.

Table 7-12: Causes of Volume Depletion

	Serum		Urine	
	Cl^-	HCO_3^-	Cl^- (mEq/L)	Osm (mOsm/kg)
Prolonged Vomiting	Low	High	Low (< 10)	High (> 300)
Prolonged Diarrhea	High	Low	Low (< 10)	High
Thiazides	Low	High	High	High
Osmotic Diuresis (hyperglycemia, mannitol)	Normal	Normal	High	250–350 (but high volume)

HYPERTENSION (HTN)

PREVIEW | REVIEW

- In which age groups does newly diagnosed hypertension (HTN) suggest that the cause might be secondary?
- What is the main cause of renovascular HTN in men > 50 years old?
- What is the main cause of renovascular HTN in women < 40 years old?
- What does the combination of a continuous abdominal bruit imply in a hypertensive patient?
- How do you confirm the diagnosis of primary aldosteronism?
- Which types of diuretics are the 1st line agents for the treatment of HTN?
- Angiotensin-converting enzyme inhibitors/angiotensin receptor blockers are absolutely contraindicated in which patients?
- Why are β -blockers not recommended as 1st line drugs for HTN?
- What is the goal for blood pressure reduction in patients who present with hypertensive crisis?

NOTE

Our recommendations for diagnosis and treatment of HTN are based on the 2017 American College of Cardiology and American Heart Association (ACC/AHA) Hypertension Guidelines.

CLASSIFICATION

HTN is diagnosed by the average of 2 or more office BP measurements. Out-of-office BP measurements (ambulatory BP monitors or home BP monitoring) are recommended to confirm the diagnosis of HTN.

HTN definitions, according to the 2017 ACC/AHA Guidelines:

- Normal: < 120/< 80 mmHg
- Elevated: 120–129/< 80 mmHg
- HTN Stage 1: 130–139/80–89 mmHg
- HTN Stage 2: > 140/> 90 mmHg

EVALUATION OF HTN

The following is the standard evaluation for newly diagnosed HTN. Initially, look for cardiovascular disease risk factors and consider **secondary causes** in patients with resistant HTN and those with indications for further screening (see [Secondary HTN](#) and [Table 7-13](#)).

History: Ask about personal and family history or symptoms of CVD (cardiovascular disease), peripheral vascular disease (PVD), cerebrovascular disease, renal disease, DM, and lipid problems. Ask about the use of alcohol, smoking, street drugs, prescribed medications, diet, and psychosocial history. Also ask about symptoms of sleep apnea, including daytime somnolence.

Perform a full physical exam, including:

- BP: Use the correct size cuff; measure at least twice, with patient seated after at least 5 minutes of rest; the arm should be resting with the cuff at the level of the heart.
- General: height, weight (for BMI calculation), and waist circumference (to evaluation for possible metabolic syndrome)
- HEENT: fundoscopic exam for hypertensive changes
- Neck: bruits, enlarged thyroid
- Lungs: rales, wheezes
- Heart: rate, rhythm, murmurs, extra heart sounds, and evaluation of the PMI (point of maximal impulse)
- Abdomen: abnormal masses, bruits, abnormal pulsations
- Extremities: decreased pulses, bruits, and edema

Initial lab tests for all hypertensive patients:

- Serum chemistries (Na^+ , K^+ , Cl^- , HCO_3^- , creatinine, fasting glucose)

Table 7-13: Causes of Secondary Hypertension

Cause	Clinical Clues
Renovascular HTN	Continuous abdominal bruit Asymmetric kidneys
Primary aldosteronism	Hypokalemia
Pheochromocytoma	Labile HTN, pallor; sometimes with medullary thyroid cancer, primary hyperparathyroidism (MEN2)
Cushing syndrome (hypercortisolism)	Moon facies, muscle weakness, striae, easy bruising
Coarctation of the aorta	Decreased BP in lower extremities or absent/delayed femoral pulses
Polycystic kidney disease	Abdominal or flank masses Family history
Chronic kidney disease	Elevated creatinine or abnormal U/A
Hyperparathyroidism Granulomatous disease	Hypercalcemia
Drugs	Use of NSAIDs, oral contraceptives, illicit drugs (cocaine, amphetamines), alcohol, VEGF inhibitors (for cancer treatment)
Obstructive sleep apnea	Snoring, daytime somnolence, obesity

- Fasting lipid panel (cholesterol, triglycerides, low-density lipoprotein, high-density lipoprotein), serum Ca^{2+}
- U/A
- 12-lead ECG

Use an online calculator to determine the patient's **10-year ASCVD (atherosclerotic cardiovascular disease) risk**. The 10-year ASCVD risk is determined by patient age, sex, race, cholesterol, BP, and history of diabetes mellitus or smoking. The 10-year ASCVD risk determines the BP threshold for HTN treatment (see [Treatment of HTN on page 7-63](#)). Assessment of 10-year ASCVD risk is recommended by both the 2017 ACC/AHA Hypertension Guidelines and by the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease.

Most (95%) of all HTN is **primary** (i.e., essential, idiopathic). Both genetic and environmental risk factors contribute to primary HTN. Morbidity and mortality in primary HTN are higher for **men** than for women and are higher for **African Americans** than for Caucasians. Risk factors for primary HTN include black race and obesity.

Secondary HTN comprises only 5% of HTN cases and is discussed next.

SECONDARY HTN

Indications for evaluation for secondary causes of HTN:

- Sudden onset of HTN
- Onset at < 30 years of age
- Signs of end-organ damage
(See [Table 7-14 on page 7-66](#).)

- Severe or resistant HTN (BP above target despite at least 3 medications, with 1 being a diuretic)
- HTN with hypokalemia or metabolic alkalosis

Table 7-13 summarizes the causes of secondary HTN.

Renovascular HTN

Renovascular HTN is caused by stenosis of one or both renal arteries. Renal artery stenosis decreases perfusion of the kidney(s), leading to increased renin production. High renin leads to high aldosterone (secondary aldosteronism) and angiotensin II, which cause HTN via 1) systemic vasoconstriction and 2) increased renal sodium retention.

Renovascular HTN is relatively common. The 2 main causes of renovascular HTN are:

- 1) Atherosclerotic renal artery stenosis (unilateral or bilateral; mainly affects patients > 50 years of age, especially patients with DM and PVD)
- 2) Fibromuscular dysplasia (often bilateral; mainly affects patients < 40 years of age; female > male)

Less common causes of renovascular HTN include scleroderma and vasculitis (e.g., Takayasu arteritis, polyarteritis nodosa).

Consider renovascular HTN when you see moderate to severe HTN with onset in patients < 30 years of age (fibromuscular dysplasia), new onset of HTN in patients > 55 years of age (atherosclerotic), HTN + unexplained hypokalemia, or accelerated HTN.

A continuous epigastric or abdominal bruit in a hypertensive patient is a clue there may be renovascular HTN—especially if they have other risk factors. The finding of asymmetric kidneys (> 1-cm size difference) is often the result of renovascular HTN affecting the side with the smaller kidney.

Bilateral renal artery stenosis can cause recurrent flash pulmonary edema and/or rapid decline in kidney function after starting an ACEI/ARB.

Screen patients for renovascular HTN only if they are likely to benefit from intervention (see Treatment of HTN on page 7-63). Definitely do not screen elderly patients with mild HTN and a normal serum K⁺.

Noninvasive tests to assess for renal artery stenosis are CT angiography, MR angiography, and duplex Doppler U/S of the renal arteries, with the first 2 being the most sensitive.

Arteriography is the gold standard for diagnosis of renovascular HTN, but the procedure is invasive, with potential for serious complications. Use it to confirm positive noninvasive screening tests when there is an indication for intervention. Fibromuscular dysplasia shows up as a “string of beads” with multiple, small aneurysmal dilatations (Figure 7-21). An atherosclerotic lesion is usually a single, proximal stenosis with distal dilation.

Figure 7-21: Aneurysmal dilatations in fibromuscular dysplasia

Treat fibromuscular dysplasia with revascularization (percutaneous transluminal renal angioplasty [PTRA])—this can be curative and is almost always indicated. For atherosclerotic renovascular HTN, intervention with angioplasty or surgery is not usually beneficial. Large clinical trials, such as the Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL) and Angioplasty and Stenting for Renal Artery Lesions (ASTRAL), have shown no benefit of PTRA (with or without stenting) for patients with atherosclerotic renovascular HTN, when compared with medical therapy alone. Therefore, patients with renovascular HTN should be treated medically. BP in renovascular HTN often responds well to ACEI/ARB treatment, but you need to watch for a decline in renal function.

Intervention in patients with atherosclerotic renovascular HTN should be considered if 1 of these is present:

- 1) Uncontrolled BP despite ≥ 3 antihypertensive medications
- 2) Recurrent “flash” pulmonary edema
- 3) Progressive decline in renal function (as an attempt to prevent progression to ESRD, often unsuccessfully)

Primary Aldosteronism

Normally, aldosterone is secreted by the adrenal zona glomerulosa (outermost layer) in response to AT II and hyperkalemia. Aldosterone increases Na⁺ reabsorption and K⁺ secretion in the principal cells of the late distal tubule and collecting duct. Suspect a high aldosterone state (primary or secondary) in a person with hypokalemia and HTN because:

- aldo → ↑ K⁺ secretion → hypokalemia and
- aldo → ↑ Na⁺ reabsorption → ↑ intravascular volume → ↑ BP.

There are 2 main causes of primary aldosteronism: aldosterone producing adenoma (70%) and bilateral adrenal hyperplasia (~ 25%). Adrenal carcinoma rarely causes primary aldosteronism.

According to the 2016 Endocrine Society Guidelines, screen patients with the following BP and HTN values for primary aldosteronism:

- BP > 150/100 mmHg on 3 different occasions on different days
- BP > 140/90 mmHg despite treatment with 3 antihypertensive drugs (including a diuretic)
- Controlled BP (< 140/90 mmHg) on 4 antihypertensive drugs
- HTN and hypokalemia
- HTN and adrenal incidentaloma
- HTN and sleep apnea
- HTN and family history of early-onset HTN or cerebrovascular accident (CVA)
- HTN and 1st degree relative with primary aldosteronism

Note: The K⁺ is normal in > 50% of patients with primary aldosteronism, so normal K⁺ does not exclude the diagnosis.

The clinical approach to screening and diagnosis of primary aldosteronism is summarized in [Figure 7-22](#) and [Figure 7-23](#). Screen with a plasma aldosterone concentration (PAC, ng/dL) and plasma renin activity (PRA, ng/mL/hour) to calculate the aldosterone:renin ratio. A ratio > 20 with a PAC > 10 ng/dL is considered positive. This makes sense: In primary aldosteronism, the aldosterone level is high, but renin is suppressed. If the renin and aldosterone are both high and aldosterone:renin ratio is < 30, consider secondary aldosteronism, including renovascular HTN, diuretic use, or (rarely) a renin-secreting tumor.

Figure 7-22: Diagnosis of primary aldosteronism

BP medications can interfere with the PAC:PRA ratio. Aldosterone antagonists and amiloride elevate the PRA; stop these at least 4 weeks before testing. ACEIs/ARBs will increase the renin and lower the aldosterone, so a high PAC:PRA ratio in a patient on an ACEI/ARB is highly suggestive of primary aldosteronism. If the PAC:PRA ratio is nondiagnostic, repeat it after stopping the ACEI/ARB (if possible).

If the PAC:PRA ratio is elevated, confirm the diagnosis of primary aldosteronism with a saline infusion test or oral Na⁺ loading. For the saline infusion test, give 2 L of normal saline IV over 4 hours while the patient is recumbent and then check the aldosterone level. Alternatively, give oral Na⁺ (5,000 mg/day, via high-Na⁺ diet or NaCl tablets) for 3 days and then check a 24-hour urine for aldosterone, Na⁺ (to assess compliance with the oral salt loading), and creatinine (to assess completeness of the collection). In either situation, if aldosterone is not suppressed, the patient has primary aldosteronism.

If the plasma aldosterone concentration is > 20 ng/dL and spontaneous hypokalemia is present, confirmatory testing with salt loading or saline suppression test is not necessary.

There are 2 main causes of primary aldosteronism: aldosterone-producing adenoma and bilateral adrenal hyperplasia. Aldosterone-producing adenoma can be treated either surgically (adrenalectomy) or medically (aldosterone antagonist, e.g., spironolactone). Bilateral adrenal hyperplasia can only be treated medically. Before pursuing further workup (e.g., imaging), determine if your patient would desire and be a candidate for surgery. If not, then you can stop here—just treat medically! If your patient is a good surgical candidate and would desire surgical management, then the next step is to determine if it is an aldosterone-producing adenoma or bilateral hyperplasia (see [Figure 7-23](#)).

Start with a CT scan of the adrenals. A solitary hypodense adrenal nodule in a young patient (< 35 years of age) with primary aldosteronism can go straight to surgical adrenalectomy. For older patients (> 35 years of age) and all patients with normal CT imaging, do adrenal vein sampling to determine if a functional adenoma is present. If an aldosterone-producing adenoma is confirmed, proceed with surgical adrenalectomy. If not, treat with spironolactone or eplerenone.

Pheochromocytoma

See the [Endocrinology](#) section for details on pheochromocytomas.

Other Secondary Causes of HTN

Endocrinologic causes of secondary HTN are pheochromocytoma, Cushing syndrome, hypothyroidism, primary hyperparathyroidism, and 11- β -hydroxylase deficiency. These are discussed in the [Endocrinology](#) section.

Other causes of secondary HTN are coarctation of the aorta, chronic kidney disease, sleep apnea, drugs (including oral contraceptive medications), excessive alcohol, and Liddle syndrome. Liddle syndrome is caused by an activating mutation in the Na⁺ channel of the collecting duct; patients present with HTN and hypokalemia from a young age. Sleep apnea is discussed in the [Pulmonary Medicine](#) section.

Figure 7-23: Primary aldosteronism subtype classification

TREATMENT OF HTN

Treatment of HTN with lifestyle interventions and BP-lowering medication is effective for both primary and secondary prevention of cardiovascular events. Lifestyle interventions are recommended in all hypertensive patients. 1st line pharmacologic agents for the treatment of HTN are thiazide diuretics, ACEIs or ARBs, and calcium channel blockers. We first discuss the lifestyle interventions and drugs used for HTN, and then we discuss BP targets. Treatment recommendations are according to the 2017 ACC/AHA Hypertension Guidelines.

Lifestyle Modification

Lifestyle modification is recommended in all adults with HTN:

- Counsel patients to **quit smoking** and to have no more than **moderate alcohol consumption** (≤ 2 drinks/day for men, ≤ 1 drink/day for women).
- For overweight and obese patients, **weight loss** will lower BP. Aim for at least 1-kg reduction in body weight in overweight adults. BP falls by about 1 mmHg for every 1 kg of weight loss!
- **Low-Na⁺ diet** ($< 1,500$ mg/day if possible) will lower BP by 5–6 mmHg.
- Recommend the **DASH diet**, a diet high in fruits, vegetables, whole grains, and low-fat dairy. Encourage fruits and vegetables—**K⁺-rich foods!**
- All forms of **exercise** are helpful: Aerobic exercise has the biggest impact, but dynamic resistance and isometric resistance are also beneficial.

Diuretics

Thiazide-Type Diuretics

Thiazide diuretics are 1st line agents for the treatment of HTN. The major thiazide-type diuretics are hydrochlorothiazide and chlorthalidone.

Hypokalemia is the most common side effect of thiazides. Diuretic-induced hypokalemia can be dangerous in patients with underlying cardiac problems and cirrhosis because of the potential for arrhythmias (especially if on digoxin) and hepatic encephalopathy/coma. Hypokalemia usually develops within the first 3 weeks of use. Use the lowest dose needed to achieve the desired effect and check the K⁺ level each time the dose is changed.

Thiazide diuretics can also cause hypomagnesemia. In HF and cirrhotic patients, it is best to keep the K⁺ > 4 mEq/L (4 mmol/L) with supplementation or K⁺-sparing diuretics. Thiazide diuretics can also cause severe hyponatremia in patients with poor solute intake, particularly the elderly.

Aldosterone Antagonists

The aldosterone antagonists are spironolactone and eplerenone. Aldosterone antagonists are not 1st line for HTN treatment but are useful in patients with resistant HTN. Hyperaldosteronism contributes to diuretic resistance, an effect that can be minimized by aldosterone antagonist therapy.

Remember: Aldosterone antagonists are K⁺ sparing, which means that they tend to cause **hyperkalemia**, not hypokalemia. They are helpful in patients with hypokalemia due to primary aldosteronism or thiazide/loop diuretics but can lead to hyperkalemia in patients on ACEIs or ARBs.

Other Diuretics

Loop diuretics are not usually used to treat chronic HTN unless there is severe volume overload and/or advanced chronic kidney disease. Other K^+ -sparing diuretics (e.g., amiloride) are sometimes used in combination with thiazide diuretics in patients with chronic HTN to prevent hypokalemia. Carbonic anhydrase inhibitors are not useful in the treatment of HTN.

ACEIs, ARBs, and Renin Inhibitors

Review

A brief review of the renin-angiotensin-aldosterone system (RAAS; [Figure 7-24](#)): Renin is released from the juxtaglomerular apparatus in the kidney in response to decreased effective arterial blood volume. Renin converts angiotensinogen to angiotensin I (AT I). AT I is converted to AT II by ACE. AT II increases BP by **direct vasoconstriction**, potentiation of the **sympathetic nervous system**, increased Na^+ reabsorption in the proximal tubule, and stimulation of **aldosterone production** by the adrenal gland.

ACEIs (e.g., lisinopril, enalapril, benazepril) inhibit conversion of AT I to AT II, decreasing AT II and aldosterone production. ARBs block the binding of AT II to its primary receptor (AT1). By blocking AT II production/effect, ACEIs/ARBs result in **dilatation** of the **efferent arteriole** (after the glomerulus), which decreases glomerular capillary pressure. This **decreased glomerular pressure** is beneficial in both **diabetic** and **hypertensive nephropathies**, as well as other types of chronic kidney disease. ACEIs/ARBs can also decrease GFR in patients with decreased effective circulating volume.

Indications for ACEIs / ARBs

ACEIs/ARBs are 1st line agents for antihypertensive drug therapy. Other indications for ACEIs/ARBs are systolic HF, history of ST-elevation myocardial infarction (STEMI) or anterior non-STEMI, chronic kidney disease (especially with proteinuria), and diabetic kidney disease (especially with increased albuminuria).

ARBs (i.e., candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan) are recommended in patients with indications for ACEIs but who are unable to tolerate them, usually due to cough.

Complications of ACEIs / ARBs

ACEIs/ARBs can cause hyperkalemia and AKI. Stop or reduce the dose of the ACEI/ARB if the creatinine increases to > 30% over baseline and/or the serum K^+ is persistently high. Patients on NSAIDs or aldosterone antagonists are particularly susceptible to hyperkalemia with ACEIs/ARBs.

Up to 20% of patients have to stop an ACEI because of cough. Angioedema is a rare but potentially fatal side effect of ACEIs. ARBs do not cause angioedema or cough.

Know that the combination of an ACEI + ARB for the treatment of HTN can cause hypotension, syncope, and acute kidney injury. Prescribe an ACEI or an ARB but **do not combine** them.

ACEIs and ARBs are **teratogenic** and therefore contraindicated in pregnancy, particularly in the 2nd and 3rd trimesters (for more information, see the [Women's and Men's Health](#) section). Although ACEIs/ARBs can be very beneficial in patients with chronic kidney disease, renovascular HTN, HF, polycystic kidney disease, or

Figure 7-24: Renin-angiotensin-aldosterone system

hypertensive nephrosclerosis, they must be used with caution because there is risk of AKI and hyperkalemia. ACEIs/ARBs have minimal CNS and sexual side effects.

Direct Renin Inhibitor

The direct renin inhibitor, **aliskiren**, blocks renin production. Aliskiren may be used in patients who would benefit from blockade of the RAAS but cannot take ACEIs/ARBs. **Do not** combine aliskiren with an ACEI/ARB. Renin inhibitors are also teratogenic so are contraindicated in pregnant patients (for more information, see the [Women's and Men's Health](#) section).

Calcium Channel Blockers (CCBs)

CCBs include:

- Dihydropyridines (e.g., amlodipine, nifedipine)
- Nondihydropyridines (e.g., verapamil, diltiazem), which **also** reduce heart rate and cardiac contractility

Both drug types are used to treat HTN, as well as angina and arrhythmias.

Complications can include **constipation** (especially with verapamil) and **edema** (especially with dihydropyridines). Because of negative inotropic and chronotropic effects, do not give verapamil or diltiazem to patients who are also taking β -blockers or those who have heart block or severe HF.

Several studies have shown adverse events (e.g., increased risk of death after MI) with short-acting CCBs (but not with long-acting ones).

β -Blockers

β -blockers (e.g., atenolol, bisoprolol, carvedilol, labetalol, metoprolol) decrease cardiac output, sympathetic tone, and renin production. Each drug differs by its amount of lipid solubility, cardioselectivity, and sympathomimetic activity. The 2017 ACC/AHA guidelines **do not** recommend β -blockers for the initial treatment of HTN because they result in a higher rate of cardiovascular death, myocardial infarction, or stroke compared with the use of an ARB, especially in the elderly.

Use β -blockers for HTN in patients with:

- Previous MI
- Stable angina
- Stable HF with reduced ejection fraction
- Atrial fibrillation (rate control)

Avoid β -blockers in patients with:

- Reactive airway disease
- Frequent hypoglycemia
- Hyperlipidemia
- PVD

Recall that nonselective β -blockers (e.g., propranolol, labetalol) increase the serum K^+ level slightly (~ 0.5 mEq/L [0.5 mmol/L]). β -blockers can exacerbate symptoms in patients with decompensated HF. Other complications include fatigue, bradycardia, erectile dysfunction, depression, and weight gain.

Other Antihypertensive Agents

Patients with resistant HTN sometimes require additional medications to meet BP targets. 2nd line agents for BP treatment include:

- α -Blockers (e.g., terazosin, prazosin)
- Central α_2 -agonists (e.g., clonidine)
- Direct vasodilators (e.g., hydralazine, minoxidil)
- Aldosterone receptor antagonists (e.g., spironolactone, eplerenone)

BP Treatment Goals

BP treatment targets have changed over the years based on clinical trials and professional guidelines. Current BP guidelines are heavily influenced by the 2015 SPRINT trial, which showed a lower BP target (SBP < 120 mmHg, compared with SBP < 140 mmHg) decreased both all-cause mortality and the primary outcomes of MI, acute coronary syndrome, CVA, HF, and CVD death.

The 2017 ACC/AHA Guidelines for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults incorporate the SPRINT results, have been endorsed by most professional organizations, and are the basis for the HTN recommendations presented here.

ACC / AHA BP Targets

For most patients, the threshold for starting pharmacologic therapy is **$> 130/80$ mmHg**, and the treatment target BP is **$< 130/80$ mmHg**. The only exception is for the lowest-risk patients, with no clinical CVD and a 10-year ASCVD risk of $< 10\%$. For these patients, initiate pharmacologic therapy at a BP $\geq 140/90$ —but once treatment is initiated, your target is still $< 130/80$ (same as everyone else).

HTN is common in older patients (a 60–80% incidence!). **Isolated systolic** HTN is particularly common in the elderly. The degree of systolic HTN and the pulse pressure (SBP minus DBP) directly correlate with poor outcomes, so isolated systolic HTN should be treated.

The ACC/AHA guidelines recommend a **systolic BP target of < 130 mmHg in patients > 65 years of age**; this is the same as for younger patients.

Recommend lifestyle modification in all hypertensive patients (see [Lifestyle Modification on page 7-63](#)). 1st line agents for treatment of HTN include thiazide and thiazide-like diuretics, ACEIs/ARBs, and CCBs. For patients with Stage 2 HTN (SBP > 140 mmHg or DBP > 90 mmHg) whose BP is $> 20/10$ mmHg above target, the ACC/AHA recommends starting two 1st line agents from different classes.

Other ACC / AHA Recommendations

Additional ACC/AHA recommendations are:

- Simultaneous use of ACEI, ARB, and/or renin inhibitor is potentially harmful and is not recommended.
- Do not use nondihydropyridine CCBs (e.g., diltiazem) in patients with HF with reduced ejection fraction.
- In patients with stable ischemic heart disease, use a β -blocker, ACEI, or ARB. If angina is present and BP goal is not met, use dihydropyridine CCB (e.g., amlodipine).
- In patients with CKD and albuminuria, an ACEI/ARB is 1st line.
- In acute intracerebral hemorrhage, immediate lowering of SBP to < 140 mmHg is not beneficial and may be harmful.
- In acute ischemic stroke treated with IV thrombolytics, lower BP to < 180/100 mmHg.
- In acute ischemic stroke and BP > 220/110 mmHg not treated with IV thrombolytics, lower BP by 15% during the first 24 hours.
- In acute ischemic stroke and BP < 220/110 mmHg not treated with IV thrombolytics, treating HTN within the first 48–72 hours is not beneficial. Wait and initiate/restart antihypertensive therapy after the patient is neurologically stable.
- In pregnant patients, 1st line agents include methyldopa, nifedipine, and labetalol (see the [Women's and Men's Health](#) section). Do not use ACEIs/ARBs or direct renin inhibitors.

HYPERTENSIVE URGENCY AND EMERGENCY

Hypertensive crisis is defined as an acute and severe increase in systolic BP $\geq$ 180 mmHg or a diastolic BP $\geq$ 120 mmHg. There are 2 types, depending on whether there are signs of target organ damage.

Hypertensive emergency is defined as a severe elevation in BP (> 180/120 mmHg) associated with new or progressive end-organ damage. Signs of target organ damage include any of the signs and symptoms in [Table 7-14](#).

American College of Cardiology (ACC)/American Heart Association (AHA) guidelines recommend that patients with hypertensive emergency be admitted to an intensive care setting for continuous BP monitoring and control of BP with IV medications. Most patients with hypertensive crisis should have BP lowered by no more than 25% in the first hour, then to 160/100 within 2–6 hours, then cautiously to normal over the next 24–48 hours.

The following are important exceptions. Patients with aortic dissection should have systolic BP lowered to < 120 mmHg. Patients with severe preeclampsia/eclampsia or pheochromocytoma crisis should have systolic BP lowered to < 140 mmHg. Patients with acute CVA should be managed as noted in [Table 7-15](#).

IV medications used to treat hypertensive emergency include nicardipine, nitroprusside, labetalol, esmolol, hydralazine, enalaprilat, and fenoldopam (a peripheral dopamine-1 receptor agonist). IV drugs are preferred for initial management because oral drugs reduce the BP in a less rapid and less predictable way (see [Table 7-15](#)). Nitroprusside is metabolized to cyanide, so its use should be limited to < 24–48 hours, and it should not be used at all in patients with chronic kidney disease or pregnancy (for more on HTN during pregnancy, see the [Women's and Men's Health](#) section). Keep in mind that **too rapid** of a drop in BP can cause an ischemic stroke or myocardial infarction.

Hypertensive urgency is a severe increase in BP in an otherwise stable patient, with no acute signs of end-organ damage. These patients do not require hospitalization or emergency department evaluation but can be treated by restarting or intensifying antihypertensive medications, with close outpatient follow-up.

Table 7-14: End-Organ Damage in Hypertensive Emergency

End Organ	Signs or Symptoms	Type of Damage
Brain	Seizure (including eclampsia)	Posterior reversible leukoencephalopathy, hypertensive encephalopathy
	Focal neurologic symptoms	Transient ischemic attack, ischemic stroke, or intracerebral or subarachnoid bleed
	Headache, confusion, nausea/vomiting	Increased intracranial pressure Hypertensive encephalopathy
Heart	Dyspnea	Acute HF
	Chest pain, ECG changes	Acute coronary syndrome
Blood vessels	Severe/Acute back pain	Acute aortic dissection
	Anemia, low platelets	Microangiopathic hemolytic anemia
Kidney	AKI, proteinuria	Thrombotic microangiopathy
Retina	Papilledema, flame hemorrhages, exudates	Hypertensive retinopathy

Table 7-15: Treatment of Hypertensive Emergencies

Clinical Scenario	BP Reduction*	IV Drug Options	Additional Considerations
Hypertensive emergency without a compelling indication (below)	Reduce systolic BP by no more than 25% within the 1 st hour; to < 160/100 mmHg within the next 2–6 hours; then cautiously to normal in the next 24–48 hours.	Labetalol, esmolol, nicardipine	All patients with hypertensive emergency should be managed in an intensive care setting.
Acute ischemic stroke	tPA candidate: • Lower BP to < 185/110 mmHg before giving tPA; maintain BP < 180/105 after tPA. tPA not planned: • If BP ≥ 220/120 mmHg, lower by 15% over first 24 hours. • If BP < 220/120, lowering BP in the first 48–72 hours is not beneficial.	Labetalol, esmolol, nicardipine	Avoid nitroprusside (can lead to intracranial edema).
Acute hemorrhagic stroke	Reduce BP to < 180/105 mmHg. Do not lower BP to < 140/90 (potential harm).	Labetalol, esmolol, nicardipine	Avoid nitroprusside (can lead to intracranial edema).
Hypertensive encephalopathy	Reduce BP by 20–25% to reduce intracranial pressure.	Labetalol, esmolol, nicardipine	Avoid nitroprusside (can lead to intracranial edema).
Acute HF	Reduce BP to improve acute pulmonary edema.	Nitroglycerin, nitroprusside, furosemide	Avoid β-blocker and calcium channel blocker.
Acute coronary syndrome	Reduce BP to reduce cardiac workload and improve coronary perfusion.	Nitroglycerin, nitroprusside, labetalol, metoprolol, esmolol, nicardipine	Consider Type A dissection as the etiology of acute coronary syndrome. Avoid selective β-blockers if cocaine abuse is suspected.
Acute aortic dissection	Reduce BP to < 120/80 mmHg (lower if tolerable) and heart rate to < 60 bpm to reduce wall shear stress.	Labetalol, nitroprusside, nicardipine	Avoid β-blockers if severe aortic regurgitation is noted.
Acute renal failure	Reduce intraglomerular pressure.	Nitroprusside, nicardipine	Avoid ACEIs/ ARBs unless scleroderma renal crisis is suspected. Avoid nitroprusside (increased toxicity risk).
Severe preeclampsia and eclampsia	Reduce systolic BP to < 140 mmHg.	Labetalol, hydralazine, nicardipine	Definitive treatment is delivery of fetus. Avoid nitroprusside (can lead to fetal cyanide poisoning).
Sympathetic crisis	Reduce BP until symptom resolution.	Phentolamine, nitroglycerin, nicardipine, labetalol	Avoid β-blocker monotherapy (except for labetalol).
Pheochromocytoma crisis	Reduce SBP to < 140 mmHg.	Labetalol, phentolamine	Always give α-blocker (phentolamine) before β-blocker.

*General rule: BP should be lowered no more than 25% within the 1st hour and then to 160/100–110 mmHg within 2–6 hours.

THE MEDSTUDY HUB: YOUR GUIDELINES AND REVIEW ARTICLES RESOURCE

For both review articles and current internal medicine practice guidelines, visit the MedStudy Hub at

medstudy.com/hub

The Hub contains the **only** online consolidated list of **all** current guidelines focused on internal medicine. Guidelines on the Hub are easy to find, continually updated, and linked to the published source. MedStudy maintains the Hub as a service to the medical community and makes it available to anyone and everyone at no cost to users.

NORMAL RED BLOOD CELL (RBC) FUNCTION

HEMOGLOBIN (Hgb)

The Hgb protein within RBCs carries oxygen from the lung to the tissues. Oxygen is carried by the iron in the heme groups.

Adult hemoglobin (HbA) is a tetramer with 2 α - and 2 β -globular protein subunits (a.k.a. globin chains; Figure 8-1). Each of these globin chains is covalently linked to a single heme, which is a complex of ferrous iron and protoporphyrin. Adult hemoglobin is mostly HbA with a little HbA₂ and very little HbF.

Figure 8-1: (A) Hemoglobin with 2 α - and 2 β -globin chains and 1 iron-containing heme group in each protein subunit. (B) The heme group with a porphyrin ring complexed with iron

Fetal hemoglobin (HbF) has 2 γ chains in the place of the 2 β chains. At birth, a child generally has 60–80% HbF, with the rest being HbA. By 1 year of age, most of the γ chains have converted to β chains.

The Hgb electrophoresis pattern in an adult is:

- HbA ($\alpha_2\beta_2$) > 97.5%
- HbA₂ ($\alpha_2\delta_2$) < 2.5%
- HbF < 0.6%

NORMAL ERYTHROPOIESIS

Erythropoietin (EPO) regulates RBC production. Normal erythropoiesis involves the maturation of pluripotent stem cells into proerythroblasts → erythroblasts → reticulocytes → mature RBCs (Figure 8-2). Reticulocytes are immature RBCs, each of which has lost its nucleus but retained its ribonucleic acid (RNA). The cytoplasmic RNA stains a gray-purple color (polychromasia) on Wright stain. Reticulocytes can be quantified by special stains or flow cytometry, yielding a reticulocyte count.

The mature RBCs contain no RNA and survive for approximately 120 days. Throughout their lifespan, RBCs pass repeatedly through the spleen, where old or damaged

Figure 8-2: Erythropoiesis

cells are ingested by macrophages. The Hgb is catabolized into its heme (protoporphyrin ring + iron) and globin components.

The porphyrin ring is metabolized into unconjugated (i.e., indirect, water insoluble) bilirubin, which is then transported to the liver, where it is conjugated (i.e., direct bilirubin). Iron released from heme or absorbed in the intestine from the diet is transported by transferrin, the blood plasma protein, to the bone marrow and other tissues, where it is stored as ferritin and hemosiderin.

RBC INDICES

The amount of oxygen delivered to tissues depends on the supply and function of RBCs and Hgb. There are laboratory tests that demonstrate this.

The **mean corpuscular volume (MCV)** reflects the **size** of the RBCs, whereas the **mean corpuscular hemoglobin (MCH)** and the **mean corpuscular hemoglobin concentration (MCHC)** reflect the **amount** of Hgb in RBCs. MCH is the average mass of Hgb in each RBC. MCHC is a related value demonstrating the ratio of Hgb mass to the volume of RBCs.

Red blood cell distribution width (RDW) measures **variability** in RBC size (a.k.a. anisocytosis). An increased RDW means increased variation in RBC size.

A **reticulocyte count** (a.k.a. **retic count**) is often reported as the percentage of reticulocytes in the blood and indicates if the bone marrow is producing an adequate number of RBCs. When interpreting a reticulocyte count, it is important to adjust the percentage based on the degree of anemia (e.g., hematocrit) and the bone marrow maturation time of the reticulocytes, which constitute the **reticulocyte production index (RPI)**. An RPI > 3% is an adequate response to the level of anemia, and an RPI < 2% is an inadequate response.

IRON

Iron Absorption and Transport

Iron is absorbed from the gut by means of **ferroportin**, a transmembrane protein that transports iron through the cell walls of enterocytes and macrophages and subsequently releases the iron to **transferrin** in the hepatportal circulation. Transferrin, a plasma protein, binds the iron and transports it to transferrin receptors on cell surfaces, where it is then absorbed.

Ferroportin itself is controlled by **hepcidin**, the key regulator hormone for iron hemostasis. Hecpudin binds ferroportin, causing a decrease in the release of iron into the bloodstream, so high levels of hepcidin cause decreased iron absorption, while low levels allow for increased iron absorption. Hecpudin levels are decreased in low iron states and increased in iron overload states.

Hecpudin is also an acute-phase protein that increases in response to inflammatory cytokines (especially interleukin-6). A low C-reactive protein (CRP) helps rule out inflammation. A CRP > 10 mg/L means the hepcidin level is likely elevated due to inflammation and therefore is not a reliable indicator for iron overload.

Iron Studies

Free iron is produced from Hgb breakdown by RBC macrophages and by absorption from the duodenum. Free iron is toxic to the tissues.

Soluble transferrin receptor (sTfR) concentration is elevated in iron deficiency and normal in anemia of chronic disease (ACD). It is mainly used for differentiating ACD from iron-deficiency anemia (IDA).

Serum iron is a measurement of circulating iron bound to transferrin.

Total iron-binding capacity (TIBC) indirectly measures transferrin by determining the total amount of iron the blood can bind. Generally, it is **not** necessary to order both a transferrin level and TIBC.

The ratio of serum iron to TIBC, measured as a percentage, is called **transferrin saturation**.

Within the cell, iron is stored in protein complexes as **ferritin** or **hemosiderin**. Low values indicate iron deficiency, and high values can indicate iron overload (i.e., hemochromatosis, hemophagic lymphohistiocytosis, and adult-onset Still disease).

Like hepcidin, ferritin is also an **acute-phase reactant** and can be elevated with inflammation or chronic disease, although inflammation generally leads to only a 3-fold increase in ferritin levels. Also like hepcidin, a low ferritin helps rule out inflammation. Additionally, a high ferritin level is often a side effect of certain malignancies, especially hematologic cancer.

- Characterize the lab values in IDA vs. anemia of chronic disease. (See [Table 8-3 on page 8-11.](#))
- Which lab tests may be abnormal in hemolytic states?
- Which cells are seen in the peripheral blood of patients with glucose-6-phosphate dehydrogenase deficiency?
- Which virus is implicated in the development of aplastic crisis or worsening of anemia in patients with sickle cell disease?
- Which cells are seen on peripheral smear in patients with hereditary spherocytosis?
- What is the clinical presentation of paroxysmal nocturnal hemoglobinuria (PNH)?
- Which tests are used to diagnose PNH?
- Which leukemia/lymphoma is associated with autoimmune hemolytic anemia?

OVERVIEW

Anemia can be caused by an array of disorders, so a thorough history and physical examination followed by specific laboratory studies are needed to determine the etiology. Broadly, Hgb levels < 12 g/dL (120 g/L) in women and < 14 g/dL (140 g/L) in men define anemia, but there is variability with athleticism, ethnicity, and the elevation where the patient normally resides.

CLINICAL MANIFESTATIONS OF ANEMIA

Patients may be asymptomatic, even with significant anemia. Symptomatic clues include:

- Ice-eating (pagophagia), lethargy: iron deficiency
- Distal paresthesias: vitamin B₁₂ deficiency
- Left upper quadrant (LUQ) abdominal pain: hereditary spherocytosis with splenomegaly
- Right upper quadrant (RUQ) pain or intolerance to fatty foods: cholelithiasis from chronic hemolysis
- Constipation and cold intolerance: iron deficiency-related thyroid disease

MECHANISMS OF ANEMIA

Approach the anemic patient systematically. Excluding acute hemorrhage and rare sequestration, anemias can be broadly classified as production defects, maturation defects (hypoproliferative), or survival defects. The etiology of most anemias can be determined using the history, physical examination, reticulocyte assessment, and a thoughtful evaluation of the peripheral blood smear and RBC indices.

The 5 causes of anemia are discussed in [Table 8-1](#); refer to the table as you go through this material. Several images of normal blood smears and bone marrow aspirates are shown for your review in [Figure 8-3](#) through [Figure 8-8](#).

ANEMIA

PREVIEW | REVIEW

- List some extrinsic survival defects that cause anemia. (See [Table 8-1.](#))
- Is reticulocytosis increased or decreased for each of these: Production defect? Maturation defect? Survival defect? (See [Table 8-1.](#))
- When are Howell-Jolly bodies seen? (See [Table 8-2 on page 8-4](#) and [Figure 8-15 on page 8-5.](#))
- What are common causes of iron deficiency anemia (IDA)?
- What are the most common abnormal CBC findings in patients with α -thalassemia minor?
- What is the characteristic hemoglobin electrophoresis finding in patients with β -thalassemia minor?
- How many lobes must a neutrophil have to be considered hypersegmented?
- Which megaloblastic anemia is associated with neurologic disease?
- What are the methylmalonic acid and homocysteine levels in vitamin B₁₂ and folate deficiencies?

Table 8-1: Summary — Causes and Mechanisms of Anemia

Mechanism		Reticulocyte Count	Morphology	Etiology	Examples
1) Production defect		Decreased	Normal	Decreased EPO Bone marrow failure	Chronic renal disease* Aplastic anemia Pure red cell aplasia
2) Maturation defect	Cytoplasmic	Decreased	Hypochromic Microcytic	Impaired Hgb synthesis Globin synthesis deficiency	Iron deficiency Sideroblastic anemia Protoporphyrin deficiency Myelodysplastic syndrome Drugs, toxins Thalassemias
	Nuclear	Decreased	Megaloblastic	DNA synthesis defects	Vitamin B ₁₂ , folate deficiencies
3) Survival defect	Intrinsic (inherited)	Increased	Specific changes (e.g., spherocytes, sickle cells, bite cells)	Membrane cytoskeleton protein Metabolic enzymes Hemoglobinopathies	G6PD deficiency Pyruvate kinase deficiency SCD syndromes Hereditary spherocytosis and elliptocytosis Paroxysmal nocturnal hemoglobinuria
	Extrinsic (acquired)	Increased	Specific changes (e.g., spherocytes, schistocytes)	Antibody or complement mediated Microangiopathy Mechanical heart valves	Autoimmune hemolysis, malaria DIC, TTP/HUS HELLP
4) Sequestration		Increased	Normal	Hypersplenism	Portal hypertension or sickle cell (SC; not SS) disease
5) Blood loss		Increased if iron stores are adequate Not elevated if iron stores are depleted (e.g., as in chronic blood loss)	Normal or hypochromic	Acute or chronic bleeding	Peptic ulcer disease GI hemorrhage Menorrhagia Lacerations Severe blunt trauma

* Rarely can present as microcytic with burr cell/echinocytes.

DIC = disseminated intravascular coagulation
G6PD = glucose-6-phosphate dehydrogenase

HELLP = pregnancy complication featuring hemolysis, elevated liver enzymes, and low platelet count

HUS = hemolytic uremic syndrome
SCD = sickle cell disease
TTP = thrombotic thrombocytopenic purpura

Figure 8-3: Normal peripheral smear (low power): RBCs, platelets, and segmented neutrophil

Figure 8-4: Normal peripheral smear (low-oil immersion): normocytic, normochromic RBCs, platelets, and normal segmented neutrophil

Figure 8-5: Normal peripheral smear (high power): RBCs, platelets, normal segmented neutrophil, and a normal lymphocyte

Figure 8-6: Normal peripheral smear (high-oil immersion): normal RBCs, segmented neutrophil, and lymphocyte; no platelets

Figure 8-7: Normal BM aspirate (low power): Myeloid:erythroid ratio is usually 3:1. This field has more than the normal number of erythroid precursors, many of which have dark, condensed nuclei.

Figure 8-8: Normal BM aspirate (low-oil immersion): 5 erythroid precursors (dark condensed nuclei); remaining cells are myeloid precursors/cells (from myoblasts to segs).

Table 8-2: Significance of Specific Changes in the Peripheral Smear

Change	Finding	Meaning
RBC fragments (schistocytes)		Microangiopathic hemolytic anemia (seen in TTP, HUS, HELLP syndrome, DIC, and occasionally vasculitis), severe burns, and valve hemolysis (Figure 8-20 on page 8-12)
Spherocytes		Autoimmune hemolytic anemia and hereditary spherocytosis (Figure 8-24 on page 8-15)
Target cells		Significant liver disease, thalassemia syndromes, sickle cell disease, homozygous hemoglobin C (HbC), and other hemoglobinopathies (Figure 8-9)
Teardrop cells (dacrocytes)		Classic for myelofibrosis and other infiltrating bone marrow processes; also seen with thalassemia (Figure 8-10)
Burr cells (echinocytes; top) vs. spur cells (acanthocytes; bottom)		Burr cells (Figure 8-11) are seen in uremic patients. These are distinct and different from spur cells (Figure 8-12), which are seen in liver diseases.
Hypersegmented polymorphonuclear leukocytes (neutrophils)		Megaloblastic anemia (e.g., pernicious anemia/B ₁₂ deficiency, folate deficiency; Figure 8-13)
Elliptocytes		Hereditary elliptocytosis, severe iron deficiency anemia; Figure 8-14
Sickle cells (crescent shaped)		Sickle cell disease (HbSS and HbS β -thalassemia; less common in HbSC; Figure 8-23 on page 8-14)
Howell-Jolly bodies (nuclear remnants)		Splenectomy or functional asplenia (as seen in sickle cell disease) Howell-Jolly bodies (Figure 8-15) are the result of nuclear remnants, causing the formation of small, round, black particles in erythrocytes. This is a normal occurrence, and the functioning spleen efficiently removes them.
Basophilic stippling (RNA)		Indicates ineffective erythropoiesis; lead poisoning, thalassemia, pyrimidine 5'-nucleotidase deficiency; Figure 8-16

Table 8-2 identifies the significance of some changes in the peripheral blood smear.

Causes and mechanisms of anemia:

1) **Production** defects result from chronic disease, acute inflammatory conditions, impaired renal function, bone marrow damage, and hypometabolic states (e.g., hypothyroidism, hypogonadism, adrenal insufficiency). Very little polychromasia and few reticulocytes are seen.

2) **Maturation** defects:

- Cytoplasmic—caused by:
 - Impaired hemoglobin synthesis—iron deficiency, sideroblastic anemia (the inability to incorporate iron into hemoglobin), protoporphyria deficiency, myelodysplastic syndrome, drugs, toxins
 - Globin synthesis deficiency (e.g., thalassemias)

- Nuclear: DNA synthesis defects (e.g., folate and vitamin B₁₂ deficiencies, myelodysplastic syndrome)

3) **Survival** defects result in premature destruction of RBCs:

- **Intrinsic (inherited):** membrane cytoskeletal protein (i.e., spherocytosis, elliptocytosis), metabolic enzymes (glucose-6-phosphate dehydrogenase [G6PD] deficiency), or hemoglobinopathies (e.g., sickle cell disease, thalassemias)
- **Extrinsic (acquired):** antibody- or complement-mediated, microangiopathy, mechanical heart valves (e.g., patients with autoimmune hemolysis, malaria, DIC, thrombotic thrombocytopenic purpura [TTP], hemolytic-uremic syndrome [HUS], or HELLP [pregnancy complication featuring hemolysis, elevated liver enzymes, and low platelet count])

Figure 8-9: Target cells (low-oil immersion)

Figure 8-10: Teardrop cells. This patient has myeloid metaplasia. Also seen in thalassemias and other hemoglobinopathies

Figure 8-11: Burr cells (echinocytes) in uremia. These are RBCs with regularly spaced, short, spiny projections. These membrane changes disappear when uremia is corrected.

Figure 8-12: Spur cells (acanthocytes). Nucleated RBCs. Spur cells are RBCs with multiple irregular projections that vary in length, width, and regularity. The usual cause is hepatic failure.

Figure 8-13: Various views of hypersegmented neutrophils

Figure 8-14: Elliptocytes

Figure 8-15: Postsplenectomy: Howell-Jolly bodies are the dense inclusion bodies in the RBCs. Also see target cells and a burr cell in this field.

Figure 8-16: Basophilic stippling

- 4) **Sequestration:** hypersplenism (e.g., portal hypertension, early childhood sickle cell disease)
- 5) **Acute blood loss** with resultant iron deficiency (e.g., gastrointestinal [GI] hemorrhage, especially peptic ulcer disease) is the most common cause of anemia in the U.S.

WORKING UP ANEMIA

To evaluate the patient with anemia, use a combination of:

- 1) **Morphologic data:** peripheral smear to review for the presence of polychromasia and RBC indices (MCV, MCH, MCHC, and RDW)
- 2) **Kinetic data** as revealed by the presence of an appropriate reticulocyte response (with RPI, reticulocyte count [%], and/or absolute reticulocyte count): An appropriate reticulocyte response indicates that the bone marrow has the structural and functional ability to respond to an EPO-mediated stimulus of RBC production (a hyperproliferative anemia). With anemia, the count should always be elevated.

Reticulocyte response is an important fork in the road for both the etiology and treatment of the anemia. Look at the just-reviewed 5 causes of anemia (under [Mechanisms of Anemia on page 8-2](#)). Production and maturation defects lead to low RPI and reticulocyte count (< 2% of RBCs or < 100,000 cells/ μ L [10×10^{10} cells/L]), whereas shortened RBC survival, splenic sequestration, or blood loss stimulate a high reticulocyte count as new RBCs are produced. With a high reticulocyte count in the presence of anemia, assess the bone marrow response with the RPI; if it is low, there could be a combination of causes (i.e., additional production or maturation defects).

Initial lab work includes CBC, peripheral smear, retic count, and iron studies.

After taking a careful history and performing a full physical examination, check the MCV. Follow along in [Figure 8-17](#). The MCV quickly differentiates between microcytic, normocytic, and macrocytic anemias, each of which has generally nonoverlapping causes.

Microcytic RBCs (MCV < 80 fL/cell [8×10^{-15} L/cell]) are seen in IDA, thalassemia, and acquired sideroblastic anemias.

Normocytic anemia (MCV = 80–100 fL/cell) has many causes (i.e., acute blood loss, chronic disease states, and endocrine disorders). These anemias are either hypoproliferative (retic count < 2%) or hyperproliferative (retic count > 2%). Hemolytic anemias are a common cause. So, check the reticulocyte count and the peripheral smear to look for clues of hemolysis, including RBC fragments (microangiopathy) and spherocytes (hereditary spherocytosis); [Table 8-2 on page 8-4](#) has additional examples. ACD can result from kidney disease, cancer, or autoimmune or inflammatory disorders (e.g., rheumatoid arthritis). The MCV is an average of cell sizes, so it can have normal results even if the blood has populations of both small and large RBCs (dimorphic anisocytosis). Refer to [Table 8-3 on page 8-11](#) for lab value comparison of IDA and ACD.

Macrocytic RBCs (MCV > 100 fL/cell) are caused by either megaloblastic conditions (e.g., vitamin B₁₂ or folate deficiency, leukemia, myelodysplastic syndrome) or nonmegaloblastic conditions (e.g., chronic alcohol use, hypothyroidism, liver disease).

Notes of caution:

- 1) Note that both microcytic and macrocytic causes of anemia are maturation defects and, therefore, are hypoproliferative with a low reticulocyte count—so reticulocyte count is **not** considered for these conditions in [Figure 8-17](#). But if you have a mixed disorder

Figure 8-17: Anemia workup

with, for example, hemolysis or acute blood loss, you could have an abnormally high RPI. So, **always** check retic count in all cases of anemia.

- 2) Remember that MCV is an **average** of all RBC sizes and that you can get a normal MCV when there is a mixture of large and small RBCs (i.e., dimorphic population). In this case, a high RDW helps because it indicates a large variation in cell sizes.

Normal MCV with a high RDW occurs in the following contexts:

- Iron deficiency and/or thalassemia (i.e., microcytic RBCs) can be found with macrocytic RBCs of any cause.
- After blood transfusion for iron-deficiency or macrocytic anemias, there is a residual population of affected cells of small or large size and a new population of transfused normal-size cells.
- When reticulocytes are present, these larger cells coexist with small RBCs, such as those in iron deficiency or thalassemia.
- An unusual example is hereditary spherocytosis with microspherocytes and folate deficiency (from high compensatory RBC turnover).

Now let's learn a bit more about the different causes of anemia. The type of defect is noted in the heading of each main topic; this is to help you keep each one categorized into 1 of the 5 types of anemia.

ANEMIAS

Microcytic Anemias

Iron-Deficiency Anemia (IDA; Cytoplasmic Maturation Defect)

Iron is essential for the production of Hgb, and a deficiency leads to a cytoplasmic maturation defect of the RBC termed IDA. It features microcytosis, impaired erythropoiesis, and anemia.

Signs and symptoms include fatigue, pallor, weakness, irritability, koilonychia, and poor exercise tolerance. IDA is one of the major causes of restless leg syndrome. Pica for ice (a.k.a. pagophagia) is occasionally seen and is fairly specific for IDA.

Labs in IDA:

- RBCs are microcytic (MCV < 80 fL/cell [8×10^{-15} L/cell]) and hypochromic (decreased MCHC) with a low reticulocyte count.
- Serum iron is low. Low serum iron causes increased production of transferrin, which is measured as total iron-binding capacity (TIBC). So, with IDA, serum iron and ferritin are low and TIBC is elevated, and the ratio of serum iron to the TIBC is usually < 10% (normal is 25–40%).
- The serum ferritin level is considered the best test for assessing iron stores. In the patient with no known inflammatory or infectious disease, a ferritin level ≤ 40 ng/mL (89.88 pmol/L) is 98% sensitive and 98% specific for IDA.

Remember that ferritin is an acute-phase reactant and can increase during states of inflammation, so this test has poor sensitivity for IDA in patients who have ongoing inflammation. sTfR concentration is normally elevated in iron deficiency and normal in anemia of inflammation.

Once you diagnose IDA, you **must** pursue the etiology:

- Chronic blood loss is the most common cause:
 - In menstruating women, the source is usually menorrhagia.
 - In all others, it is GI bleed (e.g., NSAIDs, peptic ulcer disease, angiodysplasia, cancer) until proved otherwise!
 - If > 60 years of age, diagnosis is GI cancer until proved otherwise!
 - Also remember genitourinary (GU) blood loss and check U/A.
 - Worldwide, hookworm infection (*Necator americanus* or *Ancylostoma duodenale*) is the most common cause of chronic GI blood loss.
- Pregnancy can cause iron deficiency because of increased iron requirements.
- Insufficient dietary iron
- Malabsorption (e.g., celiac disease, gastric bypass surgery)
- Chronic low-grade intravascular hemolysis (as in paroxysmal nocturnal hemoglobinuria)

Celiac disease is a common cause of chronic, unresponsive IDA in a young person with a history of bulky, foul-smelling stools. However, presentation may be subtler in older patients. Screen with serologic testing—IgA anti-tissue transglutaminase (tTG) antibody is the preferred test.

Workup to define etiology almost always begins with GI evaluation with colonoscopy and possible esophagogastroduodenoscopy (EGD), depending on presentation.

Treatment of IDA begins with addressing the underlying cause, followed by iron replacement. Oral iron is the 1st choice because it is inexpensive and accessible. However, many patients are unable to tolerate oral iron or have difficulty with absorption (e.g., gastric surgery); they may be candidates for IV iron replacement. With adequate iron replacement, the Hgb should be close to normal level after 6 weeks.

Thalassemias (Cytoplasmic Maturation Defect)

Thalassemias are a group of inherited gene defects causing abnormal Hgb production. See [Normal Erythropoiesis on page 8-1](#) for normal Hgb production. Hgb is responsible for the oxygen-carrying capacity of the blood. These Hgb disorders are most prevalent in malaria-prone regions, such as southeast Asia, the Middle East, the Mediterranean, and sub-Saharan Africa. Like sickle cell trait, a small abnormality in the Hgb chain is thought to be protective against malaria (see [Sickle Cell Disease \(SCD\) on page 8-14](#)). Symptoms can vary from none to death in utero.

Thalassemias are characterized most commonly by absent or decreased production of either the α chain (α -thalassemia) or the β chain (β -thalassemia), leading to decreased production of Hgb tetramers and fewer healthy RBCs (review the structure of normal Hgb under Hemoglobin (Hgb) on page 8-1). In addition, there is unbalanced globin chain synthesis such that homotetramers are formed; these are insoluble and precipitate inside RBCs, leading to hemolysis and ineffective erythropoiesis. These processes result in anemia. Mutations can be deletional or nondeletional and affect many different aspects of transcription and translation.

Thalassemias (α - and β -thalassemia minor) are often misdiagnosed as IDA, and patients are incorrectly put on iron supplements. Iron therapy does not improve the microcytosis, and, even worse, it can cause secondary hemochromatosis (which can lead to cardiac failure, hepatomegaly, and diabetes). In both types, rule out IDA with normal iron studies (i.e., serum iron, ferritin, TIBC).

α -Thalassemia

α -Thalassemia is the most common hemoglobin genetic disease. Carrier state prevalence ranges from 2% to 98% depending on the population. In the U.S., it is very low in Caucasians but up to 15% in African Americans.

Chromosome 16 contains 2 copies of the α -gene at 2 different loci on each of the 2 genes. There are, therefore, 4 α -genes in normal individuals. The clinical manifestations correlate with the number of α -genes that are affected: The more loci affected, the worse are the symptoms (Figure 8-18).

There are 4 types of α -thalassemia:

- 1) **α -Thalassemia silent carrier:** 1 locus ($\alpha\alpha/\alpha-$), asymptomatic, no hematologic abnormalities
- 2) **α -Thalassemia minor** (a.k.a. α -thalassemia trait): 2 loci ($\alpha-/ \alpha-$) or ($\alpha\alpha/ - -$), asymptomatic, low MCV (often < 80 fL/cell [8×10^{-15} L/cell]), low Hgb, MCH < 27 pg/cell, little to no anemia
- 3) **HbH:** 3 loci ($\alpha-/-$); unpaired β chains form β_4 tetramers called HbH inclusions—these form faint blue precipitates near the RBC membrane in peripheral cells but not in the marrow. These precipitates are seen only with supravital stains and are not visible on the normal peripheral smear. Clinical features are intermediate and variable and can include moderately severe hemolytic anemia, requiring periodic transfusions. Extramedullary hematopoiesis is common with some level of iron overload.

Figure 8-18: α -Thalassemia: pathogenesis and clinical findings

- 4) **α -Thalassemia major** (a.k.a. Hb Barts): 4 loci (---/---); no effective Hgb is produced beyond the embryonic stage. γ_4 tetramers form and have such high oxygen affinity that they do not deliver **any** oxygen to the tissues, causing death in utero (i.e., hydrops fetalis).

Diagnosis: Suspect α -thalassemia carrier from family history. Suspect α -thalassemia minor in patients with microcytic anemia, normal iron studies, and a normal Hgb electrophoresis. Because of the microcytic anemia, α -thalassemia minor is often misdiagnosed as IDA—which is why you should do iron studies for all patients with microcytic anemia. Molecular genetic testing is the only way to confirm the diagnosis.

In clinical practice, adult patients with a microcytosis and normal iron studies are assumed to have α -thalassemia minor, and even the electrophoresis is rarely ordered.

Treatment: No treatment is needed for an α -thalassemia carrier or a patient with α -thalassemia minor. HbH disease treatment is blood transfusions as needed.

β -Thalassemia

Patients with β -thalassemia have decreased β chain production and compensatory δ and γ chain production, leading to increases in HbA₂ ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$). A range of mutations within the β -globin locus of chromosome 11 cause β -thalassemia.

There are 3 categories of β -thalassemia:

- 1) **β -Thalassemia minor** (heterozygotes; see Figure 8-19): mild or no anemia, with a disproportionately high number of microcytes. These patients are

asymptomatic and have no clinical sequelae. In most patients, this disorder has the specific finding of 2- to 3-fold elevations of HbA₂ ($\alpha_2\delta_2$) and the nonspecific finding of slight increases in HbF ($\alpha_2\gamma_2$) on Hgb electrophoresis.

- 2) **β -Thalassemia major** (homozygous): Patients with β -thalassemia major (a.k.a. Cooley anemia) have essentially no β -globin production. The remaining highly insoluble α -globin precipitates into homotetramers (a type of inclusion body), which are toxic to erythrocytes and cause them to die within the marrow. Surviving erythrocytes carry inclusion bodies that are detected by the spleen, leading to removal of the erythrocytes and chronic hemolytic anemia. The resulting severe anemia (developing over the 1st year of life) results in elevated EPO levels and, thus, erythroid hyperplasia. If the erythroid hyperplasia is severe, it can lead to **extramedullary hematopoiesis** in the liver and spleen, with an expanded bone marrow production in the cranial bones resulting in facial changes in children called chipmunk facies. Often, patients are transfusion dependent and develop iron overload. Hgb electrophoresis shows high HbF and HbA₂ and, in severe cases, no HbA production.

- 3) **β -Thalassemia intermedia** (homozygous): Not all patients with homozygous defects of β -globin production have the full clinical severity described previously. Modulating factors are minor qualitative defects of the β -globin; coinheritance of α -thalassemia trait, leading to decreased formation of the toxic RBC inclusion and, therefore, to less precipitation of insoluble homotetramers

Figure 8-19: β -Thalassemia minor: pathogenesis and clinical findings

and less hemolysis; and increased production of HbF. The term “ β -thalassemia intermedia” is used to convey this heterogeneity and to describe those patients who range from asymptomatic to transfusion-dependent states.

Diagnosis: β -thalassemia minor has a mild microcytic anemia with normal iron studies. The key diagnostic finding is an increase in HbA₂. Patients usually have a smaller and less specific increase in HgF. As with α -thalassemia, molecular genetic testing confirms the diagnosis.

Treatment: No treatment for β -thalassemia minor. Transfusions as needed for intermedia and major types. Luspatercept is a recombinant fusion protein that inhibits the TGF- β superfamily, resulting in increased differentiation and proliferation of erythroid precursors, and improves hematology parameters associated with ineffective erythropoiesis. It is indicated for the treatment of anemia in adult patients with β -thalassemia who require regular RBC transfusions.

Macrocytic Anemias

Megaloblastic Anemia (Nuclear Maturation Defect)

Megaloblastic anemias result from impaired DNA synthesis. They are often the result of deficiencies of vitamin B₁₂ and/or folate but can also result from drugs that impair DNA metabolism.

Folate deficiency is caused by:

- Poor diet
- Increased demand (e.g., pregnancy, lactation)
- Alcohol use
- Medications:
 - Drugs that interfere with folate metabolism, such as methotrexate, phenytoin, and 5-fluorouracil
 - Drugs that interfere with folate absorption, such as metformin and cholestyramine

B₁₂ deficiency can result from:

- Pernicious anemia (due to autoimmune destruction of parietal cells that produce intrinsic factor)
- Strict vegetarian/vegan diet
- Alcohol use (rarely)
- Inability to release B₁₂ from food sources (common in the elderly, atrophic gastritis, and acid-suppressing medications; e.g., proton pump inhibitors [PPIs])
- Malabsorption of B₁₂ in the terminal ileum (e.g., inflammatory bowel disease, bacterial overgrowth, fish tapeworm, pancreatic insufficiency)
- Gastric surgery, including bariatric surgery

Know that the marrow is disturbed in these nutritional deficiencies and that multiple cell lines can be affected as the deficiencies progress. The megaloblastic RBCs are destroyed in the marrow (i.e., intramedullary hemolysis),

and erythropoiesis is ineffective. The characteristic megaloblastic findings are that surviving RBCs are macrocytic and neutrophils are hypersegmented (defined as ≥ 5 lobes in 5% of neutrophils or any neutrophil with 6 lobes). Platelets can be decreased as well.

Consider a megaloblastic process in patients who present with a macrocytic anemia, pancytopenia, and slight unconjugated (i.e., indirect) hyperbilirubinemia (from the continuous low-level intramedullary hemolysis).

In addition to anemia, deficiencies in B₁₂ can cause GI effects (e.g., glossitis, diarrhea) and neurologic deficits (ranging from paresthesias to frank psychosis). B₁₂ deficiency can be present without anemia but with serious neurologic problems. Atrophic glossitis is a classic symptom, but the less-well-defined neuropsychiatric symptoms (i.e., dementia, irritability, insomnia) may be the more common presentation. Know that folate deficiency is **not** associated with neurologic impairment.

Diagnose B₁₂ deficiency at a level < 200 pg/mL (147.56 pmol/L). If the level is borderline low (200–400 pg/mL [147.56–295.12 pmol/L]), check MMA and homocysteine (HC). Both are elevated in B₁₂ deficiency. Only HC is elevated in folate deficiency—and the serum folate level is decreased.

Once B₁₂ deficiency is diagnosed, pursue the etiology. **Pernicious anemia (PA)** is due to an autoimmune-mediated decrease in gastric IF. The absorption of vitamin B₁₂ is dependent on its forming a complex with IF. The presence of IF antibodies supports the diagnosis, but the sensitivity of the test is only ~ 70%.

If you highly suspect PA but IF antibodies are absent, check the serum gastrin and pepsinogen levels. In PA, the serum gastrin is increased and the pepsinogen I level is decreased. The ratio of pepsinogen I to pepsinogen II is also used; it is low in PA. The Schilling test, in which you follow the fate of radiolabeled B₁₂ ingested by the patient, was previously used to confirm the diagnosis but is rarely used and generally no longer available.

Treat B₁₂ deficiency initially with high-dose oral therapy. If not effective, then treatment requires daily injections for 1 week, followed by weekly injections for 1 month, and then monthly injections for life. Severely anemic patients can develop hypokalemia with treatment, so monitor K⁺ levels in these patients. Treat folate deficiency with daily oral replacement. **Do not ever** treat B₁₂ deficiency solely with folate—the anemia improves but the neurologic problems continue to worsen.

Nonmegaloblastic Macrocytic Anemias (Nuclear Maturation Defect)

Nonmegaloblastic macrocytic anemias occur much more frequently than megaloblastic anemias, so it is important to always consider the following causes when a patient presents with a macrocytic anemia.

Causes of nonmegaloblastic macrocytic anemia:

- Late pregnancy causes a mild elevation of MCV. This returns to normal after pregnancy.
- Chronic alcoholism, due to a direct toxic effect on the bone marrow
- Bone marrow disorders (e.g., myelodysplastic syndromes, lymphoma, myeloma, myelofibrosis, cancer)
- Cytotoxic drugs such as azathioprine, hydroxyurea, and 6-mercaptopurine
- Reverse transcriptase inhibitors, such as stavudine, lamivudine, and zidovudine, because these drugs interfere with DNA metabolism

Again, these anemias are macrocytic but do **not** have the megaloblastic findings (i.e., large RBCs and hypersegmented neutrophils).

Normocytic Anemias

Anemia of Chronic Disease (ACD; Production Defect)

ACD (a.k.a. anemia of chronic inflammation) results from decreased RBC production and impaired iron utilization, despite normal or increased iron stores.

In inflammatory states, macrophages produce interleukin 6 (IL-6), which induces the production of hepcidin by the liver. Hepcidin then inhibits iron absorption from the GI tract and decreases release of iron from macrophages. More on this process is described in [Iron Absorption and Transport on page 8-1](#).

The most common causes of ACD are chronic rheumatic, infectious, and neoplastic diseases. ACD and IDA can coexist, so it is best to work up both types of anemias in patients with chronic illness ([Table 8-3](#)).

Table 8-3: Some Laboratory Characteristics of Iron-Deficiency Anemia and Anemia of Chronic Disease

	IDA	ACD
Serum Iron	Low	Low
TIBC	High	Low
Transferrin Saturation	Low	Low to normal
Ferritin	Low	High/high-normal
sTfR	High	Normal

ACD = anemia of chronic disease

IDA = iron-deficiency anemia

sTfR = soluble transferrin receptor

TIBC = total iron-binding capacity

Labs in ACD:

- RBCs are typically normochromic and normocytic (occasionally hypochromic and/or microcytic) with a low reticulocyte count.
- Serum iron and TIBC are low.
- Transferrin saturation (iron/TIBC) is usually normal to low-normal.

- Ferritin is increased or high-normal.
- The sTfR test helps differentiate ACD from IDA: It is normal in ACD and increased in iron deficiency.

Anemia in chronic kidney disease is due to decreased EPO production and is commonly responsive to recombinant EPO. These patients can also have increased hepcidin, which binds ferroportin and decreases intestinal iron absorption. 20% of diabetics with Stage 3 chronic kidney disease (CKD) have anemia. This topic is discussed more fully in the [Nephrology](#) section.

Anemia of hypometabolic states can result from deficiencies in thyroid hormone, glucocorticoids, testosterone, or growth hormone and can be 1 of the presenting features of hypothyroidism, primary adrenal insufficiency, or pituitary disease (hypogonadism or panhypopituitarism).

Anemia from bone marrow damage includes the following:

- **Aplastic anemia:** pancytopenia secondary to a primary stem cell disorder, an autoimmune process, or a drug (Aplastic anemia is covered under [Disorders of the Bone Marrow on page 8-37](#).)
- **Pure red cell aplasia:** severe anemia due to decreased RBC precursors in the bone marrow. This can be congenital due to abnormal stem cells or acquired due to viral infection, thymoma (paraneoplastic), autoimmune disorders, lymphoproliferative disorders, or drugs. Suspect parvovirus B19 in these patients with severe anemia who also have HIV infection or sickle cell disease.
- **Marrow infiltrative disorders:** Fibrosis, granulomas, or malignancy can cause changes in the peripheral blood smear, including teardrop cells and immature red and white blood cells. These leukoerythroblastic changes reflect a weakened bone marrow (myelophthisis).

Sideroblastic Anemia (Cytoplasmic Maturation Defect)

Sideroblastic anemia can be congenital or acquired (e.g., alcohol, medications, copper deficiency). It is the result of disruption of heme synthesis and mitochondrial function, and its mechanism can be variable and complex. It is characterized by ring sideroblasts that are due to the accumulation of mitochondrial iron in erythroblasts on the bone marrow aspirate smear.

Sideroblastic anemia due to **copper deficiency** can be precipitated by zinc ingestion/intoxication. Copper deficiency has low serum copper and ceruloplasmin levels much like Wilson disease, but unlike those with Wilson disease, these patients have neutropenia and do not have Kayser-Fleischer rings. The urinary copper excretion is high in Wilson disease. See the [Gastroenterology](#) section for more details.

Lead poisoning often is cited as a cause of sideroblastic anemia, but sideroblasts often are not found on workup.

Medications linked to sideroblastic anemia most commonly include isoniazid, linezolid, and chloramphenicol.

Excessive alcohol use results in sideroblastic anemia in 25–30% of patients with alcoholism. Acquired forms of the anemia often respond to removal of the offending agent.

Hemolytic Anemia (Survival Defect)

Features

Hemolysis is the premature destruction of RBCs. Findings that indicate the possibility of hemolysis:

- Dark urine
- Jaundice
- Heart murmur
- Enlarged spleen
- Enlarged liver

Routine labs reveal anemia and elevated lactate dehydrogenase (LDH).

Causes of Hemolytic Anemia

Hemolytic anemias can be grouped by the underlying cause of premature RBC destruction:

- **Intrinsic** (or intracorpuscular):
 - Molecular defect inside the RBC (e.g., G6PD deficiency, hemoglobinopathies)
 - An abnormality in membrane structure or function (e.g., hereditary spherocytosis)
- **Extrinsic** (or extracorpuscular): an environmental factor outside the RBC (e.g., DIC; autoantibodies; thrombotic thrombocytopenic purpura/hemolytic uremic syndrome [TTP/HUS]; hemolysis with a microangiopathic blood smear, elevated liver enzymes, and low platelet count [i.e., HELLP syndrome]).

Additionally, hemolytic anemias can be grouped by location as intravascular or extravascular. Hemolysis is termed extravascular when RBCs are outside the vascular space, trapped in the reticuloendothelial system (mainly the spleen), and engulfed by macrophages. Intravascular hemolysis occurs when RBCs are lysed within the lumen of the blood vessels. This can result from nonimmunological mechanisms, including DIC, TTP/HUS, HELLP, and severe heart valve abnormalities that shear RBCs (Figure 8-20).

Figure 8-20: Hemolytic anemia with schistocytes

Lab Results with Hemolytic Anemia

Know all of the following.

CBC with low Hgb and hematocrit is the definition of all anemias. With hemolytic anemia, the WBC and platelet counts are usually normal.

Low haptoglobin occurs with both intravascular and extravascular hemolysis; released Hgb is quickly bound to haptoglobin and then engulfed by macrophages. The resultant low level of haptoglobin can be used to diagnose hemolysis—but does **not** help distinguish the type.

High unconjugated bilirubin = hemolysis. During normal breakdown, heme loses iron and the resultant porphyrin ring is converted to bilirubin and cleared in the urine or stool. With excessive hemolysis of either type, more of the bilirubin is **unconjugated** (indirect).

Elevated LDH levels can be caused by hemolysis. LDH is a sensitive test for hemolysis but is not very specific.

Elevated reticulocyte count is an indication of high RBC turnover. Like LDH level, high reticulocyte count is sensitive but not specific for hemolytic anemia.

RPI is elevated in hemolysis with an adequately functioning bone marrow.

Peripheral smear with **schistocytes** indicates **microangiopathic** hemolytic anemia (MAHA), in which damaged vascular endothelium causes traumatic breakage of RBCs.

High urine hemosiderin = intravascular hemolysis. More iron is lost in the urine with intravascular hemolysis, and this can be detected by the urine hemosiderin test.

A positive direct antiglobulin test (DAT; a.k.a. direct Coombs test) = antibody- or complement-mediated hemolysis. The direct antiglobulin test identifies antibody or complement on the RBC surface, causing hemolysis. The indirect antiglobulin test method looks for specific anti-RBC antibodies in the serum. Let's review the "Coombs tests" a bit. Follow along using Figure 8-21.

The **direct antiglobulin test** (DAT; direct Coombs test) is done only if a patient's labs are **suggestive of hemolysis** (i.e., anemia with undetectable haptoglobin level and elevated bilirubin and LDH). DAT is used to determine if the hemolysis is **immune-related**. A positive test confirms that there is **IgG or C3** coating the surface of the patient's RBCs. This is usually caused by autoimmune hemolytic anemia (AIHA). In a newborn, the coating could be the result of hemolytic IgG from the mother due to Rh incompatibility.

Hemolysis due to intrinsic RBC membrane defects or enzyme deficiency such as HS and G6PD deficiency are **not** immune based and are DAT negative.

The **indirect antiglobulin test** (IAT; indirect Coombs test) is more of a **test method** used in screening tests that look for specific IgG in the patient's plasma that is known to cause hemolysis. Because there are many IgGs that can do this, you never simply order an IAT; rather, you order the test that reflects the antibody for which you are screening.

Direct Antiglobulin (Direct Coombs) Test

Indirect Antiglobulin (Indirect Coombs) Test

Figure 8-21: Antiglobulin (Coombs) testing

These tests are preventive; you are doing due diligence to prevent hemolysis. The most common screening tests that use the IAT method are those looking for:

- ABO antibodies in a patient prior to receiving a blood transfusion (RBCs with A antigens and ones with B antigens are tested against the patient's serum.)
- Rh antibodies in a Rh- mother's serum (due to having had an Rh+ baby [i.e., A+, AB+, B+, O+] indicating a danger of her next baby developing hemolytic disease of the fetus and newborn [HDFN])

Let's delve a little deeper. Common to both tests is the use of the same **antiglobulin agent**, which has the superpower of reacting with and cross-linking IgG (or C3) that is coating the surface of RBCs and thereby cause visible RBC agglutination—which is the same endpoint in each test.

The antiglobulin agent (a.k.a. antisera; anti-human IgG; Coombs reagent) is derived from the serum of animals that were injected with human IgG or C3 and have developed an immune response, now with immune globulins against human IgG (or C3). Originally, the animals used were rabbits, but now larger animals like sheep, goats, and horses are used. Monoclonal antibodies have been developed.

The DAT is quick and simple. The antiglobulin agent is mixed with a patient's washed RBCs (i.e., free of patient's plasma). Cross-linking with agglutination occurs if they are coated with IgG (or C3).

The IAT, instead of using the patient's RBCs (as in the DAT), uses nonpatient RBCs that express the antigen in question mixed with the patient's plasma (which may have the IgG in question). After incubation (to allow time for the patient's IgG to attach to the RBCs), the antiglobulin agent is added, and visible agglutination is a positive result.

Intrinsic Survival Defects

G6PD Deficiency

There are > 400 variants of the **X-linked G6PD** gene, affecting > 400 million people worldwide. Being X-linked means that if a male gets the *G6PD* gene, 100% of his RBCs are affected. If a woman gets 1 affected X chromosome, 50% of her RBCs are affected. Together, these result in widely variable deficiencies in the reduced state of glutathione, this reduced state being a protective mechanism against oxidative stress. Common strong oxidative stressors are infections, medications (including dapsone, sulfa drugs, and antimalarials), fava beans, and diabetic ketoacidosis.

Hemolysis in G6PD deficiency can be mild to massive. G6PD levels normally decline over the RBC lifespan, so measured levels of G6PD can be normal during an acute hemolytic episode if young cells enrich the test population;

i.e., a false-negative test is possible during acute hemolysis with brisk reticulocytosis. Measure G6PD levels 2–3 months after the hemolytic event if the original test is negative and suspicion remains. Other hematologic findings (and buzzwords) include **bite cells** on peripheral smear and **Heinz bodies** seen only with special stains (not seen on peripheral smear!). Heinz bodies are chunks of denatured Hgb (Figure 8-22). So, if a patient has hemolysis of unknown cause and bite cells, check a G6PD assay, order a special smear for Heinz bodies, and do the DAT (just to be sure the hemolysis is not autoimmune; it should be negative).

Figure 8-22: Heinz bodies in G6PD. Special stains are required.

Pyruvate Kinase Deficiency

Although G6PD deficiency is more common than pyruvate kinase deficiency, the latter is more likely to result in a symptomatic hemolytic anemia. Pyruvate kinase

deficiency and other enzyme deficiencies within the glycolytic pathway are subject to hemolytic crisis without exposure to oxidative stress. In fact, the mechanism of hemolysis in pyruvate kinase deficiency is not clearly understood. In contrast with other types of hemolysis, the peripheral blood smear does not reveal characteristic RBC abnormalities.

Sickle Cell Disease (SCD)

SCD is a group of disorders resulting from a point mutation in the β -globin gene ($\beta^{\text{Glu} \rightarrow \text{Val}}$), in which valine is substituted in place of glutamine on chromosome 11. When **both** β -globin chains are affected, the patient has **HbSS disease**. Typically, when we talk about SCD, we mean HbSS disease. The deoxygenated hemoglobin S (HbS) stiffens and distorts the RBC membrane, causing the characteristic sickle shape seen on peripheral blood smear; this shape prevents the cells from passing easily through small vessels. See [Figure 8-23](#).

Figure 8-23: Sickle cell disease

Other SCDs result when only **1** β -globin gene is affected:

- **Sickle cell trait (HbS/A):** Half the Hgb in each RBC is HbS and half is HbA. Patients are typically asymptomatic but can have renal papillary necrosis with painless hematuria and isosthenuria.
- **HbSC disease ($\beta^{\text{Glu}} \rightarrow \text{Val}$ $\beta^{\text{Glu}} \rightarrow \text{Lys}$):** RBCs are rigid—but **not** sickled—and have a short lifespan. Symptoms are similar to those with SS disease but are less severe. Because the spleen does not always undergo early autoinfarction, as it does in HbSS disease, splenic sequestration is much more likely to be seen in adults with HbSC disease; consider this in adult SC patients presenting with a tender spleen and worsening anemia. Retinal problems are also common.
- Other Hgb disorders can be seen in combination with HbS in double-heterozygous individuals. They include HbS/ β -thalassemia and HbSD (D is an abnormal type of hemoglobin). Clinical features are varied.

SCD is confirmed with Hgb electrophoresis—usually when the patient is a child. You can screen prospective parents for the carrier state and provide genetic counseling.

Recurrent microinfarcts of the kidney lead to isosthenuria (inability to concentrate urine). Recurrent infarcts

of the spleen lead to functional asplenia with increased risk of infection from **encapsulated** organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae*, and *Salmonella*. To protect against these organisms, penicillin prophylaxis is used in children until 5 years of age. Give all patients pneumococcal, meningococcal, *H. influenzae*, hepatitis B, and influenza vaccines.

Chronic hemolysis can cause bilirubin gallstones.

In SCD patients, a **parvovirus B19** infection can decrease erythropoiesis, causing a worsening of the anemia or even a pure red cell aplasia.

Recurrent vaso-occlusion pain episodes are the characteristic feature of SCD.

Vaso-occlusive pain in SCD can be mild to debilitating and last hours to days. Typically, it occurs in long bones, chest, back, and abdomen. Pain is typically deep and aching. Mild associated redness, warmth, and tenderness with a low-grade fever is common. Pain resolves with aggressive pain management.

With functionally asplenic patients, be sure to have a low threshold of concern for infection. Obtain blood cultures and start empiric IV antibiotics if any of the following is present:

- Temperature is $> 101.5^{\circ}\text{F}$ (38.6°C) (administer antibiotics within 1 hour of triage)
- Pain persists despite aggressive pain management (i.e., splenic sequestration, acute chest syndrome)
- There is localized swelling of a single painful site (e.g., osteomyelitis)

With increasing age, HbSS patients tend to also develop chronic neuropathic pain.

Acute chest syndrome (ACS) is vaso-occlusion causing chest pain and desaturation of oxygen. It often follows a vaso-occlusive pain episode in the abdomen or bones and is the main cause of death in patients with SCD. Patients can present with chest, rib, sternal, arm, and leg pain and shortness of breath. Differential includes pulmonary embolism and acute coronary syndrome. By definition, an ACS diagnosis requires an infiltrate on chest x-ray (CXR) or respiratory symptoms and fever, making it difficult to distinguish from pneumonia. ACS is categorized as:

- Mild— O_2 sat on room air $> 90\%$, 1 lobe infiltrate
- Moderate— O_2 sat on room air $> 85\%$, 1–2 lobes with infiltrate
- Severe—respiratory failure ($\text{P}_a\text{O}_2 < 60$ mmHg), $< 85\%$ O_2 sat on room air, ≥ 3 lobes with infiltrate
- Very severe—with acute respiratory distress syndrome (ARDS) or acute lung failure

Initial treatment of ACS includes IV fluids, antibiotics, analgesia, and oxygen supplementation. Transfusion requirements vary depending on degree of severity:

- Mild—often no blood transfusion needed
- Moderate—simple blood transfusion
- Severe—exchange transfusion until HbA level is $\geq 70\%$

Exchange transfusion is also sometimes required for treatment of priapism, cerebral sickling, and aplastic crisis. Occasionally, more conservative therapy with a simple transfusion and/or supportive care treats these presentations. A partial exchange transfusion program is reserved for those with a history of stroke. Folate supplementation is important. Medications such as hydroxyurea are used to increase HbF production, which offers some protection against sickle crisis.

Two new medications are available:

- Voxelotor (Oxbryta), approved in 2019 (mechanism: reduced HbS polymerization), is an option for individuals ≥ 12 years of age who continue to have vaso-occlusive pain episodes despite appropriately dosed hydroxyurea or who cannot tolerate hydroxyurea for any reason.
- Crizanlizumab (Adakveo), approved in 2019 (mechanism: anti-P-selectin), is an option for individuals ≥ 16 years of age with SCD who have acute vaso-occlusive pain episodes unresponsive to hydroxyurea, L-glutamine, or both. Crizanlizumab is a monoclonal antibody directed against P-selectin, an adhesion molecule expressed on activated platelets and endothelial cells. It is thought to reduce vaso-occlusive pain by reducing interactions between endothelial cells and circulating blood cells.

Long-term effects of SCD include avascular necrosis of the femoral head, sickle retinopathy, sickle nephropathy, and pulmonary hypertension.

Hereditary Spherocytosis (HS) and Elliptocytosis

HS and elliptocytosis are autosomal-dominant (AD) disorders of the RBC cytoskeleton that result in loss of membrane flexibility and are associated with chronic hemolysis. These disorders are seen in Northern European populations.

Complications of spherocytosis and elliptocytosis can include cholelithiasis, due to bilirubin stones, and splenomegaly. Think about these disorders in patients who demonstrate evidence of hemolysis and have spherocytes (Figure 8-24) or elliptocytes (Figure 8-14 on page 8-5) on their peripheral smear. Coombs test is negative.

Figure 8-24: Hereditary spherocytosis. Note the lack of central pallor. The normal-size lymphocyte shows that these are microcytic spherocytes.

The osmotic fragility test was traditionally used in diagnosing HS. (The reduced surface:volume ratio makes spherocytes more susceptible to osmotic stress.) The eosin-5-maleimide (EMA) binding test is the favored diagnostic test due to its superior sensitivity and specificity and its rapid turnaround time. Sophisticated molecular membrane studies (usually available at research institutions) can be done to make a definitive diagnosis (e.g., sodium dodecyl sulfate–polyacrylamide gel electrophoresis [SDS-PAGE]), but it does not change management.

Treatment includes recombinant EPO with iron and folate supplementation and, if needed, supportive blood transfusions. Total or partial splenectomy may be required to prolong RBC survival.

Paroxysmal Nocturnal Hemoglobinuria (PNH)

PNH is a rare, acquired stem cell disorder resulting from a defective *PIGA* gene. The result is the loss of a membrane-bound protein, which, when present, anchors other proteins to the cell membrane. Some of these anchored proteins serve to protect the cell against complement-mediated lysis. Without the anchor protein, this protection is lost.

Clinical presentation includes a variable degree of complement-mediated intravascular hemolysis and free Hgb, which can lead to chronic hemoglobinuria and iron deficiency. The free Hgb causes a reduction in nitric oxide (NO), which then causes the classic symptoms of episodic abdominal and chest pain. NO effects on smooth muscle cause diffuse esophageal spasms that coincide with hemoglobinuria. The other major potential complication is arterial or venous thrombosis (especially of abdominal veins; think about PNH in cases of Budd-Chiari syndrome). Rarely, transformations to aplastic anemia, acute leukemia, and myelofibrosis occur.

Diagnosis is made using specific flow cytometry assays for CD55 (decay accelerating factor) and CD59 (homologous restriction factor)—complement proteins that are lost from the cell membrane when the anchor protein is absent.

Definitive treatment is allogeneic bone marrow transplant. Otherwise, treat hemolysis with corticosteroids. Use anticoagulants to treat thrombotic events. Eculizumab, an antibody to the C5 terminal component, decreases hemolysis and the need for transfusion and improves quality of life.

Extrinsic Survival Defects

Microangiopathic Hemolytic Anemia (MAHA)

MAHA is the nonimmune (i.e., Coombs-negative) destruction of erythrocytes, usually caused by physical shearing during passage through small vessels that have had endothelial damage with platelet aggregation or fibrin deposition. This platelet aggregation causes thrombocytopenia. See Table 8-4 on page 8-16.

Table 8-4: Classification of Thrombotic Microangiopathies

Microangiopathy	Causes
Thrombotic thrombocytopenic purpura (TTP)	Acquired (autoimmune)—antibodies against ADAMTS13 Congenital—ADAMTS13 mutations (Upshaw-Schulman syndrome)
Shiga toxin–producing <i>Escherichia coli</i> hemolytic uremic syndrome (STEC-HUS)	Shiga toxin–producing <i>E. coli</i> <i>Shigella dysenteriae</i>
Atypical hemolytic uremic syndrome (aHUS)	Complement alternate pathway regulatory defects Diacylglycerol kinase epsilon (DGKE) defects Cobalamin metabolic defects
Secondary thrombotic microangiopathy, associated with:	Malignant hypertension Mechanical hemolysis—malfunctioning aortic or mitral valve prostheses Pregnancy—preeclampsia/eclampsia, HELLP syndrome Infections—viral, bacterial, fungal Disseminated intravascular coagulation Cancer Hematopoietic stem cell or solid organ transplantation Antiphospholipid antibody syndrome Autoimmune disease Vasculitis Ionizing radiation Drugs (e.g., calcineurin inhibitors, mitomycin C, gemcitabine, vascular endothelial growth factor [VEGF] inhibitors, ticlopidine, quinine)

Adapted from Majerus, E.M. and Sadler, J.E., "Microangiopathic Hemolytic Anemia" in *Anemia: Pathophysiology, Diagnosis, and Management*. Benz, E., Berliner, N., and Schiffman, F.J. (eds). Cambridge University Press. 2018.

MAHA is seen in:

- TTP
- HUS
- Secondary thrombotic microangiopathy
- DIC
- Mechanical heart valve malfunction
- Intraaortic balloon pumps

Autoimmune Hemolytic Anemia (AIHA)

AIHA is usually caused by IgG or IgM antibodies. Antibodies that react with RBC membrane proteins are often IgG. These antibodies induce hemolysis either by stimulating macrophages and other cells in the spleen and reticuloendothelial system to gradually snip portions of membrane away (causing spherocytes) or by causing complement-mediated destruction. Review Table 8-5 during the following discussion.

IgG antibodies react best at body temperature (a.k.a. **warm antibodies**). They can be idiopathic or secondary to neoplasm or connective tissue disease. In AIHA, the direct Coombs test, which detects antibodies on the RBC surface, is positive using antibodies to IgG. Treat with corticosteroids. Splenectomy is reserved for refractory cases. The anti-CD20 monoclonal antibody rituximab is sometimes also used in difficult-to-treat patients.

IgM antibodies often bind to polysaccharides or complement. These antibodies react better at room temperature (a.k.a. **cold antibodies**). The direct Coombs test uses an antibody to C3 to detect complement (rather than the IgM antibody itself). IgG antibodies rarely induce complement fixation on RBC surfaces.

These IgM autoantibodies may be secondary to:

- Neoplasm (especially chronic lymphocytic leukemia [CLL] and, less frequently, non-Hodgkin lymphoma)
- Infection, **especially** *Mycoplasma pneumoniae* and infectious mononucleosis
- Systemic lupus erythematosus (SLE)

Treatment is best accomplished by maintaining a warm environment and identifying and treating the underlying cause. Steroids are **ineffective**.

Table 8-5: Autoimmune Hemolytic Anemia

	Warm Ab	Cold Ab
Temperature at which RBCs agglutinate	Body temperature	Below body temperature
Ab Type	IgG	IgM
Causes	Viral, autoimmune, transfusions, malignancy (e.g., CLL)	Infection (e.g., <i>Mycoplasma</i> , Epstein-Barr virus), lymphoma
Diagnosis	DAT-IgG or C3 fragment	DAT-C3 (negative for DAT-IgG)
Treatment	Corticosteroids/splenectomy/rituximab	Keep warm/treat the underlying cause/rituximab

Ab = antibody
CLL = chronic lymphocytic leukemia
DAT = direct antiglobulin test
RBC = red blood cell

Drug-Associated Hemolysis

Many drugs can cause hemolysis. Penicillin bound to RBCs may elicit an antibody response that can cause hemolysis. Quinine, methyldopa, and certain cephalosporin antibiotics are also known culprits. The pattern of abnormal Coombs testing varies with the type of drug. Treatment, of course, begins with discontinuing the offending agent.

Microbe-Induced Hemolytic Anemia

Several infections can cause hemolytic anemia through extrinsic mechanisms. Malaria, bartonellosis, and babesiosis cause anemia by direct parasitization of the RBCs. *Clostridium perfringens* and *Haemophilus influenzae* Type b cause hemolysis through bacterial byproducts. Treatment is aimed at the underlying infection and supportive care. This is also covered in the [Infectious Disease](#) section.

Sequestration Defect

Sequestration anemia occurs with overactive, often enlarged spleens in a variety of disorders—especially portal hypertension, where RBCs, WBCs, and platelets may be sequestered. Splenic sequestration may occur in early childhood with HbSC and HbS/β-thalassemia (before splenic infarction and fibrosis are seen). In fact, in adults with HbSC, splenic infarction and splenic sequestration crises (which is mainly seen in the young with HbSS) can occur.

Blood Loss

Anemia from acute blood loss is often obvious from injuries or GU and GI tract loss but can be less obvious in intrapulmonary, retroperitoneal, and rectus abdominis sites. And remember, again, any IDA is considered to be due to chronic blood loss until proved otherwise (see [Microcytic Anemias on page 8-7](#)).

Liver Disease

Anemia is common in liver disease:

- Cirrhosis causes spur cell anemia (see [Figure 8-12 on page 8-5](#)) due to abnormal cholesterol production. RBCs change shape and are hemolyzed.
- Portal hypertension causes splenic sequestration and cytopenias.
- Alcohol use is associated with nutritional (megaloblastic) anemias, especially from folate deficiency.
- Alcohol directly inhibits EPO production and erythropoiesis.
- Viral hepatitis can cause anemia through direct inhibition of the marrow and via autoimmune hemolysis.
- GI blood loss is common, especially if the patient has esophageal varices.

Chronic Kidney Disease (CKD)

Anemia in CKD is discussed extensively in the [Nephrology](#) section.

Cancer Patients

Cancer patients may have coexisting causes of anemia. Consider these possibilities:

- Bone marrow infiltration by cancer cells
- Chemotherapy-induced anemia
- Infection-causing bone marrow suppression
- Medications, including antibiotics/antivirals
- Autoimmune hemolytic anemia (e.g., lymphoproliferative disorders, such as CLL)
- Sequestration
- ACD
- Blood loss from bleeding tumors
- Iron deficiency (especially in GI cancers)
- Malnutrition

Treatment is often supportive, with transfusions provided as needed. EPO-stimulating agents are almost never indicated except in very specific scenarios, including some cases of myelodysplastic syndrome. These agents can be considered when chemotherapy for noncurative intent causes symptomatic anemia—but even in this context, they are still controversial.

MISCELLANEOUS DISORDERS THAT AFFECT RBCs

PREVIEW | REVIEW

- What is the most common neurologic manifestation of porphyria?
- What is the typical presentation of hereditary hemochromatosis (HH)?
- Which tests are used to diagnose HH?
- Which disorder(s) cause(s) a high ferritin? A high ferritin with multiple cytopenias and hemophagocytosis in the bone marrow?

METHEMOGLOBINEMIA

Oxidation of heme iron from the ferrous Fe^{2+} to the ferric Fe^{3+} state forms altered Hgb (methemoglobin), which has an impaired ability to reversibly bind oxygen. Methemoglobin gives the blood a dark color, so patients appear cyanotic despite a normal PaO_2 on arterial blood gas. Pulse oximetry is not reliable. The preferred diagnostic method is direct analysis for methemoglobin, rather than assessment of oxygen saturation or blood gas analysis. Symptoms include headache, dizziness, dyspnea, tachypnea, tachycardia, and obtundation. Severe tissue

hypoxia and death can result as levels rise. Causes are hereditary and/or acquired and can include industrial chemicals and drugs: nitrates/nitrites (e.g., nitroglycerin, amyl nitrite [a.k.a. Poppers], nitroprusside—but rarely NO), phenazopyridine (e.g., over-the-counter bladder analgesic), dapsone, sulfonamides, and anesthetics (e.g., oral benzocaine, lidocaine). Treat severe cases with methylene blue.

PORPHYRIAS

The porphyrias are inherited (most cases) or acquired metabolic disorders in which heme biosynthetic pathway enzymes are deficient, resulting in excess accumulation and excretion of porphyrins and their precursors. Porphyria cutanea tarda (PCT), the most common of the porphyrias, is an acquired mutation.

The porphyrias are classified as either acute or cutaneous. **Acute porphyrias** (especially acute intermittent porphyria) affect the **neurologic** system, causing neurovisceral abdominal pain (most common), psychiatric disorders, and other neurologic manifestations (e.g., neuropathic pain, encephalopathy). **Cutaneous porphyrias** cause either acute nonblistering or chronic blistering reactions (PCT) in sun-exposed areas.

Clinical manifestations can be extremely subtle and can mimic many other disorders.

Administer dextrose via intravenous infusion as the initial treatment in the absence of neurologic symptoms or organ failure. Treat severe cases with intravenous hematin. Both of these treatments decrease heme synthesis and slow the buildup of the toxic precursors.

Treat PCT with regular phlebotomy to decrease ferritin to less than ≤ 20 ng/mL.

HEREDITARY HEMOCHROMATOSIS (HH)

HH is an iron-overload disorder due to ≥ 1 mutations, with *HFE* gene mutations being the most common. These mutations cause the body's appetite for iron to be insensitive to the presence of adequate iron stores. The 2 most common *HFE* mutations are *C282Y* and *H63D*. Caucasians have the highest incidence of *C282Y* homozygosity, followed by Native Americans. Compound heterozygosity (*C282Y* with *H63D*) and heterozygosity for either *C282Y* or *H63D* are the next most common genotypes.

Other genotypic variations include mutations in genes that code for the transferrin receptor ferroportin and for hepcidin, a peptide that plays a central role in human iron metabolism. HH is ordinarily inherited in an autosomal-recessive (AR) fashion. HH should be distinguished from acquired secondary causes of hemochromatosis, including transfusional iron overload (think of a sickle cell patient requiring multiple blood transfusions). Iron can accumulate in the liver and other organs in a variety of both hereditary and acquired conditions when there is a genetic basis. In hereditary hemochromatosis, iron overload of the parenchyma of various organs—especially the

liver, pancreas, and heart—is progressive. Hemosiderosis is associated with systemic macrophage and reticuloendothelial iron accumulation from blood transfusions, hemolytic states, and ACD, and in some hepatitises, such as hepatitis C, alcoholic liver disease, PCT, and cirrhosis. Liver parenchyma and heart muscle can be secondarily affected in hemosiderosis.

Clinical disease does not develop in all patients who inherit the mutations, even with *C282Y* homozygosity. The phenotype of skin hyperpigmentation, arthropathy, cirrhosis, cardiomyopathy, and endocrinopathies that characterize fully penetrant HH may require ≥ 1 mutations in the *HFE* gene plus inheritance of ≥ 1 of the other genetic variations and/or exposure to environmental risk factors (e.g., excessive alcohol use).

The *HFE* protein is expressed in the deep crypt cells of the duodenum and normally acts as a sensor of the body's iron stores, modulating the uptake of transferrin-bound iron into these cells. *HFE* mutations decrease this transferrin receptor-mediated uptake of iron into crypt cells, sending a false signal of low iron stores to the intestinal cells and causing an up-regulation of the intestinal iron transporter DMT (divalent metal transporter) protein in the lumen. DMT also regulates lead, zinc, and copper. This unchecked absorption of intestinal iron leads to elevated levels of serum ferritin, with concomitant iron deposition into multiple organ systems, including the liver, heart, skin, gonads, joints, and pancreas.

Although classically described as a triad of cirrhosis, bronzed skin pigmentation, and diabetes mellitus, HH is more commonly diagnosed at an earlier stage in the disease. Patients most often present in middle age with early signs and symptoms of iron overload, including (from most to least common):

- Fatigue and weakness
- Abnormal liver transaminases
- Bronzing of the skin
- Diabetes mellitus
- Joint pain +/- calcium pyrophosphate crystalline disease (i.e., pseudogout, chondrocalcinosis)
- Erectile dysfunction/hypogonadism
- Restrictive cardiomyopathy

Women may present with symptoms after menopause (in their mid-to-late 50s) because the monthly menses served as adequate phlebotomy during their younger years.

The most sensitive test to diagnose HH is transferrin saturation (serum iron/TIBC $\times 100\%$). Once you suspect HH based on a transferrin saturation of $> 45\%$, include iron studies in the diagnostic workup to further quantify iron overload. A ferritin level $> 1,000$ ng/mL (2247 pmol/L) suggests iron overload. Genetic testing can be done for the most common underlying genetic mutations. Liver biopsy, the diagnostic gold standard, is largely used as a prognostic indicator or, in cases in which laboratory and genetic testing is equivocal, in the face of high clinical suspicion. Magnetic resonance imaging (MRI) at an

experienced facility can detect iron in the liver, heart, joints, and pituitary.

Also test 1st degree family members for the disease. (The role of population screening for HH remains uncertain.) Early diagnosis of HH is extremely important, however, because devastating consequences of the disease are easily preventable with timely treatment.

Phlebotomy remains the foundation of management of iron overload. Because it is not known who develops cirrhosis and hepatocellular carcinoma, treatment is recommended for those with elevated liver iron content. Initially remove one to two 500-mL units of blood (each containing about 250 mg of iron) weekly until the serum ferritin is 20–50 ng/mL (44.94–112.35 pmol/L) and the transferrin saturation is < 30%. The typical patient requires removal of 20–25 units of blood to complete this 1st stage. Even after treatment, transferrin saturation may remain high.

Lifelong maintenance phlebotomy, usually 2–4×/year, with regular monitoring of serum Hgb is then needed to keep serum ferritin levels < 50–100 ng/mL (112.35–224.7 pmol/L) and transferrin saturations < 50%. Although this regimen does not reverse previously established cirrhosis or other sequelae of iron deposition, progression can slow and new disease development prevented.

All patients are at increased risk for infection with *Listeria* (because the excess iron impairs macrophage function) and with bacteria that utilize iron as a substrate (e.g., *Vibrio* and *Yersinia*).

Patients need to avoid uncooked seafood because of the risk of disseminated *V. vulnificus*.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH)

HLH is a rare syndrome that mainly affects children but can affect adults. HLH is an **extreme** inflammatory state characterized by **uncontrolled** immune system activation.

There are genetic linkages (**familial** HLH), and there are several conditions that can trigger this disorder (**acquired** HLH), including rheumatologic, infectious, metabolic, and malignant conditions. Malignancies include leukemias and lymphoid cancers (especially T, NK, and anaplastic large cell lymphomas). Rarely, solid tumors trigger HLH.

HLH is not a malignancy, but it is often confused with or may accompany malignancies.

The **uncontrolled** immune activation can result in:

- Hepatosplenomegaly, lymphadenopathy, neurologic symptoms, and rash
- Cytopenia, usually involving ≥ 2 cell lines, is common.
- Very high serum ferritin levels (> 3,000 ng/mL [6741 pmol/L] is indicative of HLH, but it can exceed 50,000 [~112,000]; normal is < 300 [675].)

- Hemophagocytosis seen on bone marrow examination and in lymph node, spleen, and liver biopsies
- Fevers
- Hypertriglyceridemia
- Neurologic manifestations (i.e., seizures, mental status changes)

Other disorders with high serum ferritin levels include hemochromatosis and adult-onset Still disease.

Diagnosis of HLH can be difficult; not only are each of these findings fairly nonspecific, but patients usually do not have all of them on presentation! TTP, HUS, and drug-induced thrombotic microangiopathy (DITMA) can be confused with HLH. Given a transfusion history, transfusion-associated graft-versus-host disease is also in the differential diagnosis.

Urgently treat deteriorating clinical status with dexamethasone and etoposide. Methotrexate and alemtuzumab can also be used.

HEMOSTASIS

OVERVIEW

Clotting after a vascular injury consists of 2 stages: primary hemostasis and secondary hemostasis. Primary hemostasis is the function of the platelets, whereas secondary hemostasis is dependent upon the coagulation factors.

PRIMARY HEMOSTASIS

PREVIEW | REVIEW

- Explain how aspirin and nonsteroidal antiinflammatory drugs work to decrease platelet function.
- What is the lifespan of a platelet?

Primary hemostasis consists of platelet plug formation, vascular spasm, and capillary endothelial adhesion, with capillaries collapsing and sticking closed when empty. This “fix” is temporary and lasts for only 12–24 hours. (This is why hemophiliacs often do not have a deep bleed until 12–24 hours after trauma, as their platelet function is intact.)

Platelet plug formation = platelet attachment → platelet activation → platelet aggregation.

After endothelial injury, platelets rapidly attach to the newly exposed subendothelial collagen. The von Willebrand factor (vWF), released from the endothelium, reacts with the platelet surface glycoprotein 1b/9 to increase stickiness of platelets to each other and to exposed collagen. Platelets are then activated, releasing cytokines, including adenosine diphosphate (ADP) and arachidonic acid, which further stimulate platelet release and aggregation. Arachidonic acid is converted by cyclooxygenase into precursors of thromboxane A₂. Thromboxane A₂ recruits

more platelets and exposes platelet surface glycoprotein 2b/3a (GP 2b/3a). Thromboxane A₂ is also a potent vasoconstrictor. Fibrinogen then cross-connects the 2b/3a protein on platelets to form platelet plugs.

Therapeutic implications: There are several FDA-approved GP 2b/3a receptor inhibitors available (e.g., abciximab, eptifibatide, tirofiban). Approved indications include unstable angina and adjunctive therapy during coronary angioplasty. Aspirin (ASA) irreversibly acetylates cyclooxygenase and thus decreases platelet function. Chronic ASA use of as little as 40 mg/day causes suppression of 95% of thromboxane A₂. Nonsteroidal antiinflammatory drugs (NSAIDs) bind reversibly with cyclooxygenase; they may block the desired effect of ASA if they are administered at the same time. Clopidogrel irreversibly inhibits ADP binding to the platelet receptor, resulting in decreased platelet aggregation. The average lifespan of a platelet is about 1 week, which is why aspirin and NSAIDs are held for 7 days before surgery.

SECONDARY HEMOSTASIS — THE COAGULATION CASCADE

Follow along in Figure 8-25 as we go through the coagulation cascade. The green lines and arrows are the pathways that result in coagulation (i.e., clot formation).

The **extrinsic pathway** is where it all starts. Virtually all coagulation is initiated by **tissue factor** (released at the site of injury) interacting with Factor 7. Tissue factor is short lived and in short supply—so the extrinsic pathway can produce only a small amount of **thrombin**.

The **intrinsic pathway** (a.k.a. contact activation pathway, intrinsic amplification pathway) consists of Factors 8, 9, 11, and 12. It serves mainly to amplify the formation of **thrombin**, but it can do so only after a small amount of thrombin is first formed by the extrinsic pathway.

Thrombin is the key. As you can see in Figure 8-25, while it builds the **fibrin** clot, this little bit of thrombin also activates the intrinsic pathway to amplify the production of more thrombin.

Thrombin does the following:

- Converts **fibrinogen** to **fibrin**
- Activates Factor 13, which causes this fibrin to cross-link and form the thrombus
- Activates Factor 11, which, in turn, activates Factor 9
- Activates Factor 8; Factors 8a and 9a together activate Factor 10.

So, the first 2 processes help make the thrombus, while the second 2 are part of a powerful intrinsic amplification system that makes more thrombin.

Figure 8-25: Coagulation cascade

Note that even though Factor 12 can be activated by negative ions on newly exposed tissue, this process and Factor 12 itself play a minor role in coagulation. Patients with Factor 12 deficiency have **no** bleeding problems.

Okay, so how does the body **stop** this process? Thrombus dissolution, or **fibrinolysis**, is initiated by tissue plasminogen activator (tPA) and released from the endothelial cells. tPA converts **plasminogen** to **plasmin**, which then breaks down fibrin and fibrinogen and limits the size of the thrombus. Proteins C and S are natural anticoagulants; they inactivate Factors 5a and 8a. Protein C also blocks the inhibitor of tPA, plasminogen activator inhibitor-1 (PAI-1). In healthy people, this results in fibrinolysis. In the absence of proteins C and S, thrombosis goes unchecked.

AN APPROACH TO THE PATIENT

PREVIEW | REVIEW

- At the bedside, how can you tell whether a hemostatic problem is primary or secondary?
- What are the 4 tests initially used to evaluate a bleeding disorder? What do they measure?

It is often possible to differentiate between a primary and a secondary hemostatic problem at the bedside:

- **Primary hemostatic problems** (90% involve either platelet dysfunction or low platelets) result in multiple, tiny, superficial hemorrhages, causing petechiae, purpura (large petechiae), ecchymoses, and **mucocutaneous bleeding** (e.g., gingival bleeding, menorrhagia, epistaxis).
- **Secondary hemostatic disorders** (e.g., hemophilia), on the other hand, develop **deep tissue bleeding**, including hematomas or hemarthroses.

Typically, 4 tests can quickly assess coagulation and platelet status:

- 1) Prothrombin time (PT) measures the function of extrinsic and common pathways.
- 2) Activated partial thromboplastin time (aPTT) measures the function of the intrinsic and common pathways.
- 3) Platelet count
- 4) Platelet function tests evaluate platelet aggregation when stimulated by epinephrine, ADP, and collagen.

DISORDERS OF PRIMARY HEMOSTASIS

PREVIEW | REVIEW

- What is the usual clinical presentation of immune thrombocytopenia (ITP) in an adult patient?
- What are the 1st and 2nd line treatments for ITP?
- Thrombotic thrombocytopenic purpura (TTP) is due to problems with which enzyme?

- Which 5 clinical manifestations occur with TTP? With atypical hemolytic uremic syndrome (aHUS)?
- What is the treatment of choice for TTP? For aHUS?
- Which bacterial infections are implicated with diarrhea-associated HUS?
- What do the letters in HELLP syndrome stand for? In which patients does it occur?
- Does heparin-induced thrombocytopenia Type II (HIT-II) cause bleeding or thrombosis?
- What is the treatment for HIT-II?
- When does posttransfusion purpura occur?
- What are Factor 8 activity levels in patients with von Willebrand disease (vWD)?
- What are the 2 most common types of vWD?
- What are the differences between Bernard-Soulier syndrome and Glanzmann thrombasthenia?

Disorders of primary hemostasis involve the vascular endothelium or platelets. This review focuses on platelet disorders of primary hemostasis, which include both quantitative and qualitative defects.

Thrombocytopenia has multiple etiologies, which can be categorized into defects of production, sequestration, and destruction.

Pseudothrombocytopenia (a.k.a. spurious thrombocytopenia) is due to platelet clumping after the blood draw, resulting in low platelets being detected by the automated counter. Such an artifact occurs fairly often, so the 1st test to do after observing a low platelet count result is a repeat platelet count. You can also get a peripheral blood smear to look for platelet clumping.

You can see **abnormal platelet function** after aspirin ingestion and in von Willebrand disease (vWD), Bernard-Soulier (giant platelet) syndrome, Glanzmann thrombasthenia, paraproteinemia (multiple myeloma), chronic kidney disease (CKD), and connective tissue disease.

Clotting factor deficiencies often present with deep bleeding, such as hemarthrosis and large hematomas, whereas disorders of platelet number or function typically involve mucocutaneous sites with petechiae or superficial bleeding.

Primary Hemostasis Disorders — Thrombocytopenias

Thrombocytopenia has 3 causes:

- 1) **Decreased production:** due to bone marrow failure from toxins (including alcohol), infiltration, aplasia, sepsis, and HIV infection. Often there is concomitant anemia and/or leukopenia.

- 2) **Sequestration:** pooling in an enlarged spleen (hypersplenism). Thrombocytopenia is typically modest and accompanied by a reduction in the other cell lines (leukopenia and anemia).
- 3) **Survival defects** (i.e., increased destruction):
 - Consumptive process, such as DIC, heparin-induced thrombocytopenia (HIT), TTP/HUS, and HELLP
 - Immune thrombocytopenia, either primary, secondary, or drug induced. Common drug offenders include quinidine, rifampin, sulfonamide combinations, and digoxin.

If the platelet count is $> 20,000/\mu\text{L}$ ($20 \times 10^9/\text{L}$), there is usually no serious spontaneous bleeding. When the count is $< 10,000/\mu\text{L}$ ($10 \times 10^9/\text{L}$), the risk of serious bleeding increases and platelet transfusions are often considered. Do not transfuse platelets if you suspect HIT or TTP unless the patient has active life-threatening bleeding.

Immune Thrombocytopenia (ITP)

ITP is an **autoimmune** syndrome that occurs in children and adults. In children, it often has an acute presentation, occurs after a viral illness, and is usually self-limited with a good prognosis. Chronic ITP generally occurs in adults and has a relapsing course. Both acute and chronic ITP are associated with IgG antibodies directed against the GP 2b/3a glycoproteins on platelets that lead to destruction of platelets. When associated with an underlying disease in which antiplatelet antibodies are formed, patients are said to have secondary ITP.

Underlying diseases that can be associated with secondary ITP include SLE, antiphospholipid syndrome, CLL, and viruses, including HIV and hepatitis C. Recall that many of these same diseases are also associated with autoimmune hemolytic anemias.

The adult patient with ITP typically presents with easy bruising, petechiae, and **nonpalpable** purpura (Figure 8-26; in contrast, IgA vasculitis is palpable.) Patients with ITP have **mucosal bleeding** (e.g., gingival bleeding, menorrhagia, epistaxis). When ITP occurs in an elderly patient, the patient can present with a GI or central nervous system bleed.

Platelets in patients with ITP are often hyperfunctional; and, even with severe thrombocytopenia, significant spontaneous bleeding is rare.

Primary ITP is a diagnosis of exclusion, so rule out other causes. Do **not** order an antiplatelet antibody test. The result is too nonspecific to be helpful!

Do the following:

- As with **all** cases of thrombocytopenia, repeat the platelet count.
- Examine the peripheral smear to make sure platelets are not clumping and that schistocytes

Figure 8-26: Petechiae and purpura

are absent. (Presence of schistocytes along with thrombocytopenia suggests TTP is the underlying diagnosis, not ITP.) Around 1/1,000 automated platelet counts are falsely low. Clumping is caused by platelet activation by ethylenediaminetetraacetic acid (EDTA). Collecting the sample in a citrate tube corrects this problem.

- The peripheral smear in ITP typically reveals few but **large** (young) **platelets** and normal RBCs and WBCs.
- Patients > 60 years of age may need a bone marrow biopsy to exclude myelodysplasia before being diagnosed with ITP. In ITP, marrow cellularity is normal with evidence of megakaryocyte hyperplasia.

Treat chronic ITP **only** if symptomatic or if the platelet count is very low ($< 30,000/\mu\text{L}$):

- Corticosteroids (prednisone 1 mg/kg or equivalent daily) are 1st line treatment.
- Give IV immunoglobulin (IVIG) as an adjunctive treatment when a rapid improvement in platelet count is desired, as in a preoperative or bleeding patient. IVIG satiates voracious macrophages, which then become less hungry for antibody-coated platelets, leading to an increase in platelet count. Response, however, is regularly transient—lasting only several weeks.
- Historically, many hematologists tried anti-D immunoglobulin if patients were Rh+ and had a functional spleen. This induces a mild hemolytic state, with resultant RBC stromal release and uptake by reticuloendothelial cells. The uptake of RBC stroma (as with IVIG) interferes with the ingestion of antibody-coated platelets and results in the elevation of platelet counts. Use of anti-D has now fallen out of favor with most hematologists due to an FDA black box warning of rare but potentially life-threatening acute hemolytic transfusion reactions.

- 2nd line therapy for ITP is indicated when you have:
 - No response to steroids
 - Frequent relapses
 - Inability to taper off steroids within 3-6 months
- 2nd line therapy options include splenectomy, thrombopoietin receptor agonists (TPO-RAs), or rituximab.
 - Splenectomy induces a complete response in 2/3 of patients, but there may be relapses. Remember: Give all patients vaccinations for *S. pneumoniae*, *H. influenzae*, and *N. meningitidis* at least 2 weeks prior to elective splenectomy, because splenectomized patients are at an increased risk of infections from these organisms.
 - Rituximab is an alternative to splenectomy and can achieve durable responses in steroid-refractory patients. Rituximab is a monoclonal antibody directed against CD20 present on B lymphocytes.
 - Romiplostim and eltrombopag are TPO-RAs approved by the FDA for refractory ITP. These may also be used to avoid splenectomy.
 - Fostatinib is a prodrug tyrosine kinase inhibitor approved by the FDA for refractory ITP after the TPO-RAs have failed.
 - Azathioprine, cyclosporine, and mycophenolate have also been used with some success.

Give platelet transfusions if there are signs of severe bleeding and prior to invasive procedures. While platelet counts may not rise, transfusions can be hemostatically effective. Even so, they are not effective for long-term management.

Thrombotic Microangiopathies

Thrombotic Thrombocytopenic Purpura (TTP)

Acquired TTP and atypical hemolytic uremic syndrome (aHUS) in adults were once considered variants on a spectrum of disease, although it is now understood they have different pathophysiologies. Both TTP and HUS are considered to be thrombotic microangiopathies. (See Table 8-4 on page 8-16.) In general, there are 2 types of TTP (inherited and acquired) and 2 types of HUS: atypical HUS and typical diarrhea-associated HUS (a.k.a. Shiga toxin-producing *E. coli* hemolytic uremic syndrome [STEC-HUS] and Shiga toxin-associated hemolytic uremic syndrome [ST-HUS]).

Inherited (congenital) TTP is extremely rare and is due to a defect in the *ADAMTS* gene that causes a deficiency in the ADAMTS13 enzyme.

Acquired (autoimmune) TTP affects adults and is due to an inhibitor that causes decreased activity of the ADAMTS13 enzyme. This enzyme is responsible for cleaving the ultra-large multimers of vWF. Such multimers otherwise build up, leading to platelet consumption and hemolysis.

TTP is a fulminant disorder of increased platelet consumption, with high mortality, that is marked by thrombocytopenia and microangiopathic hemolytic anemia. TTP generally affects younger adults, with a peak in the 3rd decade of life. Most commonly, TTP is idiopathic, but it is also associated with:

- Drug exposures (e.g., quinine, cancer chemotherapy, clopidogrel, ticlopidine)
- Post hematopoietic stem cell transplantation
- Pregnancy
- Oral contraceptives
- Disseminated occult mucin-producing adenocarcinomas
- HIV infection
- SLE
- Antiphospholipid syndrome (APS)

Clinical manifestations of TTP:

- 1) Hemolytic anemia (microangiopathic, with schistocytes on peripheral blood smear)
- 2) Thrombocytopenia
- 3) Neurologic changes (e.g., confusion, severe headache, seizure)
- 4) Fever
- 5) Chronic kidney disease (mild if it occurs; more common in HUS)

Patients infrequently present with all 5 findings. The dyad of thrombocytopenia and microangiopathic hemolytic anemia is sufficient to narrow the differential to TTP vs. aHUS (vs. HUS if patient is pregnant). TTP typically presents with neurologic involvement and minimal or no renal dysfunction.

Peripheral blood smear in TTP shows thrombocytopenia and anemia with schistocytes. Labs commonly indicate a Coombs-negative hemolysis with an elevated LDH and indirect bilirubin +/- increased creatinine. The reticulocyte count is elevated in the face of hemolytic anemia. TTP and DIC can have similar clinical presentation with microangiopathic hemolytic anemia and thrombocytopenia in an acutely ill patient.

Unlike in DIC, the PT, aPTT, fibrinogen, Factor 5, and Factor 8 are usually normal because the coagulation cascade is not activated in TTP.

Low functional ADAMTS13 enzyme levels can be used to support a TTP diagnosis, but results are generally not available in a timely manner.

Treat TTP with plasma exchange, using fresh frozen plasma (FFP) or cryosupernatant (plasma from which cryoprecipitate has been removed—because the cryoprecipitate contains vWF multimers that can contribute to increased clotting). Know that there are 2 situations where plasmapheresis has not been shown to have any effect:

- 1) In conjunction with cancer chemotherapy drugs
- 2) After hematopoietic stem cell transplantation

For acquired forms of TTP, glucocorticoids play a therapeutic role, and evidence for rituximab use is evolving.

LDH levels serve as a marker of hemolysis and platelet destruction; follow them to gauge the effect of therapy.

Unless life-threatening bleeding is present, do **not** give platelet transfusions because the extra platelets are simply consumed and cause more thrombosis. If the patient does not respond to plasmapheresis, then corticosteroids and/or rituximab are additional options.

Clinical question: When a previously healthy patient presents with petechiae, ecchymosis, normal mental status, thrombocytopenia, and anemia, what further evaluation is required?

Answer: Do a peripheral blood smear, PT, and LDH. If there are schistocytes, a normal PT, and elevated LDH, the patient likely has TTP. If there are no schistocytes, a normal PT, and normal LDH, the patient likely has ITP. This is a **very important** distinction, because TTP is a medical emergency even if the patient is feeling fine. The patient can have a precipitous stroke or deterioration in cognition or renal function. Check renal chemistries (BUN, creatinine) to evaluate for renal dysfunction, which is seen in TTP.

Atypical Hemolytic Uremic Syndrome (aHUS)

aHUS, a rare disorder, can be confused with TTP because aHUS has the same 5 manifestations and same labs as TTP except that **renal involvement** occurs in all cases and neurologic involvement either does not occur or is minimal.

aHUS has many causes, quite a few of which are related to disorders in complement regulation. ADAMTS13 enzyme levels are > 10% and generally stay within normal reference intervals.

Treatment is eculizumab, a monoclonal antibody that selectively inhibits the terminal complement cascade. Note that eculizumab predisposes the patient to fulminant meningococcal infections. For some types of aHUS, eculizumab is not effective and plasma exchange transfusion is done.

Diarrhea-Associated HUS

The most common form of the life-threatening HUS (same labs as TTP) is often precipitated by food- or waterborne infections with enterohemorrhagic Shiga toxin-producing *E. coli* O157:H7 or O104:H4 (STEC) or Shiga toxin-producing *Shigella sonnei* and is associated with a prodrome of bloody diarrhea. This presentation is termed diarrhea-associated or Shiga toxin-associated hemolytic uremic syndrome (**ST-HUS**) to differentiate the disease from aHUS. The Shiga toxin is absorbed into the circulation and binds to globotriaosylceramide receptors on the surface of vascular endothelial cells, with a predilection for the brain (e.g., seizures, cortical blindness) and kidney (e.g., renal failure). It directly activates the complement pathway, resulting in more inflammation.

Treatment is supportive, with IV hydration and possibly blood products. Eculizumab is sometimes tried in severe cases, as some individuals appear to respond rapidly, but in larger trials, no differences in outcomes were noted. There is no standard role for plasma exchange. Many patients require hemodialysis. Antibiotics are thought to worsen the HUS, so do not use. Those with neurologic sequelae have a higher morbidity. While the majority survive, some have permanent neurologic or renal impairment.

Also see [Hemolytic Anemia \(Survival Defect\)](#) on page 8-12.

HELLP Syndrome

HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) occurs in 20% of patients with pre-eclampsia and in 10% of patients with eclampsia. The anemia is microangiopathic hemolytic, with schistocytes on the peripheral blood smear (as with TTP and aHUS). Hepatic rupture is an uncommon, but potentially devastating, complication. Treatment is delivery of the fetus, with no role for plasma exchange. Both HELLP syndrome and TTP/HUS can occur in the peripartum period, so it is important to consider each in the evaluation. TTP/HUS additionally has fever, renal involvement, and/or neurologic symptoms.

Heparin-Induced Thrombocytopenia (HIT)

HIT Type I is a clinically insignificant, nonimmune drop in platelets after starting heparin; platelets return to normal within 2 days.

HIT Type II occurs when an antibody is formed that recognizes heparin/platelet Factor 4 (heparin-PF4) complexes. The antibody activates platelets, causing clumping and thrombocytopenia within **5-10 days** of heparin initiation. Previous exposure to heparin and an anamnestic response may shorten the onset to < 12 hours. Venous and/or arterial **thrombosis**, not bleeding, is the major complication of HIT-II. Always suspect HIT-II in a patient presenting with clotting 1-2 weeks after a hospitalization, even if the platelet count is normal. (The highest risk of thrombosis occurs when the platelet count has returned to normal.)

Suspect HIT in any of the following scenarios involving patients with heparin exposure within the preceding 5-10 days:

- New-onset thrombocytopenia
- > 50% drop in platelet count within normal range
- Venous or arterial thrombosis
- Necrotic skin lesions at heparin injection sites
- Acute systemic reactions (i.e., fever, tachycardia, hypertension) occurring after heparin IV bolus administration

Making the diagnosis of HIT ([Figure 8-27](#)):

- Order heparin-PF4 antibody ELISA **first**. While awaiting the results of the ELISA test, use a clinical scoring system to assess the likelihood of HIT-II.

Two different clinical scoring systems, the 4 Ts and HIT Expert Probability (HEP) Score, are available. (See [The 4 Ts](#) and [HIT Expert Probability \(HEP\) Score](#).)

- **Stop all heparin products** if HIT is suspected.
- Depending on the ELISA optical density (OD), HIT antibody testing is limited to those with an intermediate- or high-probability 4 Ts score:
 - In patients with a low 4 Ts score: If the ELISA OD is < 0.40, HIT is excluded and no further testing is needed.
 - In patients with a high 4 Ts score: If the ELISA OD is > 2.00, HIT is confirmed and no further testing is needed.
 - In patients with an intermediate 4 Ts score: If the ELISA OD is 0.40–2.00, then a functional assay such as a serotonin release assay (SRA) or heparin-induced platelet aggregation (HIPA) assay is performed. (Note: Immunoassays that detect antibodies against platelet Factor 4 complexes are of limited value [i.e., are sensitive but not specific], whereas the SRA is specific and sensitive, though with a long turnaround time.)

Figure 8-27: Approach to the patient with suspected heparin-induced thrombocytopenia

Continue nonheparin anticoagulants until the results of the functional assays are available.

The 4 Ts

To assess the likelihood of HIT-II, the 4 Ts scoring system evaluates the presence, timing, sequelae, and causes of the thrombocytopenia. See [Table 8-6 on page 8-26](#). Understand the key features; do not memorize the details!

HIT Expert Probability (HEP) Score

Another scoring system, based on the opinion of 26 HIT experts, yielded similar results to the 4 Ts.

The HEP Score is generated from the percentage of decrease in platelets, timing, nadir, thrombosis, skin necrosis, and acute systemic reaction to heparin, bleeding, and other causes.

Treatment of HIT-II

Stop all heparin exposure (including low molecular weight heparin [LMWH]), even though this does not fully resolve the problem. This is because once the antibodies to heparin-PF4 complex are formed, the antibodies continue to bind to PF4 alone and, thus, continue to activate platelets, causing clots. Do **not** substitute LMWH because of antibody cross-reactivity.

Treat this hypercoagulable state with nonheparin-like anticoagulants, such as IV direct thrombin inhibitors (e.g., argatroban, bivalirudin), fondaparinux, or a direct oral anticoagulant (DOAC; e.g., dabigatran, apixaban, edoxaban, rivaroxaban) at the time of diagnosis, even in the face of thrombocytopenia, whether or not a clot is present. Continue to administer the anticoagulant until the platelet count recovers. Remember that argatroban artificially elevates the INR (international normalized ratio); the goal INR during argatroban/warfarin overlap is > 4.

Do **not** start warfarin until the platelet count returns to normal. Since it transiently lowers levels of proteins C and S and can contribute to clot formation, do **not** start warfarin alone. Continue warfarin for at least 3 months. There is no role for platelet transfusions ([Figure 8-27](#)).

Once again: Remember that TTP and HIT are **thrombotic** thrombocytopenic disorders—so you **never** give these patients platelet transfusions for the thrombocytopenia unless there is life-threatening bleeding present.

Dilutional Thrombocytopenia

Dilutional thrombocytopenia occurs when massive transfusions of platelet-poor blood products are given, typically after major trauma. Treat with platelets.

Posttransfusion Purpura

Posttransfusion purpura is rare, occurring primarily in women sensitized by pregnancy. It occurs ~ 1 week after transfusion and can last days to weeks. The platelet count is extremely low, and the patient can present with petechiae or purpura. An anti-HPA-1a antibody (human platelet antigen-1a) is formed by alloimmunization from previous blood transfusions or pregnancies, and, inexplicably, it reacts against the patient's HPA-1a **negative** platelets, causing thrombocytopenia.

Table 8-6: 4 Ts Clinical Scoring for Probability of HIT-II

Variable	Score		
	2	1	0
Thrombocytopenia—is it present?	> 50% decrease in platelet count but remains $\geq 20,000/\mu\text{L}$	30–50% decrease in platelet count or nadir 10,000–19,000/ μL	< 30% decrease in platelet count or falls < 10,000/ μL
Timing of the thrombocytopenia	Days 5–10 of heparin exposure or $\leq$ Day 1 if anamnestic response + heparin exposure within past 30 days	> Day 10 of heparin exposure or Unclear heparin exposure (but probably days 5–10 of heparin exposure) or $\leq$ Day 1 if anamnestic response + heparin exposure within past 30–100 days	$\leq$ Day 4 without previous HIT-II
Thrombosis (or other sequelae)	New clot, necrotic skin lesion, or systemic reaction after heparin bolus	Recurrent clot or worsening of clot, skin lesion (necrotic), possible clot	None
Thrombocytopenia—other causes?	None	Possible	Definite
Probability of HIT-II*	6–8 = High	4–5 = Intermediate	0–3 = Low

HIT-II = heparin-induced thrombocytopenia Type II
Day 0 = the day heparin was started
Onset of HIT = the day platelet count begins to decrease
* Further evaluation is required for patients with an intermediate or high score or if scoring is difficult due to missing platelet count values or coexisting conditions causing thrombocytopenia.

Unlike patients with TTP, patients with posttransfusion purpura do not have evidence of microangiopathic hemolytic anemia on the peripheral smear (no schistocytes), and there is no CNS or renal failure.

Treat with IVIG. Steroids and plasma exchange have also been used, but the responses are slower than with IVIG. Platelet transfusions are not very effective because the transfused platelets are also destroyed by the underlying process.

Thrombocytopenia — Quinine and Other Medications

Quinine is an important cause of thrombocytopenia. It is available over the counter and used for nocturnal leg cramps. It was also once the “tonic” in gin and tonic, and in the 1970s this side effect was described as cock-tail purpura. Now, however, tonic water contains only a medically insignificant amount of quinine. Other drugs that can cause thrombocytopenia include sulfa combinations, rifampin, digoxin, and vancomycin.

Other Causes of Thrombocytopenia

If there is a dramatic drop in platelets from one day to the next (e.g., from 300,000/ μL to 5,000/ μL [$300 \times 10^9/\text{L}$ to $5 \times 10^9/\text{L}$]), suspect pseudothrombocytopenia. HIT platelet counts usually do not drop below 20,000. The EDTA anticoagulant in blood collection tubes can cause platelet clumping in some patients, resulting in a reading of low platelets and giant platelets by an automated counter.

Platelet Function Disorders

von Willebrand Disease (vWD)

The von Willebrand factor (vWF) binds platelets to exposed subendothelial collagen and to other platelets with the platelet receptors 1b/10 and 2b/3a, respectively. vWF is also the carrier protein for Factor 8, which is degraded in its absence.

vWF multimers in the bloodstream have little affinity for platelets. But this affinity increases dramatically when vWF attaches to an altered vascular surface, thereby causing an increased aggregation of platelets at that spot. vWF multimers in the bloodstream are various sizes, ranging from small to ultra-large. The larger the multimer, the more hemostatic potential.

vWD is the most common inherited bleeding disorder. Patients typically have mucocutaneous bleeding, including epistaxis, menorrhagia, postpartum and surgical bleeding, excessive bleeding after dental extractions, and excessive bruising.

The inheritance pattern of vWD is usually autosomal dominant (AD). Penetrance is variable, with some patients experiencing bleeding only after surgery or major trauma and others suffering from frequent spontaneous bleeds of the mucosal surfaces of the gastrointestinal and genitourinary tracts.

Individuals with Type O blood have lower baseline levels of vWF. Levels of vWF increase during pregnancy and with estrogen use.

The aPTT is often increased because of decreased levels of Factor 8. The bleeding time is prolonged.

Classification of vWD:

- **Type 1:** a **quantitative** defect with decrease in level and activity of vWF:Ag; most common type (~ 75%)
- **Type 2:** 4 subtypes (A, B, M, N)—all **qualitative** defects; disproportionate decrease in activity of vWF (ristocetin cofactor), compared with vWF:Ag
- **Type 3:** rare and severe; autosomal recessive (AR) inheritance. Minimal-to-undetectable levels of vWF lead to spontaneous bleeding. The presentation resembles that of classic hemophilia.

Diagnosis of Type 1 is confirmed with a combination of the following:

- Abnormal platelet function tests
- Decreased vWF antigen
- Proportional decrease in Factor 8 activity
- Proportional decrease in biologic activity as measured by the ristocetin cofactor (RCoF) assay

Note that the proportional decrease in vWF antigen and RCoF activity indicates that the decreased activity is due to a decrease in the **concentration** of vWF—not to dysfunctional vWF.

Patients with mild defects can have varying laboratory test results over time, often requiring repeated testing to confirm the diagnosis.

Treat most mild-to-moderate cases of vWD with desmopressin, which causes a release of vWF and Factor 8 from endothelial cells. Watch for hyponatremia when treating with desmopressin. Do not use desmopressin for the rare Type 2B variant, as it can worsen thrombocytopenia. For active bleeding, use Factor 8 concentrates, which typically have some vWF as well. Cryoprecipitate is almost never required.

Note: Desmopressin is a synthetic analog of antidiuretic hormone (i.e., ADH, vasopressin), which boosts plasma levels of Factor 8 and vWF. It does not have vasopressor activity, and it is **not** effective in severe vWD or severe Factor 8 deficiency. Recombinant vWF is increasingly being used, but more clinical experience is required.

Other Platelet Function Disorders

In **Bernard-Soulier syndrome**, patients have severely decreased platelet adhesion because they have no glycoprotein 1b-9-5 receptor (so platelets cannot bind vWF). The peripheral smear demonstrates giant platelets. These patients also have a modestly low platelet count due to accelerated platelet clearance. The inheritance pattern is AR.

Glanzmann thrombasthenia results from deficient glycoprotein 2b/3a complex (so fibrinogen does not cross-connect). Platelet count is normal. The inheritance pattern is AR.

ASA/NSAIDs: Platelet-release defects are often caused by ASA and NSAIDs, which block the synthesis of thromboxane A₂ by binding to cyclooxygenase. The effects of ASA

and clopidogrel last for the lifetime of the platelets, but those of non-ASA NSAIDs are transient.

Paraproteinemia, as in multiple myeloma (MM) or connective tissue disease, can cause platelet dysfunction. In these disorders, the paraprotein coats the platelets, inhibiting their function and interfering with fibrin formation.

Uremia causes platelet dysfunction with a reduction in platelet adhesion and aggregation from an increase in nitric oxide (NO) release from endothelial cells in uremic states. Treat with platelet transfusions (for active bleeding), conjugated estrogens (reduces NO), or desmopressin (improves platelet function). Conjugated estrogens have a longer effect than desmopressin in uremia and usually are reserved for chronic bleeding. Desmopressin is considered 1st line due to its rapid onset of action and its having the fewest side effects. If severe bleeding persists, then infuse cryoprecipitate.

DISORDERS OF SECONDARY HEMOSTASIS

PREVIEW | REVIEW

- Characterize the prothrombin time (PT) and activated partial thromboplastin time (aPTT) in patients with antiphospholipid syndrome.
- What are mixing studies, and when are they used?
- What is the usual cause when a mixing study shows the aPTT initially normalizing, but 2 hours later it is again prolonged?
- What determines the risk of bleeding in a patient with Factor 8 deficiency (hemophilia A)?
- When do you begin the treatment of a bleeding episode in a patient with Factor 8 deficiency?
- What is the clinical presentation of Factor 11 deficiency?
- How do patients present if they have Factor 12 deficiency?
- Which special diagnostic test is used to diagnose Factor 13 deficiency?
- How do the PT and aPTT differ in disseminated intravascular coagulation (DIC) vs. thrombotic thrombocytopenic purpura?
- Which disease states are associated with chronic DIC?
- How do broad-spectrum antibiotics cause vitamin K deficiency? How do certain cephalosporins cause vitamin K deficiency?
- With which deficiency are patients more likely to experience venous thrombosis during initial anticoagulation with warfarin?

People with coagulation factor disorders tend to experience discrete episodes of **deep tissue bleeding**, including

hemarthroses, muscle hematomas, and retroperitoneal hemorrhage. Refer to [Table 8-7](#), [Table 8-8](#), and [Table 8-9](#) as you review disorders of secondary hemostasis.

Prothrombin Time (PT) and Activated Partial Thromboplastin Time (aPTT) Variations

Review the following 3 variations of the PT and aPTT:

- 1) **PT is prolonged and the aPTT is normal:** There is a problem with the vitamin K-dependent Factors 2, 7, 9, or 10 or with fibrinogen. See [Figure 8-25 on page 8-20](#). The most common cause is the use of **warfarin** (a vitamin K inhibitor). See [Table 8-8](#). Vitamin K deficiency in the malnourished or postoperative patient also occurs. (See [Vitamin K Deficiency on page 8-31](#) and [Figure 8-25 on page 8-20](#).)
- 2) **PT is normal and aPTT is prolonged:** There is a problem with Factors 8, 9, 11, or 12. The most common cause is **heparin** in the blood sent to the laboratory. (See [Figure 8-25 on page 8-20](#) and [Table 8-8](#).) In the bleeding patient, think inhibitor to Factor 8 (see

below) or vWD. In the thrombotic patient, think **antiphospholipid syndrome** (discussed in the [Rheumatology](#) section).

- 3) **PT and aPTT are both high:** There is a defect in the common pathway or else a multiple factor deficiency involving both pathways (e.g., DIC). See [Table 8-9](#).

Regarding variation #2: If there is a greatly prolonged aPTT with a normal PT and normal platelet count, 1st check a heparin neutralization study. If there is no correction, then do a mixing study.

Mixing studies are done on plasma to differentiate factor deficiency from factor inhibitor. In a mixing study, the patient's plasma is mixed 50:50 with normal plasma. If the patient's prolonged aPTT is due to factor deficiency, the mixing with normal plasma provides the missing factor and corrects the problem (and the PTT). If the aPTT is still prolonged after the 1:1 mix with normal plasma, the problem is likely to be an inhibitor, usually a lupus anticoagulant (antiphospholipid syndrome) or Factor 8 inhibitor.

Table 8-7: Bleeding Disorder Evaluation — PT, aPTT, Bleeding Time, and Platelet Aggregation

Lab Results	Etiology
Elevated PT and aPTT	Factor deficiency from common pathway Multiple factor deficiency Warfarin affects Factors 2, 7, 9, and 10, so it can affect both PT and aPTT, but PT is more sensitive to warfarin. Liver disease DIC Combined heparin and warfarin administration Direct thrombin inhibitor (e.g., argatroban, dabigatran) Direct Factor 10a inhibitor (e.g., rivaroxaban, apixaban, edoxaban) Amyloidosis-associated Factor 10 deficiency
Elevated PT, nl aPTT	Factor 7 deficiency Vitamin K deficiency Warfarin Liver disease
Elevated aPTT, nl PT: immediate and sustained (2 hours) correction of aPTT by addition of normal plasma	Factor 8, 9, 11, or 12 deficiencies vWD
Elevated aPTT, nl PT: aPTT not corrected (or no sustained correction at 2 hours) by addition of normal plasma	Inhibitor syndrome (circulating anticoagulant): • If clotting: ◦ Antiphospholipid syndrome (esp. lupus anticoagulant) ◦ aPTT not normalized immediately • If bleeding: ◦ Factor 8 inhibitor ◦ aPTT initially normalized but not normalized at 2 hours
Elevated aPTT, nl PT—but no clinical bleeding disorder	Factor 12, prekallikrein, or HMW kininogen deficiency
Nl PT and aPTT, except elevated bleeding time: • Elevated bleeding time with nl platelet aggregation • Elevated bleeding time with nl platelet aggregation and decreased platelet count • Elevated bleeding time with abnormal platelet aggregation	Platelet problem vWD (has decreased platelet adhesion but normal aggregation) Bernard-Soulier (giant platelet) syndrome (absent GP1b) has similar presentation as vWD except lab also shows decreased platelet count. Glanzmann thrombasthenia (absent GP 2b/3a)
aPTT = activated partial thromboplastin time DIC = disseminated intravascular coagulation HMW = high molecular weight nl = normal PT = prothrombin time vWD = von Willebrand disease	

Some factor inhibitors take time to react with the factor. Factor 8 inhibitors are especially likely to be time dependent. For example, with acquired idiopathic or postpartum Factor 8 inhibitor antibodies, the aPTT may initially correct to normal with the mixing study, but after incubation with the normal serum for 2 hours, the inhibiting antibody begins to bind to the added Factor 8, and the aPTT is once again prolonged.

The **thrombin time** measures the time of conversion of fibrinogen to fibrin. A prolonged thrombin time reflects decreased or defective fibrinogen, elevated fibrin degradation products, or heparin or heparin-like anticoagulants.

Hereditary Coagulation Deficiencies

Factor 8 and 9 Deficiencies

Hemophilia is due to a Factor 8 (hemophilia A) or 9 (hemophilia B) deficiency; these are inherited deficiencies typically diagnosed in childhood. In the intrinsic pathway, activated Factor 8 accelerates by 1,000-fold the cleavage of Factor 10 by activated Factor 9. With both Factor 8 and 9 deficiencies, the aPTT is increased and the PT is normal.

Clinical presentation is similar in both Factor 8 and 9 deficiencies, with easy bruising, muscle and joint hemorrhages, and prolonged hemorrhage after surgery or trauma **but** no excessive bleeding after minor cuts.

Table 8-8: Effects of Anticoagulants on Coagulation Tests

Anticoagulant	Platelet Count	PT	aPTT	TT	Anti-Factor 10a Activity
Direct Factor 10a inhibitor	Normal	Variable to increased	N/A	N/A	Increased
Direct thrombin inhibitor	Normal	N/A	Variable to increased	Increased	N/A
Warfarin	Normal	Increased	Normal	N/A	N/A
Heparins	Normal (in absence of HIT)	Normal	Increased	Increased	Increased

aPTT = activated partial thromboplastin time
PT = prothrombin time
TT = thrombin time

Table 8-9: Test Results for Selected Bleeding Disorders

Bleeding Disorder	Platelet Count	PT	aPTT	TT	Fibrinogen
Disseminated intravascular coagulation	Low	Prolonged	Prolonged	Prolonged	Low
Factor 13	Normal	Normal	Normal	N/A	N/A
Hemophilia A (Factor 8 deficiency), Factor 9	Normal	Normal	Prolonged	Normal	Normal
Qualitative platelet abnormalities	Normal or low	Normal	Normal	Normal	Normal
Thrombocytopenia*	Low	Normal	Normal	Normal	Normal
Vasculopathies, connective tissue diseases, or collagen disorders affecting skin	Normal	Normal	Normal	Normal	Normal or increased [†]
vWD	Normal [‡]	Normal	Normal or Prolonged (if Factor 8 > 40%) [§]	Normal	Normal

* The platelet count in myeloproliferative disorders is usually high (e.g., essential thrombocythemia), and platelets may also be qualitatively abnormal, predisposing to hemorrhagic and thrombotic diatheses.

[†] Fibrinogen may be elevated as an acute-phase reactant in disorders of inflammation.

[‡] The platelet count may be low in some patients with Type 2B vWD.

[§] The aPTT may be normal in those with Factor 8 activity > 40%.

aPTT = activated partial thromboplastin time

PT = prothrombin time

TT = thrombin time

vWD = von Willebrand disease

Both Factor 8 and Factor 9 deficiencies are **X-linked recessive**. (Daughters, with only 1 chromosome affected, are carriers and exhibit no symptoms.)

In **Factor 8 deficiency**, the risk of bleeding correlates with Factor 8 serum levels. Patients with levels < 1% of normal have severe disease (bleeding even without trauma); patients with levels > 5% have mild disease.

Use desmopressin for mild Factor 8 deficiency. It works by causing a release of vWF and Factor 8 stores from endothelial cells. It is used as treatment for an acute hemorrhage and prophylactically for a tooth extraction in patients with Factor 8 levels > 5%.

For more severe Factor 8 deficiency, use Factor 8 (human concentrate or recombinant) to treat acute bleeds. Previously, human Factor 8 concentrate carried a risk of transmission of hepatitis viruses and HIV. Since 1985, all plasma used to produce Factor 8 concentrate is screened for HIV and hepatitis C virus, and steps that specifically inactivate these viruses are included in the production process.

Symptoms of a bleed often precede objective evidence by several days, and patients frequently inform their physician when a bleed is beginning. Early treatment delays or prevents hemophilia arthropathy, is cost effective, and can be lifesaving. Some centers advocate 2–3× weekly prophylactic Factor 8 infusions to keep levels above 1% and thus reduce bleeding risk. Prophylactic factor administration reduces the incidence of arthropathy in adult hemophiliacs, but the product is expensive and can cause an increased rate of development of Factor 8 inhibitors. Avoid use of ASA in patients with hemophilia.

Factor 9 deficiency (hemophilia B) is clinically indistinguishable from hemophilia A. Hemophilia B is only 1/10 as common as hemophilia A. Multiple recombinant Factor 9 concentrates are available for prophylaxis and treatment of bleeding. Gene therapy with a high-specific-activity Factor 9 variant is under development, with promising results thus far.

Manage acute bleeding episodes with either recombinant or highly purified human Factor 9 concentrate.

Factor 11 Deficiency

Factor 11 deficiency is an AR disorder that is less prevalent than hemophilia A or B. The risk of bleeding depends more on the gene mutation leading to the disorder than on the actual serum level of Factor 11. The disorder is more common in certain ethnic groups, with an especially high prevalence in Ashkenazi Jews.

Patients with Factor 11 deficiency tend to bleed at mucosal sites (epistaxis and menorrhagia), where fibrinolytic activity is high. Surgeries at sites with less fibrinolytic activity (e.g., orthopedic surgery, appendectomy) tend to have fewer bleeding complications. Antifibrinolytic agents alone can be used as prophylaxis for dental surgery.

Acute bleeds can be managed with FFP, recombinant Factor 11, or desmopressin.

Factor 12 Deficiency

Patients with a decreased Factor 12 (Hageman factor; AR inheritance) have a normal PT and a very prolonged aPTT (as with Factor 8, 9, and 11 deficiencies), but they do not have a clinical bleeding disorder and can even undergo surgery without worry of bleeding.

Factor 13 Deficiency

Factor 13 deficiency is an AR disorder. Severe bleeding results from the inability to cross-link fibrin strands. Coagulation tests, including PT, aPTT, and platelet function studies, are **normal**. Think about this in patients who have late postsurgical bleeding and poor wound healing.

Diagnose Factor 13 deficiency by performing a specialized **clot lysis assay**, in which dissolution of a clot is attempted, using urea. If the clot is solubilized with urea, then a Factor 13 deficiency exists. Treat with small amounts of FFP or specialized plasma derivative every 3–4 weeks.

Review of Basic Principles of Bleeding Disorders

As mentioned, while people with **platelet** dysfunction tend to experience **mucosal** bleeding (e.g., bruising, nosebleeds, menorrhagia), people with **coagulation factor** disorders tend to experience discrete episodes of **deep tissue** bleeding (e.g., hemarthroses, muscle hematomas, retroperitoneal hemorrhage). So, since platelets are required for thrombus formation, just as coagulation factors are required, why does a platelet deficiency cause only mucosal bleeding? The answer is that early thrombus formation only requires a few platelets to do the job.

What bleeding disorders can appear with a **normal** platelet count, PT, aPTT, and bleeding time? The major disorders to consider are:

- Mild vWD
- Mild hemophilia
- Factor 13 deficiency

Acquired Coagulation Deficiencies

Disseminated Intravascular Coagulation (DIC)

DIC is one of the most common acquired coagulopathies. It is always a **secondary** condition, so the underlying disease must be treated for the DIC to resolve.

DIC occurs in diseases that promote tissue factor release, including the following:

- Massive trauma
- Production of tumor necrosis factor, especially seen in solid tumors
- Sepsis, especially with endotoxin release
- Retained placental tissue in obstetric patients with placenta abruption, dead fetus, or amniotic fluid embolus
- Acute promyelocytic leukemia (APML)

Acute (Decompensated) DIC

Large amounts of released tissue factor activate Factor 7 and initiate the coagulation cascade. Excessive thrombin and plasmin are produced, resulting in both increased clot formation (via thrombin cleaving fibrinogen to fibrin) and clot breakdown (via plasmin degradation of fibrin clots). The plasmin breaks down fibrinogen and fibrin into fibrinogen/fibrin degradation products (FDPs, a.k.a. fibrin split products).

The massive depletion of coagulation factors and platelets and the increased FDPs (including D-dimer) can result in bleeding. Symptoms of DIC result from bleeding or microvascular thrombosis, as well as the underlying disorder. Patients with acute DIC become acutely ill with bleeding from IV sites/wounds and often multisystem organ dysfunction and shock.

Diagnosis of DIC:

- PT and aPTT prolonged (remember, normal in TTP, ITP, and HUS)
- Thrombocytopenia (from consumption)
- Fibrinogen level is decreased and trends downward during the disease process.
- Thrombin time is increased (due to both decreased fibrinogen and increased FDPs).
- Schistocytes (RBC fragments) are found in the peripheral smear in up to 50% of patients; they indicate microangiopathic hemolytic anemia. (The fibrin strands span the small blood vessels and shear the RBCs.)
- FDP/D-dimer increased. These are nearly always elevated in DIC but also occur in many other conditions. FDP and D-dimer are therefore a sensitive but not specific test.

Chronic (Compensated) DIC

Patients with chronic DIC can have either bleeding or thrombotic disorders. The thrombotic disorders range from migratory chronic thrombophlebitis (a.k.a. Trousseau syndrome) to pulmonary emboli.

Chronic DIC virtually always occurs in association with solid tumors.

With chronic DIC, a slower consumption of coagulation factors is compensated by increased synthesis of these same coagulation factors. Because of this, the lab results differ from acute DIC, and all may be normal except FDP/D-dimer (elevated).

In the setting of an underlying malignancy, diagnosis of chronic DIC can be made with the finding of microangiopathic hemolytic anemia on peripheral smear and increased FDP/D-dimer.

Treatment of DIC

Again, treat the underlying disorder, or the DIC does not stop. With severe bleeding, give fresh frozen plasma

(FFP) and platelets. Heparin is **not** usually effective except in specific, infrequent clinical situations (e.g., chronic DIC due to malignancy).

You can give cryoprecipitate if the fibrinogen level is < 100 mg/dL, and you can use FFP to replace other coagulation factors if PT and aPTT remain prolonged. Platelets are given only if platelet count is < 10,000–20,000/μL, there is an acute bleed, or to prepare a patient for surgery.

Vitamin K Deficiency

Vitamin K deficiency causes decreased production of the vitamin K-dependent factors (2, 7, 9, 10) and proteins C and S. Lab shows a prolonged PT.

Causes of vitamin K deficiency include decreased dietary intake, malabsorption, antibiotic use, and decreased storage resulting from liver disease.

Vitamin K deficiency results from:

- Decreased intake—patient is on total parenteral nutrition.
- Decreased production—broad-spectrum antibiotics can cause vitamin K deficiency by reducing the number of organisms in the intestine that synthesize vitamin K.
- Decreased storage—liver disease
- Decreased effectiveness—cefotetan or cefoperazone have *N*-methylthiotetrazole (NMTT) or similar side chains that block vitamin K epoxide reductase.

With vitamin K deficiency, the PT is prolonged and the aPTT is often normal. To further differentiate from DIC, check thrombin time and D-dimer, which are normal in patients with vitamin K deficiency.

Patients who are not bleeding can often be managed with vitamin K supplementation. If the patient has a normal GI tract, oral forms are more predictably absorbed than subcutaneous injections. IV vitamin K carries a very small risk for anaphylaxis. Do not administer IM vitamin K due to risk of hematoma formation. Vitamin K can take approximately 8 hours to work, so use FFP for immediate treatment if there is life-threatening hemorrhage.

Warfarin is a vitamin K antagonist, causing an effective vitamin K deficiency. Initiation of warfarin therapy carries a theoretical increased risk of thrombosis as the levels of proteins C and S (the proteins with the shortest half-lives) drop. This initial thrombotic effect can, for a short time, outweigh the antithrombotic effect on Factor 7; this is more likely with large loading doses of warfarin or if the patient is already protein C deficient. In patients with preexisting protein C deficiency, initial overlapping therapy with a parenteral anticoagulant (i.e., heparin) can prevent this transient hypercoagulable state. 1/3 of patients who develop warfarin-related skin necrosis have a protein C deficiency.

Encourage patients to report any new medications or dietary changes since these may inhibit or potentiate warfarin's effect.

Primary Fibrinolysis

Primary fibrinolysis is a rare disorder often associated with prostate cancer and/or surgery. This disorder occurs when plasmin is released into the circulation in response to endothelial agents like tissue plasminogen activator (tPA). The pathophysiology differs from that of secondary fibrinolytic states, such as DIC, which occur in response to thrombi formation in the microvasculature.

As in DIC, both primary and secondary fibrinolysis cause abnormalities of the PT, aPTT, fibrinogen level, FDPs, and D-dimer. Unlike in DIC, patients with primary fibrinolysis often have a normal platelet count.

Factor 8 Inhibitor

Factor 8 inhibitors are associated with:

- Hemophilia
- Malignancies (especially CLL, adenocarcinomas)
- Infections
- Pregnancy or the postpartum state
- Autoimmune disorders (e.g., SLE, rheumatoid arthritis)
- Aging
- Drugs

However, many cases are idiopathic. Most patients who develop a Factor 8 inhibitor have never had a blood transfusion. Patients with an inhibitor can present with severe bleeding, similar to hemophilia. In contrast to the lupus anticoagulant, mixing normal plasma and the patient's plasma may initially correct the aPTT, but after a 2-hour incubation, the inhibitor antibody inactivates Factor 8 and the aPTT again becomes prolonged. Therefore, a mixing study that does **not** maintain a **sustained** normalization of the aPTT suggests a Factor 8 inhibitor rather than factor deficiency.

THROMBOTIC DISORDERS

PREVIEW | REVIEW

- What are the most common genetic mutations that cause venous thrombosis?
- What battery of tests is done on patients with possible thrombophilia?
- What are the classes of oral anticoagulant drug therapies available for treatment of deep venous thrombosis (DVT)?
- What are established indications for an inferior vena cava filter in a patient with a DVT?

The **Virchow triad** (Figure 8-28) describes 3 factors that predispose patients to thrombosis:

- 1) Vascular damage
- 2) Stasis
- 3) Hypercoagulable state

Figure 8-28: Virchow triad

Vascular damage can be caused by smoking and hypertension, as well as trauma from surgery or catheters, such as peripherally inserted central catheter (PICC) lines.

Stasis factors include immobility and polycythemia, which can also cause vascular damage.

Hypercoagulable states include both acquired and hereditary disorders. Note that patients may develop a thromboembolic event only after they have multiple prothrombotic conditions. For example, a woman with a moderately hypercoagulable state due to a Factor 5 Leiden mutation may not have her 1st deep vein thrombosis until she is pregnant or is immobilized after knee surgery.

Acquired Thrombotic Disorders

Acquired thrombotic disorders include:

- Malignancy
- Pregnancy (especially immediate postpartum period)
- Smoking
- Estrogen use (e.g., oral contraceptive pills [OCPs], hormone replacement therapy [HRT])
- Immobilization
- Major surgery
- Heparin-induced thrombocytopenia (HIT)
- Myeloproliferative disorders (especially polycythemia vera and essential thrombocythosis)
- Paroxysmal nocturnal hemoglobinuria (PNH)
- Multiple myeloma
- Antiphospholipid syndrome (APS)

Note: **Antiphospholipid syndrome** is a term used to describe the clinical relationship between a hypercoagulable state

and the presence of antiphospholipid antibodies. It is a systemic autoimmune disorder that can be primary or in the setting of autoimmune disorder, most commonly SLE. It is characterized by venous, arterial, or small vessel thrombosis. Often pregnancy complications, including repeated fetal loss, lead to its diagnosis. APS is discussed further in the [Rheumatology](#) section.

Inherited Thrombotic Disorders

The most common inherited causes of venous thromboembolism are the Factor 5 Leiden gene mutation and the prothrombin gene mutation (*G20210A*). These mutations typically cause thrombosis before 50 years of age and present more often when other acquired risks for clotting are superimposed (e.g., pregnancy, oral contraceptives, immobility).

Although Factor 5 Leiden and prothrombin gene mutations are more common, patients with protein C, protein S, or antithrombin deficiencies are **more likely** to thrombose and to have **recurrent** thromboses. In patients > 50 years of age, think about the acquired causes of thromboembolism.

Thrombophilia refers to an increased tendency to form thromboses.

Factor 5 Leiden Mutation

The Factor 5 Leiden (F5L) mutation is a very common AD disorder that expresses a modified Factor 5 with a resistance to the normally inhibitory (i.e., anticoagulant) effects of activated protein C (APC). 95% of APC resistance is the result of F5L mutation. Because APC can no longer cleave Factor 5 or Factor 5a effectively, there is both a decreased anticoagulant effect of Factor 5 and an increased coagulant effect of Factor 5a. 5% of Caucasians are heterozygous for the F5L mutation and have an ~ 20% lifetime risk of developing a venous thromboembolic problem. Homozygosity increases this risk to ~ 60%. The F5L mutation causes a mild increase in PT and aPTT.

Prothrombin Gene Mutation

Prothrombin gene mutation is a gain-of-function mutation that results in increased levels of prothrombin (Factor 2 in the coagulation cascade). Heterozygous carriers of the *G20210A* mutation have 2–3× increased risk of venous, and possibly arterial, thrombosis.

Antithrombin Deficiencies

Antithrombin (AT; formerly known as antithrombin III) inactivates thrombin both with and without the presence of heparin. In the presence of heparin, the antithrombin effects are accelerated roughly 4,000-fold. Antithrombin deficiencies include both quantitative (Type 1) and qualitative (Type 2) defects. Typically, 1st thrombotic events occur at a young age, and AT deficiencies are associated with a risk of venous thromboembolism of ~ 1% per year. Approximately 65% of patients heterozygous for AT have a thrombotic event by 50 years of age. Homozygous AT deficiency is fatal in utero.

Type 1 is diagnosed by immunoassay and Type 2 by functional studies (i.e., AT-heparin cofactor assay).

Protein C and S Deficiencies

Protein C and S deficiencies result in loss of the normal cleaving of Factors 5a and 8a. The deficiencies are normally AD inherited and increase the risk of developing venous thromboembolism. Both protein C and S are vitamin K-dependent proteins. Patients with protein C deficiency are at increased risk of developing skin necrosis while on warfarin. This is because protein C, with a very short half-life (6 hours) compared with the other vitamin K-dependent clotting factors, is rapidly depleted with warfarin initiation, resulting in a transient hypercoagulable state, which can lead to vascular occlusion and tissue infarction.

Testing for Thrombophilia

Who to Test?

Consider testing for thrombophilia when a patient has at least 1 of the following:

- 1st clot prior to 50 years of age
- Recurrent thrombosis
- 1st degree family members with clots prior to 50 years of age
- Thrombosis in multiple venous sites or unusual vascular beds (i.e., portal, mesenteric, hepatic, cerebral veins)

What to Test For?

Screen these patients for all of the following:

- F5L mutation
- Prothrombin *G20210A* mutation
- AT deficiency
- Protein C and S deficiencies
- APS
- JAK2 and PNH (if hepatic or portal vein thrombosis)

Again, the less common deficiencies (AT and proteins C and S) and APS are more severe, and these patients have recurrent clots more often than those with APC resistance and prothrombin *G20210A* mutations.

If the 1st clot occurs after 50 years of age, with negative family history, then an inherited thrombophilia is less likely. An acquired hypercoagulable state is most likely due to a malignancy. In most patients, a primary malignancy is already diagnosed at the time of clot. Screen for the following:

- APS, especially if the patient has any signs or symptoms of SLE
- Malignancy (e.g., solid tumors, lymphomas, myeloproliferative disorders)
- Use of certain drugs (especially hydralazine, procainamide, hydrochlorothiazide, propranolol, phenytoin, or phenothiazines)

When to Test?

Test for thrombophilia preferably at least 2 weeks after discontinuation of anticoagulation, when feasible.

Remember that acute thrombosis can transiently lower levels of antithrombin, protein C, and protein S. Heparin can cause decreased antithrombin levels. Warfarin can decrease functional (and to a lesser extent, quantitative) levels of proteins C and S and can (albeit rarely) raise antithrombin levels. In addition, warfarin yields a false-positive test for lupus anticoagulant. Direct oral anticoagulants (DOACs) may overestimate antithrombin levels. So, wait to test for C, S, and AT deficiencies until 2 weeks after completion of the initial 3–6 months of warfarin or at least 2 days (preferably longer) after stopping DOAC or LMWH.

Management of Thrombosis

An extensive discussion of deep venous thromboses and pulmonary emboli (DVT/PE) is included in the [Pulmonary Medicine](#) section.

Treatment of isolated calf vein thrombosis is guided by whether or not the patient is symptomatic. Options include anticoagulation or observation only, with serial ultrasounds over the first 2 weeks to determine whether the clot is extending proximally.

Acceptable drugs for initial treatment of an established DVT include low molecular weight heparin (LMWH), unfractionated (UF) heparin, fondaparinux, and oral Factor 10a inhibitors.

The oral Factor 10a inhibitors [rivaroxaban](#), [apixaban](#), and [edoxaban](#) are approved to treat symptomatic venous thromboembolism. Caution is advised with renal failure. The oral direct thrombin inhibitor [dabigatran](#), is approved for prevention and treatment of venous thromboembolism, as well as for stroke prevention in patients with atrial fibrillation.

UF heparin is more expensive due to the need for monitoring aPTT, but the infusion is easily titrated to meet the needs of an unstable patient. Thus, UF heparin is usually recommended in unstable patients.

LMWH is the preferred parenteral agent, except in unstable patients and in those with low creatinine clearance. LMWH and [fondaparinux](#) are **not** recommended in patients with low creatinine clearance (GFR < 30 mL/minute/1.73 m²).

Be sure to monitor the platelet count in any patient taking a heparin product because of the possibility of HIT-II.

Warfarin can be started simultaneously with the heparin product or fondaparinux. Continue both drugs for at least 5 days with subsequent discontinuation of heparin/fondaparinux after the INR is therapeutic for at least 48 hours. For venous thrombosis, target INR is 2.0–3.0.

Thrombolytic therapy is reserved for patients who are unstable due to a PE (i.e., hemodynamic compromise and/or right heart strain) or a massive iliofemoral thrombus.

Duration of anticoagulation is somewhat controversial for certain patient groups, but general guidelines include the following for DVTs:

- A **provoked** thrombosis with transient risk factor (e.g., OCP use, surgery, immobilization, HIT-II)—anticoagulate for at least 3 months.
- An **unprovoked** thrombosis—anticoagulate for at least 3 months. The 2016 American College of Chest Physicians (ACCP) guidelines recommend indefinite anticoagulation be considered and benefits weighed against the risks.
- **Recurrent** thromboses, 1 unprovoked life-threatening thrombosis, 1 spontaneous thrombosis with APS—indefinite anticoagulation.
- Thrombosis in pregnancy: LMWH is more effective for preventing future thrombosis and for treatment of an acute thrombosis. Remember that warfarin is contraindicated in pregnancy (especially 1st term and during labor) because it is teratogenic and because it causes fetal bleeding. Unfractionated heparin is an alternative, but it is considered less favorable than LMWH because of the need to use an increased dose during pregnancy and to monitor aPTT, in addition to the long-term risk of bone demineralization.

Consider an inferior vena cava (IVC) filter for DVT in these situations:

- When anticoagulation is contraindicated
- When there is a failure of anticoagulation
- In the presence of severe cardiopulmonary comorbidities, making a new PE life-threatening
- Preoperative prophylaxis in high-risk cases, where pharmacologic prophylaxis is contraindicated (e.g., major trauma, high-risk spine surgery)

Prior to surgery, consult the latest recommendations by the ACCP for discontinuation and resumption of anticoagulation therapy.

Additional uses of warfarin and heparin are described in detail in the following sections:

- Treatment of pulmonary embolism—the [Pulmonary Medicine](#) section
- Treatment of patients with valvular heart disease—the [Cardiology](#) section
- Pharmacologic interactions and as a factor in surgical procedures—the [General Internal Medicine](#) section

Direct oral anticoagulants (DOACs) have changed the landscape of anticoagulation and are being increasingly used in the prevention and management of thrombotic disorders. See [Table 8-10](#). These agents directly target the enzymatic activity of either thrombin (thrombin inhibitors) or Factor 10a (10a inhibitors). DOACs are

accepted as an equivalent, and in some cases preferred, alternative to warfarin in multiple indications, including prevention and treatment of venous thrombosis and in stroke prevention during atrial fibrillation.

Table 8-10: Direct Oral Anticoagulants (DOACs)

	Factor 10a Inhibitors	Thrombin Inhibitors
Drug Names	Rivaroxaban Apixaban Edoxaban	Dabigatran
Mechanism of Action	Direct Factor 10a inhibitor	Direct Factor 2a (thrombin) inhibitor
Relevant Indications	VTE treatment and prophylaxis Atrial fibrillation treatment	VTE treatment and prophylaxis Atrial fibrillation treatment
Reversal Agents	Andexanet alfa	Idarucizumab

DOACs offer several key advantages over warfarin. Use of DOACs does not require regular drug level monitoring or dietary restrictions, presents lower bleeding risk, and has significantly fewer drug interactions. Most patients achieve greater time in therapeutic range on DOACs vs. warfarin.

However, lack of a specific antidote for certain DOACs remains a concern in the event of major bleeding or emergent surgical procedures. Idarucizumab is an available, FDA-approved humanized anti-dabigatran monoclonal antibody fragment that can be used for emergency reversal of the thrombin inhibitor dabigatran. Andexanet alfa is an inactive form of Factor 10a and an emergency reversal agent for Factor 10a inhibitors. Due to the (small) risk of thrombosis with these reversal agents, they should be reserved only for serious, life-threatening bleeding.

DOACs are not preferred in selected patient subgroups where safety and efficacy have not yet been established, including children; the obese; individuals with cancer, pregnancy, or renal dysfunction; and those who may need thrombolytic therapy.

In patients with malignancy-associated venous thrombosis, LMWH remains the preferred standard. Recent pilot studies (National Comprehensive Cancer Network in 2020) suggest efficacy and safety of DOACs as an acceptable alternative in selected patients with malignancy-associated venous thrombosis.

Similar to warfarin, DOACs may affect interpretation of certain thrombophilia studies, including lupus anticoagulant.

FIBRINOLYTIC TREATMENT

Streptokinase and urokinase (the latter is no longer available in the U.S.) cause a **systemic** lytic state. tPA is more specific; it increases the conversion of plasminogen to plasmin in the presence of fibrin, so most of the plasmin made is localized to the fibrin clot.

However, tPA also results in systemic lysis and can be used to lyse a life-threatening pulmonary embolism (very specific situations) or an acute stroke or MI.

TRANSFUSION MEDICINE

PREVIEW | REVIEW

- Except in the case of life-threatening bleeding, which patients are not given platelet transfusions, regardless of the degree of thrombocytopenia?
- What is the most common reason for an acute hemolytic transfusion reaction? What is the clinical presentation?
- Which type of transfusion is most associated with transfusion-related bacterial infections? Why?

Red Blood Cell (RBC) Transfusions

Whole blood is rarely used. Exceptions include major hemorrhage from trauma or from pediatric cardiac surgery. A donated unit of whole blood is normally separated into platelets, plasma, and packed RBCs. In the absence of ongoing losses, 1 unit of packed RBCs increases the hemoglobin (Hgb) by 1 g/dL (10 g/L).

Alloimmunization can be a problem in multiple-transfused patients, and indications for RBC transfusion are varied. Many guidelines exist that try to balance risk vs. benefit of transfusion. The 2016 AABB (formerly the American Association of Blood Banks) guidelines recommend a strategy that considers not only Hgb levels, clinical setting, and patient preferences but also alternative therapies.

Platelet Transfusions

Wait to transfuse most patients with thrombocytopenia if they are not bleeding. A low platelet count that is $> 10,000/\mu\text{L}$ ($10 \times 10^9/\text{L}$) is acceptable for nonbleeding patients with acute leukemia. Platelet counts of $50,000/\mu\text{L}$ ($50 \times 10^9/\text{L}$) are adequate for most interventional procedures (a higher number is often used for neurosurgical procedures). Patients with ITP **almost never** require platelet transfusions, even with very low platelet counts. Their younger platelets seem to work better; transfusion does not result in an appreciable rise in the platelet count but can be hemostatically effective.

Because of increased risk of thrombosis, do **not** give platelet transfusions to patients with HIT or TTP/HUS unless there is life-threatening bleeding.

White Blood Cell (WBC) Transfusions

WBC transfusions are only rarely performed. Granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) is used instead to increase the neutrophil count, most commonly in patients receiving myelosuppressive chemotherapy.

Plasma and Cryoprecipitate Transfusions

Fresh frozen plasma (FFP) is transfused to replace coagulation factors. Use it to reverse anticoagulation in the context of dangerous bleeding when the PT and/or aPTT are supratherapeutic.

Cryoprecipitate is a plasma component enriched in fibrinogen. It is used in conditions like DIC to replace fibrinogen (indicated when fibrinogen is < 100 mg/dL [$< 1 \text{ g/L}$]).

Transfusion Complications

Acute hemolytic transfusion reaction is a medical emergency caused by rapid, intravascular hemolysis, commonly due to an ABO incompatibility—and most often a result of a clerical error.

The initial signs may be only fever and chills, which are very nonspecific. While other causes should be considered, in a patient receiving a blood transfusion, blame the blood! So, if a patient receiving a transfusion develops fever and chills, **stop** the transfusion immediately—the prognosis worsens as more blood is given. Provide supportive care, including normal saline infusion. Other signs and symptoms include back pain, hypotension, renal failure, and hemoglobinuria. Alert the blood bank immediately, because another patient may also be receiving the wrong blood. Diagnostic tests include Coombs testing, serum free Hgb, hemolysis labs (i.e., indirect bilirubin, haptoglobin, LDH), and urine for Hgb testing. Repeat type and cross-match in both the patient and on any blood left in the transfusion bag. The repeat blood sample can appear pink (as can urine), and peripheral smear may show schistocytes.

Delayed hemolytic transfusion reaction is caused by extravascular hemolysis associated with Rh incompatibility or minor antigen mismatches. Patients present approximately **7 days after transfusion** with anemia, mild fever, and mild unconjugated bilirubin elevation.

No treatment is necessary in the absence of brisk hemolysis. Match future transfusions appropriately.

Febrile transfusion reactions: Fever and chills **after** a transfusion are common and represent **nonhemolytic** reactions to leukocytes in the blood product. A normal peripheral smear differentiates this mild, benign reaction from the more dangerous acute hemolysis.

Stop the transfusion and assess for hemolysis by sending off the same labs listed above for acute hemolytic transfusion reaction. If the Coombs is negative, the symptoms are probably due to anti-HLA antibodies against the WBCs, which are transfused along with the component blood product.

Give antipyretics. Filters are used to remove WBCs in the transfused product (i.e., leukocyte depletion) to minimize this reaction. But filters do not remove cytokines, which can also cause the reaction.

Posttransfusion purpura is discussed under [Post-transfusion Purpura on page 8-25](#).

Transfusional hemosiderosis is iron overload from chronic repeat transfusions, usually in patients with sickle cell disease, thalassemia, or transfusion-dependent myeloproliferative or myelodysplastic disorders. Each 250 mL of packed RBCs contains approximately 250 mg of iron. Patients can become symptomatic after as few as 20 units. After 100 units (20–25 g of iron), patients almost always show some symptoms of iron overload, which include:

- Glucose intolerance
- Cirrhosis
- Cardiomyopathy
- Hypogonadism

Diagnosis of transfusional hemosiderosis is established by an elevated ferritin and an iron-laden liver biopsy. As with hemochromatosis, MRI can detect iron in the liver, heart, joints, and pituitary (use an experienced facility only). Start iron chelation treatment (deferoxamine or deferasirox) before symptoms appear, because symptoms are usually not reversible. Consider chelation after 20–25 units of packed RBCs (approximately 5 g of iron) if transfusions are ongoing.

Transfusion-related acute lung injury (TRALI) is a severe pulmonary reaction caused by antibodies present in transfused FFP. TRALI is one of the most common causes of transfusion-related fatalities. The timing of TRALI is typically during or shortly after transfusion (1–2 hours), but TRALI can be more delayed, occurring up to 6 hours after transfusion. Clinically, there is sudden onset of respiratory distress. This can include alveolitis, noncardiogenic pulmonary edema, and acute respiratory distress syndrome (ARDS). Treatment is supportive and can include mechanical ventilation. Stop the transfusion, and never use blood products from that donor again!

Pretransplant alloimmunization can occur if transfusions are given before transplant. To reduce risk:

- Do not use family members as donors.
- Use leukocyte-poor irradiated blood components.
- Use single-donor platelets if needed.

Allergic/Anaphylactic reactions to transfused blood: Simple urticaria and anaphylaxis can occur. Symptoms of anaphylaxis—including hypotension, shock, angioedema, and respiratory distress with wheezing—can begin immediately on starting transfusion. This requires immediate treatment, including discontinuing transfusion and giving epinephrine. Treatment of anaphylaxis is covered in the [Allergy & Immunology](#) section. Know that recipient IgA deficiency leads to anti-IgA antibody formation and donor blood with normal IgA levels can provoke anaphylaxis. Use IgA-deficient donors for such recipients.

Infectious complications are most likely to occur with platelet products, because they are stored at room temperature. Skin flora and gram-negative bacteria (e.g., *E. coli*, *Yersinia*, *Pseudomonas*) are the usual organisms.

Symptoms can be similar to other transfusion reactions and include fever, chills, and hypotension. Symptoms may develop during or up to 30 minutes after the transfusion. Management includes stopping the transfusion, supportive care, and blood cultures from the opposite arm, among others. Broad-spectrum antibiotics may be indicated if suspicion is high. Blood banks screen for the most common infectious agents as follows:

- HIV-1 and HIV-2
 - Risk of contracting HIV-1 or -2 from the U.S. blood supply is 1 in 2 million.
- Human T-lymphotropic virus 1 and 2 (HTLV-1 and HTLV-2)
 - Risk is < 1 in 2 million.
- Hepatitis C virus (HCV)
 - Risk is 1 in 1.3 million.
- Hepatitis B virus (HBV)
 - Risk is 1 in 200,000–500,000.
- West Nile virus
- *Treponema pallidum*
- *Trypanosoma cruzi*
 - Trypanosomiasis is of particular concern in South America.
 - Many U.S. blood banks are implementing universal screening using an enzyme immunoassay (EIA) test for *T. cruzi* antibody.
- Cytomegalovirus (CMV)
 - EIA for antibody
 - Only CMV-negative blood is transfused in CMV-negative transplant patients, and leukocyte-depleted blood is used to further reduce risk.

Hypotensive reactions can be seen in patients on ACE inhibitors whose blood is filtered through coils, such as those used to filter out WBCs. Kinin activation is the probable cause. Prestorage filtration eliminates this problem.

Graft-versus-host (GVH) reaction: Immunocompromised patients can develop GVH from lymphocytes in transfused blood, especially if receiving donations from a 1st degree relative (because they can be HLA-haploidentical), and the lymphocytes may engraft. Order irradiated blood for immunocompromised patients to ensure that the potentially harmful lymphocytes have been destroyed.

Transfusion-associated circulatory overload (TACO) is another common cause of transfusion-related fatalities. Symptoms and signs of respiratory distress and circulatory overload—including hypertension, tachycardia, and pulmonary edema—typically occur < 6 hours after transfusion. Prevent TACO by slowing the infusion and using diuretics.

Know how to differentiate between TRALI and TACO. Brain natriuretic peptide is often elevated in TACO but not in TRALI, because TRALI is not related to volume overload. Remember diuretics used to treat TACO can worsen TRALI!

DISORDERS OF THE BONE MARROW

PREVIEW | REVIEW

- What are the lab findings in a patient with aplastic anemia?
- How can you tell the difference between acute and chronic leukemias?
- What is the treatment for leukemic patients who have hyperviscosity symptoms due to a large number of circulating blasts (i.e., leukostasis)?
- What percentage of marrow blasts defines acute myeloid leukemia (AML)?
- What is a characteristic peripheral blood finding in a patient with AML?
- Characterize the acute promyelocytic leukemia (APML) genetic translocation and describe how it affects treatment. What is the prognosis for APML?
- Which category of AML is associated with disseminated intravascular coagulation?
- What physical findings do patients with acute lymphoblastic leukemia (ALL) often present with?
- Which ALL abnormalities are associated with a poor prognosis?
- What is 5q deletion syndrome?
- What is the main difference between the myeloproliferative disorders (MPDs) and acute leukemia?
- What are the 4 most common MPDs?
- JAK2 is found in what disease states?
- Chronic myeloid leukemia (CML) is associated with which cytogenetic abnormality in > 90% of cases?
- What is the current standard of care for treating chronic-phase CML?
- What side effects are associated with tyrosine kinase inhibitors?
- What symptoms necessitate treatment in patients with essential thrombocythemia?
- Which peripheral blood finding is seen in patients with myelofibrosis?

PANCYTOPENIA

Pancytopenia is associated with multiple causes discussed below and defined by reduction in peripheral circulating blood cells of all three cell lines. The differential causes of pancytopenia can be secondary to infection, autoimmune, medication-associated (e.g., chemotherapy), nutritional deficiency, malignancy-associated, or genetic inborn.

MAJOR CAUSES OF BONE MARROW FAILURE

Inherited bone marrow failure syndromes:

- Fanconi anemia
- Dyskeratosis congenita
- Shwachman-Diamond syndrome
- Amegakaryocytic thrombocytopenia
- Reticular dysgenesis

Acquired causes of bone marrow failure:

- Acquired aplastic anemia caused by drugs, chemicals, or radiation
- Acquired aplastic anemia associated with viral infection or immune disorder
- Myelodysplastic syndrome
- Paroxysmal nocturnal hemoglobinuria
- Large granular lymphocytic leukemia

APLASTIC ANEMIA

Aplastic anemia is an absence of hematopoietic stem cells that results in **pancytopenia** and a **hypocellular marrow**. It can be acquired or inherited. The etiology of acquired aplastic anemia is unknown in most cases.

Dose-related causes of aplastic anemia:

- Benzene
- Industrial chemicals
- Pesticides
- Radiation

Idiosyncratic causes of aplastic anemia:

- Sulfa
- Carbamazepine
- Valproate
- Phenytoin
- Gold
- Chloramphenicol
- Nifedipine
- Methimazole
- Propylthiouracil

Aplastic anemia is occasionally associated with viral infections with parvovirus B19, hepatitis viruses, and HIV. Other associated illnesses include thymoma, paroxysmal nocturnal hemoglobinuria, and SLE.

The presentation is determined by which cell lines are affected most: fatigue and weakness with anemia, infections with neutropenia, or bleeding with thrombocytopenia.

Aplastic anemia presents with pancytopenia, decreased reticulocyte count, and a hypocellular marrow (**< 20%**) with **normal maturation** of the cell lines. Differential diagnosis includes other causes of pancytopenia, such as

B₁₂ or folic acid deficiency, primary hematologic malignancies, myelodysplastic syndrome (MDS), infiltration of bone marrow with neoplastic cells, or fibrosis.

Aplastic anemia is classified as **severe** if:

- marrow cellularity is **< 25%** of normal or
- if the marrow is hypocellular, **< 30%** of the cells are hematopoietic, **and** at least 2 of the following 3 conditions are met:
 - 1) Absolute neutrophil count (ANC) **< 500/μL** ($0.5 \times 10^9/L$)
 - 2) Platelets **< 20,000/mm³** ($2 \times 10^9/L$)
 - 3) Reticulocytes **< 1%** (corrected for hematocrit)

Classification is **very severe** if severe criteria are met but the **ANC is < 200/μL** ($0.2 \times 10^9/L$). A low ANC indicates a poor prognosis. Younger age and higher cell counts are predictive of a better response rate to treatment.

For all patients, treatment includes withdrawal of any possible offending medications. In addition, if thymoma is found, surgical excision is indicated.

Definitive treatment of aplastic anemia is with hematopoietic stem cell transplantation (HSCT) for patients who are **young** and have an HLA-matched family member (10-year survival **> 80%**). See [Hematopoietic Stem Cell Transplantation \(HSCT\) on page 8-58](#) for more information.

If there is no suitable donor or the patient is **> 45** years of age, treat with immunosuppression using either antithymocyte globulin or antilymphocyte globulin in combination with corticosteroids and cyclosporine. The complete response rate is 65%, although relapses are common.

Hematopoietic growth factors are undergoing evaluation and are not yet recommended treatment.

Know that patients with aplastic anemia are at increased risk of developing acute leukemia.

THE ACUTE LEUKEMIAS

The acute leukemias are clonal disorders of **early** hematopoietic stem cells.

Normal hematopoiesis begins with pluripotent stem cells, which, in addition to reproducing themselves, are capable of differentiating into cells of either the myeloid lineage (i.e., granulocytes, monocytes, erythrocytes, and megakaryocytes) or the lymphocyte lineage (B or T cells). See [Figure 8-34 on page 8-44](#).

Acute leukemias occur when cells of either the early myeloid (acute myeloid leukemia [AML]) or early lymphoid (acute lymphoblastic leukemia [ALL]) lines lose their ability to differentiate while retaining their ability to replicate. These immature cells, called **blasts**, accumulate in the bone marrow and crowd out normal hematopoietic elements. In addition, the blast cells often spill out into the peripheral circulation.

Patients with acute leukemias present with symptoms related to cytopenias (e.g., infections, fatigue, mucosal bleeding).

Diagnosis and prognosis are made using morphologic analysis, cytogenetic studies (karyotype), cytochemical analysis (e.g., periodic acid-Schiff [PAS], peroxidase, esterase, Sudan black), molecular markers, and cell surface markers (flow cytometry and immunophenotyping for surface antigen cluster of differentiation [CD] markers).

Suspect acute leukemia when blasts (immature cells) are seen in the peripheral blood smear without mature cells. Note that **chronic** leukemias have overproduction of ≥ 1 developing cell lines but **not of blasts**.

Refer to Figure 8-29 for a summary of the workup for acute leukemia.

The general principles of management for acute leukemias include induction, consolidation, and (in select cases) maintenance therapies.

Induction therapy is intended to eradicate the leukemic clone in hopes that normal hematopoiesis returns without continual presence of leukemic disease. Induction with chemotherapy often involves a prolonged period of pancytopenia, during which the patient is highly susceptible to infection.

Myeloid growth factors can be used to shorten the time spent in a neutropenic state in patients with acute lymphoblastic leukemia, although their use in acute myeloid leukemia may also be considered. Although these agents may reduce the length of hospitalization and decrease the incidence of infection, they have **not** been proven to increase survival. Supportive care with blood and platelet transfusions is also given during cell count recovery after induction chemotherapy.

CNS-directed therapy may be incorporated throughout the treatment as needed given the potential for CNS involvement. This can include intrathecal chemotherapy, CNS irradiation, and/or high-dose systemic chemotherapy chosen for its CNS penetrance.

Figure 8-29: Acute leukemia decisions

Once remission is achieved and cell counts have recovered, **consolidation therapy** with further systemic therapy and potentially HSCT is used to prolong remission and survival. The purpose of this phase is to kill any remaining cancer cells after initial treatment.

Gene expression profiling using DNA microarrays is becoming an increasingly important tool to assist with prognosis, to assess depth of treatment response, and to guide therapy.

Note: Neutropenic colitis (a.k.a. typhlitis) can occur in patients after prolonged neutropenia of any cause. The neutropenia can be the result of induction therapy, immunosuppressive therapy, or the disease itself (especially with acute myeloid leukemia, multiple myeloma, and aplastic anemia). It is caused by gram-negative bacteria and presents with abdominal pain and (sometimes bloody) diarrhea. Appropriate therapy includes piperacillin-tazobactam, cefepime + metronidazole, or ceftazidime + metronidazole. Surgical intervention is reserved for perforation.

In select cases, a **maintenance phase** with chemotherapy and/or targeted agents may be incorporated after induction and consolidation with the intent to reduce the risk of disease recurrence.

Acute Myeloid Leukemia (AML)

Recall that during normal hematopoiesis, myeloid blast cells (Figure 8-30 and Figure 8-31) differentiate into granulocytes, monocytes, erythrocytes, or megakaryocytes. AML (a.k.a. acute myelogenous leukemia) is a clonal disorder of the early myeloid cells; there is overproduction of myeloblasts with reduced production of RBCs, platelets, and mature granulocytes. The blast forms accumulate in the peripheral circulation, marrow, and sometimes lymphoid tissues.

The disorder can develop from exposure to chemicals, such as benzene and certain chemotherapeutic agents. (Alkylators and topoisomerase inhibitors are the hallmark 2 classes that can cause therapy-related AML.) It can also arise after transformation from myeloproliferative disorders, myelodysplastic disorders, aplastic anemia, and paroxysmal nocturnal hemoglobinuria (PNH). Typically, these secondary leukemias have a worse prognosis than de novo AML.

Patients often seek medical care because of symptoms related to disordered hematopoiesis with pancytopenia. Patients often have fatigue and pallor related to anemia. The bone pain seen in ALL is uncommon with AML. When fever is present, it's usually from infection.

Know: Large numbers of blasts in the peripheral blood ($> 100,000/\mu\text{L}$ [$100 \times 10^9/\text{L}$]) can increase blood viscosity and cause end-organ disease, such as brain ischemia and hemorrhage (presents as altered sensorium), and sludging in the pulmonary vasculature (presents as respiratory distress). This combination of greatly increased blast cell count and decreased tissue perfusion is called **leukostasis**, a medical emergency. Urgent treatment often includes intravenous fluids, leukapheresis, hydroxyurea, and induction chemotherapy.

Thrombocytopenia predisposes to hemorrhage, especially in the presence of a high blast count. Qualitative and quantitative WBC problems predispose to serious infection of all kinds. Concurrent anemia may require RBC transfusions but should be avoided in the setting of profound leukostasis due to the potential of worsening hyperviscosity.

Diagnose AML by bone marrow biopsy if blasts are seen in the peripheral blood. Marrow and/or peripheral **blasts $\geq 20\%$** is the definition of acute myeloid leukemia. Because the blasts of AML and ALL look alike, cytochemical tests, immunophenotyping, and chromosomal analysis are performed on marrow cells in order to differentiate between the two. Note: The presence of certain cytogenetic changes ($t(15;17)$, $t(8;21)$, or $inv(16)$) is diagnostic of AML, regardless of the blast percentage. Know, however, that finding **Auer rods** inside peripheral blood blast cells (Figure 8-32) helps make the diagnosis of AML. Auer rods are azurophilic, reddish purple, needle-shaped crystals found in the cytoplasm of AML blast cells.

In 2016, a revision to the World Health Organization classification of myeloid neoplasms and acute leukemia was published. It attempts to incorporate clinical, prognostic, morphologic, immunophenotypic, and genetic data.

Currently, several factors are used to establish AML prognosis. Cytogenetic/Molecular findings represent one of the most powerful prognostic indicators. These genetic features can be used to classify patients into different risk

Figure 8-30: Normal myeloblast (high-oil immersion), few cytoplasmic granules, and several nucleoli

Figure 8-31: Myeloblast vs. lymphoblast: (A) young mono and a myeloblast; (B) myeloblast; and (C) lymphoblast. (D) Normal lymphocytes are smaller.

Figure 8-32: AML: bone marrow aspirate with peroxidase-positive blasts and 2 peroxidase-positive Auer rods

groups and allow for stratification of patients who would benefit from an earlier allogeneic HSCT in the 1st complete remission:

- **Favorable** → t(8;21), t(15;17), inv(16), or normal cytogenetics with *nucleophosmin 1* (*NPM1*) mutation
- **Intermediate** → normal karyotype, +8, or t(9;11)
- **Unfavorable** → monosomal karyotype, 11q23, t(6;9), t(9;22), inv(3), -5/5q-, -7/7q-, TP53 mutation, FLT3-ITD mutation, or more complex cytogenetics (≥ 3 aberrations)

Other **unfavorable** prognosticators for AML include:

- > 60 years of age
- Poor performance status
- WBC count > 100,000/μL ($100 \times 10^9/L$)
- Prior disease of the bone marrow (e.g., myelodysplasia, myeloproliferative disorder)

Standard induction therapy for AML is evolving, although it is historically based on the “7 + 3” combination of 7 days of cytosine arabinoside (ara-C) and 3 days of daunorubicin. Consolidation therapy can take the form of further chemotherapy with the same agents. For older patients, especially those with a poor performance status, the hypomethylating agents azacitidine or decitabine can be used. In the era of targeted therapies, agents targeting various mutations evident in AML (e.g., *FLT3*, *IDH*) are also being increasingly utilized in the various phases of treatment.

With standard therapy, remission is achieved in ~ 40–50% of patients > 60 years of age, but long-term, event-free survival is achieved in < 10%. For patients < 60 years of age, long-term survival, on average, is 20–30%.

Of particular importance is acute **promyelocytic leukemia** (**APML**), which is characterized by a translocation between chromosomes 15 and 17, involving the promyelocytic leukemia gene and retinoic acid receptor α gene. The expression of the PML-RAR α fusion protein renders physiologic levels of retinoic acid ineffective in their innate function to differentiate myeloid blasts, resulting in the development of APML.

Treatment of APML differs from treatment of other types of AML. It includes all-*trans* retinoic acid (ATRA), which is used to induce differentiation, along with either arsenic trioxide (ATO) or daunorubicin. In patients with low- to intermediate-risk APML, ATRA and ATO are as beneficial as ATRA + chemotherapy. Prognosis for APML is **very favorable**, and therapy provides a remission rate of > 80% and a cure rate of > 70%. These rates are much better than with other forms of AML.

Patients with APML are classically at an increased risk for developing disseminated intravascular coagulation (DIC) due to release of procoagulants from cytoplasmic granules. The diagnosis of APML needs to be made quickly, because DIC can change APML from a curable disease into a fatal one within hours.

Know that **differentiation syndrome** (formerly ATRA syndrome) is a potentially life-threatening adverse effect of

ATRA and ATO therapy. Clinical presentation includes fever, volume overload with pleural and pericardial effusions, respiratory distress, and hypotension. Treat with high-dose dexamethasone and withhold ATRA and ATO until resolution of symptoms.

An important distinction in AML with t(9;22) is whether the disease is de novo AML or chronic myeloid leukemia (CML) in degenerated blast crisis. CML in blast crisis arises because of the presence of the Philadelphia chromosome (Ph; *BCR-ABL* gene translocation or t(9;22)) and is vulnerable to treatment with a tyrosine kinase inhibitor (TKI), such as imatinib. See **Chronic Myeloid Leukemia (CML)** on page 8-43.

Allogeneic hematopoietic stem cell transplantation (HSCT) is an important treatment option in some patients with AML. It is typically reserved for physiologically fit patients with good organ function in whom the disease is prognostically intermediate or unfavorable or has relapsed after achieving a prior complete response. Morbidity and mortality are influenced by the level of disease before transplant, histocompatibility between donor and recipient, stem cell source (umbilical cord, bone marrow, or peripheral blood), conditioning regimen, and expertise of transplantation center.

Acute Lymphoblastic Leukemia (ALL)

ALL is a clonal disorder of early **lymphocytic** precursors. The blasts of ALL can be of B- or T-cell lineage. B-cell ALL characteristically stains positive for TdT, CD19, CD20, and does **not** stain for myeloperoxidase (a myeloid cell marker). While ALL is **primarily** a disorder of children, there is a bimodal age distribution with increased incidence **also** in patients > 45 years of age. ALL represents ~ 20% of adult leukemias. There are B- and T-cell types, and mediastinal masses may be present.

The 2016 WHO classification uses cytogenetic and molecular changes to classify subtypes of ALL.

Clinically, patients often present with cytopenias, constitutional symptoms, symptoms of CNS involvement (e.g., cranial nerve and/or retinal abnormalities; symptoms of meningeal irritation), and enlargement of the liver, spleen, lymph nodes, and testicles due to extramedullary deposits of blast cells.

The peripheral blood smear may show leukopenia or leukocytosis with blast counts > 100,000/μL ($100 \times 10^9/L$; **Figure 8-33**). Definitive diagnosis and important prognosticators are made by immunophenotyping and chromosomal analysis of the leukemic cells.

Figure 8-33: ALL: peripheral blood smear showing excessive lymphoblasts

Unfavorable prognostic factors in ALL:

- < 1 year or > 35 years of age
- WBC > 100,000/ μ L (100×10^9 /L) for T cell and > 30,000 for B cell
- Mature B-cell or early T-cell types
- Persistent minimal residual disease, as detected by flow cytometry after induction
- Complex cytogenetics (≥ 5 changes), hypodiploidy (< 46 chromosomes), t(4;11), Philadelphia chromosome t(9;22)
- CNS involvement

Treatment is with **multiple** chemotherapy agents, used in induction, consolidation, and maintenance phases. Prednisone, vincristine, and daunorubicin form the foundation, and cyclophosphamide + L-asparaginase are often added (may increase response). Complete response rates are in excess of 80%. Patients who have a Ph+ ALL are often considered for tyrosine kinase inhibitors (TKIs), such as imatinib, dasatinib, or ponatinib throughout the various phases of their treatment.

Postremission therapy in ALL includes CNS prophylaxis with intrathecal chemotherapy +/- cranial radiation, consolidative therapy, and 2–3 years of maintenance therapy.

For patients **without** unfavorable prognostic factors, chemotherapy alone results in a 60% long-term, disease-free survival. For patients with ≥ 1 unfavorable prognostic indicators, consider HSCT. (See [Hematopoietic Stem Cell Transplantation \(HSCT\)](#) on page 8-58.)

Other forms of therapy for those patients who relapse include monoclonal antibodies targeting CD19 receptors commonly found on B lymphocytes and, especially for younger patients at approved centers, the use of anti-CD19-directed, chimeric antigen receptor T cells (CAR-T therapy).

Supportive care is an important component of treatment. In addition to the effects of cytopenias, patients often have hyperuricemia, hyperphosphatemia, and hypocalcemia reflective of **tumor lysis syndrome**—all secondary to the high cell turnover. As mentioned under [Acute Myeloid Leukemia \(AML\)](#) on page 8-40, leukostasis is an oncologic emergency in this population and needs to be treated aggressively with IV hydration, cytoreduction with steroids, and leukapheresis. Red blood cell transfusions should be avoided in the setting of leukostasis given the risk for exacerbating hyperviscosity.

CHRONIC LEUKEMIAS

The chronic leukemias are:

- Chronic myeloid leukemia (CML)
- Chronic lymphocytic leukemia (CLL)

CML is a myeloproliferative disorder discussed under [Chronic Myeloid Leukemia \(CML\)](#).

CLL is an early form of small lymphocytic lymphoma (SLL); we discuss both under [Chronic Lymphocytic Leukemia \(CLL\)](#) / [Small Lymphocytic Lymphoma \(SLL\)](#) on page 8-49.

MYELOYDYSPLASTIC SYNDROME (MDS)

MDS includes clonal stem cell disorders that are characterized by ineffective blood cell production and variable progression to acute leukemia. MDS occurs de novo or secondary to previous chemotherapy (a.k.a. therapy-related MDS). While both MDS and the myeloproliferative disorders are clonal stem cell disorders, only patients with MDS exhibit cytopenias and inadequate (dysplastic) maturation of blood cells. (See [Myelodysplastic / Myeloproliferative Disorders](#) for additional information.)

MDS presents with symptoms secondary to cytopenias, including weakness, infection, and bleeding. Platelets can be dysfunctional and result in bleeding that is out of proportion to the degree of thrombocytopenia. Bone marrow biopsy reveals a **hypercellular** marrow (peripheral cytopenias due to ineffective hematopoiesis) and dysplasia. However, in the absence of dysplasia, an MDS diagnosis may also be considered on the basis of MDS-defining cytogenetics in patients in whom alternate causes of bone marrow disorders have been ruled out. Patients who have MDS with **> 20% blasts** are considered to have **AML**.

There are several prognostic point system scoring scales to risk stratify patients with MDS, including the International Prognostic Scoring System (IPSS), WHO classification-based Prognostic Scoring System (WPSS), and the revised international prognostic scoring system (Revised IPSS), which all help risk stratify patients, consider management strategies, and predict survival. Points are assigned based on percentage of blasts (the most important prognostic indicator), number/extent of cytopenias, and cytogenetic risks. The various scoring systems employ various iterations, and their use can be institutionally variable.

Unfavorable prognosticators for MDS:

- High percentage of bone marrow blasts
- Number/Severity of cytopenias
- Cytogenetic abnormalities, including complex cytogenetics (≥ 3 abnormalities), especially involving chromosome 7

The following factors confer a more **favorable** prognosis and are individually incorporated into the staging system:

- Bone marrow blasts < 2%
- Generally preserved cell counts with hemoglobin > 10 g/dL, platelets > 100,000/ μ L, absolute neutrophil count > 800/ μ L
- Normal cytogenetics, or -Y, del(20q), or del(12p)
- Deletion of chromosome 5q or 20q

Know 5q deletion syndrome: Patients with the favorable 5q deletion have refractory anemia and thrombocytosis. Know that these patients generally respond to lenalidomide therapy allowing transfusion independence lasting > 2 years and a more favorable biologic risk profile.

See [Table 8-11](#) for differential diagnoses of MDS.

Table 8-11: Differential Diagnoses of Myelodysplastic Syndrome

B ₁₂ deficiency
Folate deficiency
Copper deficiency
Excessive alcohol intake
Heavy metal exposure (e.g., lead, arsenic)
Autoimmune cytopenias
HIV infection
Anemia of chronic disorders (infection, inflammation, cancer)
Secondary MDS (cytotoxic therapy, irradiation)
Other hematopoietic stem cell disorders (AML, myeloproliferative disorders, aplastic anemia, paroxysmal nocturnal hemoglobinuria, large granular lymphocytic leukemia)

Treatment depends on patient performance status, comorbidities, and aggressiveness of disease necessitating transfusions. Treatments can include supportive measures, including transfusion, erythropoietin-stimulating agents, hypomethylating agents (e.g., azacitidine, decitabine), or intensive chemotherapy followed by an allogeneic HSCT for biologically adverse-risk disease. Mortality in MDS is usually a result of progressive cytopenias or progression to AML.

MYELOYDYSPLASTIC / MYELOPROLIFERATIVE DISORDERS

Chronic **myelomonocytic** leukemia (CMML) is classified as an overlap myelodysplastic/myeloproliferative disorder that includes features of both, including dysplasia with cytopenias (MDS-like) and hyperproliferative cell lines with splenomegaly (myeloproliferative disorders). CMML is a cousin of CML. It is a malignant hematopoietic stem cell disorder that requires persistent monocytosis ($\geq 1,000/\text{dL}$) over 3 months with the exclusion of alternate causes including CML and hypereosinophilic syndrome (especially among those with eosinophilia). Treatment is reserved for patients with profound leukocytosis and/or symptomatic splenomegaly. Optimal treatment for this condition is poorly defined but often utilizes cytoreductive agents, such as hydroxyurea. Check patients with CMML for the t(5;12)(q33;p13) oncogenic product. These patients may respond to imatinib therapy (tyrosine kinase inhibitor). General prognosis is poor, and the only curative approach with this disease is an allogeneic HSCT.

MYELOPROLIFERATIVE DISORDERS (MPDs)

MPDs are **clonal** malignancies of early hematopoietic stem cells, characterized by loss of the regulation of cell proliferation. The result is the overproduction of the entire pyramid of maturation of granulocytes, erythrocytes, and platelets. (Contrast this with acute leukemia, marked

by maturation arrest and proliferation of blasts.) MPDs variably progress to acute leukemias or myelodysplasia (Figure 8-34 on page 8-44).

The 4 most common MPDs:

- 1) Chronic myeloid leukemia (CML)
- 2) Essential thrombocythemia (ET)
- 3) Polycythemia vera (PV)
- 4) Primary myelofibrosis (MF; the rarest of these 4 MPDs)

JAK2 (Janus kinase, a tyrosine kinase) is an intracellular signaling molecule that is coupled to cell surface hematopoietic growth factor receptors (like the erythropoietin receptor). A **JAK2** mutation causes constitutive activation of the JAK2 kinase domain, inducing unregulated erythropoiesis. The mutation is found in almost all patients with PV and ~ 50% of those with ET or MF. The presence of this genetic lesion can be useful in the diagnosis and therapeutic targeting of the disease.

Thrombopoietin receptor gene (a.k.a. *myeloproliferative leukemia* gene [MPL]) and *calreticulin* (CALR) gene mutations are other markers, which may be mutually occurring in the MPDs, particularly ET.

Chronic Myeloid Leukemia (CML)

CML is a clonal stem cell disorder of myeloid cells. The clinical hallmark is one of uncontrolled production of **mature** neutrophils with relatively preserved function. Most patients present in the chronic phase with an elevated WBC count and a predominance of **granulocytes** (Figure 8-35 on page 8-45). There is often an elevated **basophil** count, eosinophilia, thrombocytosis, and a **low** leukocyte alkaline phosphatase (LAP) score. The expanded myeloid pool can lead to organ infiltration, causing hepatosplenomegaly.

The diagnosis of CML is dependent on detection of the **Philadelphia chromosome** (i.e., t(9;22)), or its products: BCR-ABL fusion mRNA or the BCR-ABL protein, a tyrosine kinase. > 90% of patients demonstrate this abnormality at the time of diagnosis.

Uncontrolled replication of the myeloid stem cells as the disease progresses inevitably leads to further genetic errors. The myeloid cells begin to lose their ability to differentiate from their blast stages, and the disease degenerates into acute leukemia (AML or ALL). This 2nd, or accelerated, phase of CML is characterized by increasing numbers of blasts (10–20%) and basophils and a declining platelet count.

The patient is considered to be in the **blast phase** once the percentage of blasts has progressed to > 20%. (See Figure 8-36 on page 8-45 and Figure 8-37 on page 8-45.) Survival is greatly diminished once this blast crisis has occurred.

Most patients (85–90%) present in the stable chronic phase, while 10–15% may present in the accelerated or blast phase. Fewer patients progress to the blast phase due to improvements in treatment during the chronic phase.

Figure 8-34: Hematopoiesis

A tyrosine kinase inhibitor (TKI)—either 1st generation (imatinib) or 2nd generation (dasatinib, bosutinib, or nilotinib)—is the 1st line treatment of CML in **chronic** phase. The 2nd generation TKIs provide faster hematologic and cytogenetic responses than imatinib, but so far no survival advantage has been shown. The 3rd generation of TKIs is reserved to ponatinib, which is only indicated for patients who have failed 2nd line therapies or have developed a point mutation to the T315I, rendering 1st and 2nd generation TKIs ineffective. Patients who initiate therapy with a baseline WBC > 100,000 at the time of diagnosis should be cytoreduced with hydroxyurea.

Side effects of TKIs vary depending on the agent and can include gastrointestinal intolerance, hepatotoxicity, cardiac toxicity, pulmonary toxicity, and thrombotic complications:

- Dasatinib should be avoided in patients with cardio-pulmonary effusion, pulmonary hypertension, and those on anticoagulation.
- Nilotinib may be associated with pancreatitis, arterial thrombus formation, and QT prolongation.
- Ponatinib has been demonstrated to increase the risk for thrombi and is reserved for earlier generation TKI failure as mentioned above.
- Also, TKIs are teratogens, so do not use them in women of childbearing age.

Figure 8-35: CML: peripheral blood smear showing excessive granulocytes

Figure 8-36: Myeloproliferative disorder (low power): CML. Hypercellular marrow. Myeloid elements are more abundant than the normal 3:1 myeloid:erythroid (M:E) ratio.

Figure 8-37: Myeloproliferative disorder: CML. Peripheral smear with the pyramid of maturation of granulocytes: promyelocytes, myelocytes, metamyelocytes, bands, and segmented neutrophils

Allogeneic HSCT remains the only proven curative therapy for CML but is reserved for select patients who develop TKI resistance.

Essential Thrombocythemia (ET)

ET (a.k.a. essential thrombocytosis) is the **least** aggressive of the myeloproliferative disorders. Suspect ET when an elevated platelet count is noted on a routine CBC. Although patients with ET have a normal life expectancy, they are at risk for thrombosis (venous and arterial) and hemorrhage.

Risk factors for clot with ET:

- > 60 years of age
- Previous history of thrombosis

Clinical presentation includes symptoms related to microthrombi (e.g., headaches, visual disturbances, erythromelalgia) as well as symptoms referable to larger clots (including miscarriages) and bleeding. **Erythromelalgia** is paroxysmal vasodilation of small arteries of the feet (mainly) and hands, causing burning pain, swelling, and erythema.

Diagnosis of ET based on the 2016 WHO criteria ultimately requires:

- the presence of > 450,000 platelets,
- megakaryocyte proliferation in the marrow,
- not meeting WHO criteria for other myeloproliferative disorders, and
- the presence of *JAK2*, *CALR*, or *MPL* mutations.

Alternatively, the diagnosis can be established by the exclusion of causes of reactive thrombocytosis (infection, inflammation, tissue injury, trauma, ischemia, splenectomy, surgery, and especially iron deficiency anemia) and the inclusion of the first 3 criteria above.

ET patients with *JAK2* mutation may have a higher risk of thrombosis than ET patients with *CALR* mutation.

Limit treatment for ET to:

- Patients with significant erythromelalgia
 - Prescribe aspirin to prevent thrombosis.
- Patients at high risk for thrombosis (i.e., > 60 years of age or any age with a history of thromboembolism or platelets > 1,000,000/ μ L)

- Give cytoreductive therapy with hydroxyurea. The goal is to reduce the platelet count < 400,000/ μ L (400×10^9 /L).
- Anagrelide, busulfan, and pegylated interferon are also used as alternative or 2nd line therapies.
- Patients with baseline platelets > 1,000,000/ μ L
 - These patients should receive a ristocetin cofactor assay to rule out acquired von Willebrand disease prior to being initiated on aspirin.
- For surgical patients with ET, there is a high perioperative risk of thrombosis and bleeding complications. Reduce very high platelet counts prior to surgery (with platelet pheresis if urgent surgery is required).

Like PV, ET can progress to MF and acute leukemia. Risk factors predicting decreased survival are age > 60, WBC > 11,000/ μ L, and history of thrombosis.

Polycythemia Vera (PV)

PV is characterized by increased RBC mass in the **absence** of erythropoietin and in association with the *JAK2* mutation. See Figure 8-38. Increased RBC mass most often results from erythropoietin stimulation, which can result from a primary or secondary disorder. Common secondary causes of increased RBC mass include hypoxemia (from obstructive sleep apnea, chronic obstructive pulmonary disease [COPD], smoking, right-to-left cardiac shunts, high altitude, carbon monoxide poisoning), tumor secretion of erythropoietin (from renal cell carcinoma, hepatocellular carcinoma), and androgens.

Figure 8-38: Myeloproliferative disorder: polycythemia vera. Bone marrow biopsy shows increased megakaryocytes and greatly increased erythroid precursors (with black condensed nuclei) and a decreased M:E ratio.

Patients with PV often present with an increased hematocrit with leukocytosis and thrombocytosis, the latter often causing erythromelalgia (more under [Essential Thrombocythemia \(ET\)](#) on page 8-45). Other common symptoms are headache, weakness, and dizziness, which are thought to be secondary to hyperviscosity from the elevated hematocrit. Patients with PV often complain of pruritus (perhaps secondary to increased histamine levels) after a hot bath or shower. Gout can result from rapid cellular turnover. Splenomegaly is common, and there is an increased risk for arterial and venous thrombosis (e.g., cerebrovascular accident, deep venous thrombosis) from disease.

Diagnose polycythemia with an elevated hemoglobin and hematocrit (Hgb/Hct) and/or RBC mass. Then evaluate for secondary causes of polycythemia via careful history and examination and pulse oximetry. Check serum erythropoietin (EPO) level, which is normal or increased in secondary causes and inappropriately low in PV. *JAK2* mutation testing is essential to confirm a diagnosis of PV, as virtually all patients will have a mutation in either exon 12 or 14 of this gene.

The 2016 WHO criteria for PV:

- Major criteria:
 - 1 of the following:
 - Hemoglobin > 16.5 g/dL (165 g/L) in men, > 16.0 g/dL (160 g/L) in women
 - Hematocrit > 49% in men, > 48% in women
 - Increased RBC mass (> 25% above mean normal predicted value)
 - Bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis), including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes (differences in size)
 - Presence of *JAK2* V617F or *JAK2* exon 12 mutation
- Minor criterion:
 - Subnormal serum erythropoietin level

Diagnosis of PV requires meeting either all 3 major criteria or the first 2 major criteria and the minor criterion.

Note that bone marrow biopsy may not be required in cases with sustained absolute erythrocytosis (hemoglobin levels > 18.5 g/dL [185 g/L] in men, > 16.5 g/dL [165 g/L] in women; hematocrit 55.5% in men, 49.5% in women) if the 3rd major criterion (presence of gene mutation) and the minor criterion are present. However, initial myelofibrosis (MF; present in up to 20% of patients) can only be detected by performing bone marrow biopsy; this finding may predict a more rapid progression to overt MF (post-PV MF).

Treatment of PV is phlebotomy to a goal hematocrit of < 45% (to induce an iron-deficient state), which reduces mortality but may transiently increase the rate of thrombosis.

Low-dose ASA lowers the risk of thrombosis during this period. Cyto reduction therapy with hydroxyurea lowers

this thrombotic risk and is considered for older patients with leukocytosis. Pegylated interferon has also been used. Consider the *JAK2* inhibitor ruxolitinib for patients intolerant or refractory to hydroxyurea, particularly in the setting of symptomatic splenomegaly or severe constitutional symptoms. Allogeneic HSCT may be indicated in patients with evolving MF.

Increased mortality in patients with PV is related to thrombosis (venous or arterial)—an elevated hematocrit is prothrombotic. Mortality also results from conversion to AML and MF.

Primary Myelofibrosis (MF)

Primary MF is a clonal stem cell disorder of unknown cause that results in hyperplasia of atypical megakaryocytes. These megakaryocytes stimulate a nonclonal proliferation of fibroblasts, which then go on to cause fibrosis of the bone marrow ([Figure 8-39](#)). Secondary MF can result from transforming PV and ET, although it shares the same clinical manifestations as primary MF.

Figure 8-39: Myeloproliferative disorder: myelophthisis (replacement of bone marrow by a disease process)—in this case, myelofibrosis (replacement by reticulin)

The most common symptom of primary MF is fatigue. Early satiety and abdominal fullness are also common, attributable to hepatosplenomegaly. Screening labs show marked anemia and variable changes in WBCs and platelets, with eventual pancytopenia developing as disease progresses. Serum LDH can be increased.

The peripheral blood smear often shows teardrop cells—a finding that is common to diseases that infiltrate the marrow (e.g., metastatic cancer, tuberculosis, fungal infections). Marrow aspirate often results in a dry tap, and marrow biopsy is often strongly positive for the reticulin stain.

Allogeneic HSCT remains the only chance for cure, but this therapy is limited to younger patients. For the vast majority of patients, treatment is primarily supportive, including splenectomy for severe splenomegaly. The oral *JAK2* inhibitor ruxolitinib is approved to treat primary MF without the *JAK2* V617F mutation. The 2012 Comfort-II Phase 3 study showed significant improvement in weight loss, fatigue, splenic volume, and improved survival with the use of ruxolitinib.

LYMPHOPROLIFERATIVE DISORDERS

PREVIEW | REVIEW

- What are the common physical findings on initial presentation of non-Hodgkin lymphoma (NHL)?
- What is the term for an NHL that produces an IgM monoclonal gammopathy and is associated with hyperviscosity?
- What are the 2 general types of NHL?
- NHL prognosis depends on which 5 factors?
- Which monoclonal antibody targeting CD20 is incorporated into the treatment for most cases of NHL—whether indolent or aggressive?
- What is the treatment for asymptomatic follicular lymphoma?
- Marginal zone lymphoma is associated with which chronic infection?
- What is the difference between chronic lymphocytic leukemia (CLL) and small lymphocytic lymphoma (SLL)?
- What does rapid enlargement of previously stable lymph nodes in a patient with CLL/SLL suggest?
- What is the treatment for CLL/SLL without symptoms?
- What is the clinical presentation of hairy cell leukemia?
- What is the standard chemo regimen for diffuse large B-cell lymphoma?
- What cytogenetic abnormality is associated with Burkitt's? Characterize the clinical presentation.
- Which diseases are seen after radiation therapy to the chest during treatment of Hodgkin lymphoma?
- Primary central nervous system lymphoma in patients with HIV/AIDS is associated with which virus?
- Which virus is associated with posttransplant lymphoma?
- Which diseases are associated with an increased risk of lymphoma?
- What are the typical symptoms of multiple myeloma? The lab findings?
- Characterize the differences among monoclonal gammopathy of undetermined significance, smoldering myeloma, and multiple myeloma.

NOTE

Lymphoproliferative disorders range from slow-growing, asymptomatic tumors to the most aggressive malignancies. Some present mainly as **lymphomas** which are neoplastic cells growing as a **solid mass** in the lymph nodes, spleen, bone marrow, or solid organs. Others present more like **leukemias** which are neoplastic cells found

in the blood and bone marrow. It is not unusual to see overlap of these 2 entities. For example, patients with chronic lymphocytic leukemia (CLL) often have a solid component to their disease, termed small lymphocytic lymphoma (SLL). When present, the combined diagnosis of CLL/SLL is used. In other words, many lymphomas have small components of leukemia to them, and some leukemias have a component of lymphoma.

NON-HODGKIN LYMPHOMA (NHL)

The term non-Hodgkin lymphoma (NHL) encompasses a group of disorders characterized by clonal proliferation of lymphocytes (virtually all B or T cells). See Table 8-12 for prevalence of the cell-type neoplasms based on the 2016 revision of the World Health Organization (WHO) classification of lymphoid neoplasms.

Table 8-12: WHO Classification of the Most Common NHLs and Leukemias

Neoplasm	Type	Frequency (%)
B-cell	Diffuse large B-cell lymphoma	33
	Follicular lymphoma	22
	Extranodal marginal zone B-cell lymphoma	8
	CLL/SLL	7
	Mantle cell lymphoma	6
	Burkitt lymphoma	2
	Nodal marginal zone B-cell lymphoma	2
	Lymphoplasmacytic lymphoma	1
	Precursor B-cell neoplasms	< 1 each
	B-cell prolymphocytic leukemia	
	Splenic marginal zone B-cell lymphoma	
	Hairy cell leukemia	
	Plasma cell myeloma	
T-cell	Mature (peripheral) T-cell neoplasms	8
	Precursor T-lymphoblastic leukemia/lymphomas	2
	Primary systemic anaplastic large cell lymphoma	2

NHL may be associated with infectious etiologies, including tick-borne diseases, bacteria, and viruses, including human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), human T-cell lymphotropic virus 1 (HTLV-1), and human herpesvirus 8 (HHV-8).

Patients with NHL often present with palpable adenopathy and constitutional symptoms (e.g., weight loss, fever, night sweats). Nodal growth can occur in nonpalpable areas as well, resulting in hepatosplenomegaly.

Airway obstruction or superior vena cava syndrome can result from nodal growth in the mediastinum; bowel or ureter obstruction may result from growth in the mesentery or retroperitoneum.

Some lymphomas, such as **Waldenström macroglobulinemia**, produce an IgM monoclonal gamma globulin that can lead to hyperviscosity (see **Waldenström Macroglobulinemia (WM)** on page 8-51) or autoimmune cytopenias (Coombs + anemia and/or thrombocytopenia), while others (CLL/SLL) cause agammaglobulinemia that leads to frequent infections. Cytopenias also can develop from hypersplenism and from bone marrow infiltration.

Diagnosis of lymphoma is made by an excisional biopsy or a core needle biopsy of a lymph node, which allows the pathologist to observe both the appearance of the cells and the architecture of the lymph node. Immunohistologic stains and flow cytometry also are performed. If there is a sizable leukemic component to the lymphoma, as in CLL/SLL, the diagnosis can be made by flow cytometry of the peripheral lymphocytes, looking for characteristic cell surface markers.

Once the diagnosis is made, staging is carried out using physical exam and CT scans of the neck, chest, abdomen, and pelvis. A bone marrow biopsy can be helpful to determine the nature of existing cytopenias.

Positron emission tomography (PET) scanning can be integrated into initial diagnostics and used in follow-up after treatment. PET uses radiolabeled glucose to image glycolysis in vivo. Areas that are relatively metabolically active (i.e., brain, heart, kidneys) take up the radiolabeled glucose and image brightly. Active malignancies also take up the tracer and become PET or 18-fluorodeoxyglucose (FDG) avid. Patients with NHL often have persistent masses seen on CT scan after treatment. These masses usually represent either residual lymphoma or fibrous scar tissue. A mass that does not fully resolve with treatment and is FDG avid represents persistent disease, while a lack of avidity likely represents remission or cure.

Indolent lymphomas have a long clinical course, measured over years. They are seldom cured with conventional chemotherapy, and early treatment has never been shown to improve survival over delayed treatment. Treatment is ordinarily held until symptoms develop, including bulky

adenopathy, constitutional complaints, or cytopenias from marrow infiltration—a close watch-and-wait strategy is employed. Treatment controls symptoms by placing the lymphoma in a temporary remission or decreasing the overall disease burden.

Aggressive NHLs grow more quickly—often becoming symptomatic early in the disease course. If left untreated, death follows within months. These rapidly growing lymphomas respond well to chemotherapy, and, while many ultimately relapse, an increasing number are being cured.

An individual patient's prognosis with NHL depends upon the subtype of lymphoma. The commonly utilized International Prognostic Index (IPI) uses 5 factors to help predict outcome:

- 1) Number of extranodal disease sites
- 2) Lugano stage (based on the Ann Arbor staging system with Cotswold modifications for both NHL and Hodgkin lymphomas; [Table 8-13](#))
- 3) Serum LDH (a marker for tumor burden)
- 4) Age
- 5) Performance status

Molecular and genetic markers can be incorporated for prognosis.

Know that there is growing use of monoclonal antibodies in the treatment of NHL.

Rituximab is a chimeric antibody directed against **CD20**, a surface marker found on many **B-cell** lymphomas. The binding of antibody to the neoplastic cell causes cell death by complement-mediated lysis, by cellular cytotoxicity, and directly by apoptosis. Rituximab is well tolerated even by elderly patients and can be used alone against indolent lymphomas or in combination with traditional chemotherapy against aggressive disease. Newer generation anti-CD20 antibodies, including **ofatumumab** and **obinutuzumab**, are being increasingly incorporated into the management of NHL.

Table 8-13: Lugano Staging System for NHL and HL

Stage		Involvement	Extranodal (E) Status*
Limited	I	1 node or a group of adjacent nodes	Single extranodal lesions without nodal involvement
	II	≥ 2 nodal groups on the same side of the diaphragm	Stage I or II by nodal extent with limited contiguous extranodal involvement
	II bulky†	Stage II as above, with bulky disease	N/A
Advanced	III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	N/A
	IV	Additional noncontiguous extralymphatic involvement	N/A

* Tonsils, Waldeyer ring, and spleen are considered nodal tissue.

† Stage II bulky disease is treated as limited or advanced disease, depending on histology and prognostic factors.

Alemtuzumab is another monoclonal antibody directed against **CD52**, a cellular marker often found in CLL. This antibody can control otherwise refractory CLL, although its use has generally fallen out of favor due to its inherent risk for infectious complications.

Indolent B-Cell NHLs

Follicular Lymphoma

Follicular lymphoma is the most common of the indolent non-Hodgkin lymphomas (NHLs). Patients are often elderly and present at a late stage with diffuse, asymptomatic, peripheral lymphadenopathy. The hallmark is overexpression of the antiapoptotic protein **BCL-2**, caused by a **t(14;18)** translocation. As with other indolent lymphomas, follicular lymphoma is usually slow growing and generally incurable (except in very-early-stage disease in which it can sometimes be cured with local radiation therapy).

Treatment is **not** indicated in asymptomatic patients, and the decision to treat is based on disease grade, disease stage, symptoms, potential for organ compromise, cytopenias, and disease bulk. (Note: Grade 3B disease is treated as diffuse large B-cell lymphoma regardless of symptoms or stage.) For patients with asymptomatic advanced-stage disease, close observation is an appropriate option. For patients with low-grade/limited stage (Stage I and II) disease, acceptable considerations include close observation, single agent rituximab, or local curative radiation. For patients with asymptomatic low-grade/advanced-stage disease (Stage III or IV), the options may include close observation, single agent rituximab (R), R-chemotherapy, obinutuzumab chemotherapy, or clinical trials.

Symptomatic and bulky disease patients should be treated with chemoimmunotherapy over single agent rituximab given the importance for more rapid cytoreduction. The vast majority of patients with follicular lymphoma achieve excellent long-term survival, although those who relapse within 2 years of prior induction exhibit inferior long-term outcomes. Salvage options in the relapsed/refractory follicular lymphoma setting include a previously unused chemoimmunotherapy approach, targeted agents (including PI3K inhibitors), and Bruton tyrosine kinase inhibitors. Radioimmunotherapy, while studied extensively, is less utilized by most hematologists due to toxicity, logistical challenges in administration, and availability of better systemic options. Allogeneic HSCT is the only curative approach to follicular lymphoma and is reserved for clinically appropriate patients. CAR-T-based therapies are experimental and demonstrate promise in this cohort of patients.

Patients progress over time to develop cytopenias and die from infection or complications of anemia; ~ 10% of follicular lymphomas undergo a transformation to a more aggressive lymphoma—diffuse large B-cell lymphoma (DLBCL). Transformed DLBCL is more resistant to chemotherapy than its de novo counterpart, and such a transformation is often a sign of a rapidly fatal outcome.

Marginal Zone Lymphoma (MZL)

MZL is an indolent lymphoma that, in part, develops from chronic antigenic stimulation. It is separated into **mucosa-associated lymphoid tissue (MALT)** (extranodal), **nodal**, and **splenic** MZLs. Unlike many indolent lymphomas, MZLs are often found at an early stage. The most common location is the gastric or intestinal mucosa (MALT lymphoma), and the most common antigenic stimulant is chronic *H. pylori* infection. MZL can also occur in bronchial mucosa and salivary glands, and splenic MZL can arise from chronic **HCV** infection. Additional infectious agents associated with cutaneous lymphoma are *Borrelia burgdorferi*, *Chlamydomphila psittaci* (implicated in adnexal ocular lymphoma), *Campylobacter jejuni* (for the small intestine), and *Mycobacterium* species (for bronchial lymphoma).

When extranodal MZL is diagnosed, rule out infectious causes (i.e., *H. pylori* and HCV).

Early-stage gastric MALT lymphoma can be treated with antibiotics alone to eradicate *H. pylori* or with added radiation if the initial treatment fails. Early treatment of the other types of MZL with lung lobectomy (bronchial-associated lymphoid tissue [BALT] lymphoma) and splenectomy (symptomatic splenic MZL without hepatitis C) can result in a prolonged symptom-free remission. In patients with symptomatic splenic MZL, treat hepatitis C prior to considering splenectomy.

Advanced-stage MZL should be managed similarly to follicular lymphoma.

Chronic Lymphocytic Leukemia (CLL) / Small Lymphocytic Lymphoma (SLL)

CLL/SLL is an indolent disease characterized by the clonal proliferation of mature but poorly functioning B-cell lymphocytes (Figure 8-40) and smudge cells.

Figure 8-40: CLL/SLL (high-oil immersion): 3 leukemic lymphocytes

CLL and SLL are the same B-cell lymphocyte disease with different manifestations, depending on where the abnormal cells are found.

Typically, there is an initial leukemic phase (CLL; cells in the blood) that progresses to a lymphoma phase (SLL; cells in the lymph nodes).
